### 38.2.3 Computations

As we said, we are just singling-out some methodological differences or gaps between different modeling techniques. On the *side of algorithms*, the main issue we want to stress here is that equational approaches force uniform phase spaces. That is, the list of pertinent observables and parameters, including space and/or time, of course, must be given a priori. Since the work by Boltzmann and Poincaré, physicists usually consider the phase space, which is made out of position and momentum or energy and time, as sufficient for writing the equational determination. By generalizing the philosopher's (Kant) remark on Newton's work, the (phase) space is the very *condition of possibility* for the mathematical intelligibility of physics. Or, to put it as H. Weyl, the main epistemological teaching of relativity theory is that physical knowledge begins when one fixes the reference system (that is to say, the way to describe the phase space) and the metrics on it. Then Einstein's invariant theory allows to inspect the relevant invariants and transformations, on the grounds of Lorentz–Poincaré symmetry groups, typically, within a pre-given list of observables and parameters.

Now, there exists a rich practice of computational modeling which does not need to pass through equations, it skips this a priori structure. *Varenne* nicely describes the dynamic mixture of different computational contexts as a *simulat*, a neologism which recalls *agrégat* (an aggregate) [38.15]. This novelty has been introduced, in particular, by the peculiar features of object oriented programming (OOP), but other *agent oriented systems* exist.

As a matter of fact, procedural languages require all values to share the same representation – this is how computer scientists name observables and parameters (Technically, an existential quantifier is opened at the beginning of the program and then everyone shares all private information). *Objects* instead may interact even with completely different representations as long as their interfaces are compatible (The existentials are opened only at the point of performing the operation). Thus, objects behave autonomously and do not require knowledge of the private (encapsulated) details of those they are interacting with. As a consequence, only the interface is important for external reactions [38.16, 17].

In biological modeling, aggregating different techniques with no common a priori *phase space* is a ma-

major contribution to knowledge construction. Organisms, niches, ecosystems may be better understood by structuring them in different levels of organization, each with a proper structure of determination, that is, phase space and description of the dynamics. For example, networks of cells are better described by tools from statistical physics, while morphogenesis, for example organ formation, is currently and mostly modeled by differential equations in continua. Each of these approaches requires pre-given phase spaces, which may radically differ (and the communities of researchers in the two fields hardly talk to each other). In a computer, thanks to its high parallelism one may mix these different techniques in spite of their differences with some more or less acceptable approximations. Even more so, ad hoc algorithms may describe specific interactions independently of a unified equational description that may be impossible. Then *objects* may interact only on the grounds of the actual interface, both within a level of organization and between different levels, without reference to the proper or internal (to the object, to the level) causal structure.

In other words, OOP allows independent objects dynamics, reminiscent of individual cell dynamics. Then, proliferation with variation and motility, which is the default state of life [38.18], may be added to the models of morphogenesis that usually consider cells as inertial bullets, which they are not; that is, their proliferation, changes, and motility are not entailed by physical forces that contribute to shape organs (in particular, when organs function for the exchange of energy and matter). By the computational power of modern computers, agent or object based programming styles (such as OOP) may implement autonomous agency for each cell, have them simultaneously interact within a morphogenetic field shaping the dynamics or a network ruled by statistical laws.

In summary, in computer simulation one may *put together* all these techniques, design very complex *simulat* as aggregation of algorithms including stochastic equations, probabilities distributions and alike. In particular, OOP allows the simulation of discrete dynamics of individual cells in an organism or of organisms in an ecosystem. And this with no need to write global first equations: one directly goes to algorithms in their changing environment.

However, let the process or images on a computer run ... then push the restart button. Since access to discrete data is exact, as we said and keep stressing, the computer will iterate on the same initial conditions exactly, with the same discrete algorithms. Thus, it will go exactly along the same computation and produce exactly the same trajectories, images, and genesis of forms. This has no physical meaning as an unstable

or chaotic system would never *iterate identically*. It is even less biologically plausible, as biology is, at least, the “never identical iteration of a morphogenetic process” [38.18]. Now observe that *exact iteration* is a form of (time-shift/process-identity) symmetry; while non-identical iteration is a symmetry breaking (see below for more on randomness versus symmetry breaking).

### 38.3 Randomness in Biology

Theoretical physics proposes at least two forms of randomness: classical and quantum. They are separated by different probability theories and underlying logic: entanglement modifies the probability correlations between quantum events [38.19]. Even the outcome of the measurement of generic states is contextual which means that this outcome depends on the other measurements performed and cannot be assumed to be predefined [38.20, 21] – this situation is different from classical ones which are not contextual. A new form of randomness seems to be emerging from computer networks or, so far at least, it is treated by yet a different kind of mathematics [38.22]. In particular, some analyses of randomness are carried out without using probabilities.

In the same way that we said the world is neither intrinsically continuous nor discrete, randomness is not in the world: it is in the interface between our theoretical descriptions and *reality* as accessed by measurement. Randomness is *unpredictability with respect to the intended theory and measurement*. Both classical and quantum randomness, though different, originate in measurement.

The classical one is present in dynamics sensitive to initial or border conditions: a fluctuation or perturbation below measurement, which cannot be exact by physical principles (it is an interval, as we said) is amplified by the dynamics, becomes measurable and “[...] we have a random phenomenon” [38.23]. This amplification is mathematically described by the nonlinearity of the intended equations or evolution function with a subtle difference though. If a solution of the nonlinear system exists, then the analysis of the Lyapounov exponents, possibly, yields some information on the speed of divergence of trajectories, initially indistinguishable by measurement: a nonmeasurable fluctuation is amplified and produces an unpredictable and measurable event, yet the amplification is computable. In the case of nonexistence or nonanalyticity of solutions of the given differential equations, one may have bifurcations or unstable homoclinic trajectories (i. e., trajectories at the intersection of stable and unstable manifolds). The

Noise, of course, may be introduced artificially, but this makes a deep conceptual difference at the core of our analysis.

Note, finally, that stochastic equations, probability values and their formal or algorithmic descriptions are *expressions* and *measurement* of randomness, they *do not* implement randomness. And this is a key issue.

choice at bifurcation, thus the physical trajectory is then highly unpredictable, thus random, and may be also physically ascribed to fluctuations or perturbations below measurement. In this case, however, one generally does not have a criterion of divergence, such as Lyapounov exponents. The fluctuation or perturbation *causes* the unpredictable event, thus Curie’s principle is preserved: a physical effect cannot have a dissymmetry absent from its efficient cause – a symmetry conservation principle, or “symmetries cannot decrease”. Yet, at the level of *measured* observables one witnesses a symmetry breaking, as the causing dissymmetry cannot be observed.

Quantum randomness is grounded in noncommutativity of the measurement of conjugated variables (position and momentum or energy and time), given by a lower bound – Planck’s  $h$ . It is represented by Schrödinger’s equation that defines the trajectory of a probability amplitude (or law) in a very abstract mathematical space (a Hilbert space). As hinted above, measurement of entangled particles gives probabilities that are different from the classical contexts (Bell inequalities are not respected [38.24]).

In quantum physics, though, there is another fundamental difference: in classical and relativistic mechanics, from Aristotle to Galileo and Einstein, it is assumed that *every event has a cause*. As mentioned above in reference to Curie’s principle, the unpredictable but measurable classical event is *caused* by the (initial or border) undetectable fluctuation. Instead, in current interpretations of quantum mechanics (QM), random events may be *acausal* – the spin up/spin down of an electron, say, is pure contingency, it does not need to have a cause. This radically changes the conceptual frame – and many still do not accept it and keep looking in vain for hidden variables (hidden causes) along the classical paradigm.

Surprisingly enough, a quantum event at the molecular level may have a phenotypic effect in biology. This is the result of recent empirical evidence, summarized and discussed in [38.25]. Thus, a phenotype that is a structural property of an organism, possibly a new or

ganism, may result from an acausal event happening at a completely different level of organization (molecular versus organs or organisms). This microevent may be amplified by classical dynamics of molecules including their enthalpic oscillations and their Brownian motion. Brownian motion is omnipresent in cells' proteome, where macromolecules are very *sticky* and their chemical interactions are largely stochastic – though canalized by strong chemical affinities and cell compartmentalization. So, quantum and classical randomness may *superpose* in a highly constrained environment. Moreover, it is increasingly recognized that gene expression is mostly stochastic [38.26, 27].

This leads to the fully general fact that *macromolecular interactions and dynamics are stochastic, they must be described in terms of probabilities and these probabilities depend on the context.*

This context includes the global proteomic composition, the torsion and pressure on the chromatin [38.28], the cell activity in a tissue [38.29, 30], the hormonal cascades etc. up to the ecosystem. The up and down interactions between different levels of organization yield a proper form of biological randomness, a resonance between levels called bioresonance in [38.25]. Bioresonance destabilizes and stabilizes organisms; it both *yields* and *follows from* variability, as correlated variations contribute also to the changing structural stability of organisms. Note that variability produces adaptation and diversity at the core of biological dynamical stability: an organism, a population, or a species is *biologically stable*, while changing and

adapting because it is diverse as well. Both stability and diversity are also the result of randomness. Also, as we said randomness is highly canalized in biology by cellular compartments of molecules, tissues tensesgrity, organismal control (hormones, immune and neural systems etc.) and the ecosystem may downward influence these constraints (methylation and demethylation, which may regulate gene expression, can be induced by the environment) [38.31]. Variability and diversity are constrained by history as well: phenotypes are the result of an evolutionary history that canalizes but does not determine (at least in view of quantum events) further evolution. For example, as for historical *canalization* there are good reasons to believe that we, the vertebrates, will never get out of the *valley* of tetrapodes – at most we may lose, as some of us have, podia and keep just traces of them.

In conclusion, randomness has a constitutive role in biology as variability and diversity contribute to structural stability, beginning with gene expression. Above, we developed a comparative analysis in terms of symmetries of physical processes with respect to their equational and computational modeling. We hinted at the different ways randomness is understood in various physical and biological frames. In biology, this later issue becomes particularly relevant in view of the organizing role of randomness, also in the case of small numbers (a population of a few thousands individuals is biologically more stable when diverse). Further on, we will propose a general thesis relating randomness and symmetry breaking.

## 38.4 Symmetries and Information in Physics and Biology

### 38.4.1 Turing, Discrete State Machines and Continuous Dynamics

We already stressed the key role of invariants and invariant preserving transformations in the construction of mathematical and physical knowledge. The sharing of construction principles in these two disciplines, among which symmetry principles and order principles, are the reason of the reasonable, though limited, effectiveness of mathematics for physics: these disciplines have been actually co-constituted on the grounds of these common construction principles [38.1]. However, since so few physical processes can be actually predicted – frictions and many-body interactions, i. e. nonlinearity, are everywhere – the effectiveness of mathematics is based mostly on the reasonable intelligibility we have of a few phenomena when we can organize them in terms of in-

variants and their transformations, thus of symmetries well beyond predictability.

In the account above, changing fundamental symmetries produced the change from one theoretical frame to another, such as from classical to relativistic physics. Further useful examples may be given by thermodynamics and hydrodynamics. The irreversibility of time, a symmetry breaking, steps in the first by the proposal of a new observable, entropy; hydrodynamics assumes incompressibility and fluidity in continua, two properties that are irreducible to the quantum mechanical ones, so far.

There is a common fashion in projecting the sciences of information onto biological and even physical processes. The deoxyribonucleic acid (DNA), the brain, even the universe would be (possibly huge) programs or Turing machines sometimes set up in networks – note

that the reference to networks is newer, it followed actual network computing by many years later.

We do not discuss here the universe nor the brain. It may suffice to quote the inventor of computing by discrete state machines, *Turing* [38.32, p. 440]:

“[...] given the initial state of the machine and the input signal it is always possible to predict all future states. This is reminiscent of Laplace’s view that from the complete state of the universe at one moment of time, as described by the positions and velocities of all particles, it should be possible to predict all future states. The prediction which we are considering is, however, rather nearer to practicability than that considered by Laplace. The system of the *universe as a whole* is such that quite small errors in the initial conditions can have an overwhelming effect at a later time. The displacement of a single electron by a billionth of a centimeter at one moment might make the difference between a man being killed by an avalanche a year later, or escaping. It is an essential property of the mechanical systems which we have called ‘discrete state machines’ that this phenomenon does not occur. Even when we consider the actual physical machines instead of the idealized machines, reasonably accurate knowledge of the state at one moment yields reasonably accurate knowledge any number of steps later.”

Note that in popular references to unstable or chaotic dynamics, instead of quoting the famous *Lorentz’s butterfly effect* proposed in 1972 on the grounds of *Lorentz’s* work of 1961, one should better refer to the *Turing’s electron effect*, published in 1952.

As for the brain, *Turing* continues [38.32, p. 451]:

“The nervous system is certainly not a discrete-state machine. A small error in the information about the size of a nervous impulse impinging on a neuron, may make a large difference to the size of the outgoing impulse.”

As a matter of fact, the notions of spontaneous symmetry breaking, catastrophic instability, and random fluctuations are at the core of *Turing’s* analysis of continuous morphogenesis [38.33], far remote from his own invention of the elaboration of information by the *discrete state machine* (DSM, his renaming in 1950 of his logical computing machine of 1936).

It is worth stressing here the breadth and originality of *Turing’s* work. He first invented the split hardware/software and the DSM in logic. Then, when moving to biophysics, he invented a continuous model for mor-

phogenesis viewed just as physical matter (hardware) that undergoes continuous deformations, triggered by (continuous) symmetry breaking of an homogeneous field in a chemical reaction-diffusion system. The model is given by nonlinear equations: a linear solution is proposed, the nonlinear case is discussed at length.

A key property of *Turing’s* continuous model is that it is “a falsification” (his words [38.33, p. 37]) of the need for a (coded) *design*. This becomes clear from the further comments on the role of genes, mentioned below. In discussions reported by *Hodges* [38.34], *Turing* turns out to be against *Huxley’s* “new synthesis”, which focused on chromosomes as fully determining ontogenesis and phylogenesis [38.35]. He never refers to the already very famous 1944 booklet by *Schrödinger* [38.36], where *Schrödinger* proposes to understand the chromosomes as loci of a coding, leading to a Laplacian determination of embryogenesis as he says explicitly (“once their structure will be fully decoded, we will be in the position of Laplace’s daemon” says *Schrödinger* [38.36, Chap. 2]). As a matter of fact, in his 1952 paper *Turing* quotes only Child, D’Arcy Thompson and Waddington as biologists, all working on dynamics of forms, at most constrained (Waddington) but not determined nor *predesigned* by chromosomes. Indeed, *Turing* discusses the role of genes in chromosomes, which differ from his *morphogenes* as generators of forms by a chemical action/reaction system. He sees the function of chromosomal genes as purely catalytic and, says [38.33, p. 38]:

“Genes may be said to influence the anatomical form of the organism by determining the rates of those reactions that they catalyze [...] if a comparison of organisms is not in question, the genes themselves may be eliminated from the discussion.”

This proposal is remarkable as for the very fuzzy, ever changing notion of *gene* [38.37]. No predefined design, no coded or programmed Aristotelian homunculus in the chromosomes (the myth of the chromosomes as a program) are needed for *Turing*, the man who invented coding and programming. This is science: an explicit proposal of a (possibly new) perspective on nature, not the transfer of familiar tools (the ones he invented, in this case!) on top of a different phenomenology.

Note finally that when comparing his DSM to a woman’s brain in [38.32], *Turing* describes an *imitation game* while he talks of a *model* as for morphogenesis. This beautiful distinction, computational imitation versus continuous model, is closely analyzed in [38.38].

### 38.4.2 Classifying Information

Let's further analyze the extensive use of *information* in biology – molecular biology in particular. Information branches in at least two theories:

- Elaboration of information (Turing, Church, Kleene and many others, later consistently extended to algorithmic information theory: Martin-Loef, Chaitin, *Calude*, see [38.39]).
- Transmission of information (*Shannon*, Brillouin, see [38.40]).

In [38.41] we stressed the key differences between these two theories that are mixed up in molecular biology with unintelligible consequences in the description of the relationship of information to entropy and complexity. The two latter notions are relevant to biology, see [38.42], where Turing–Kolmogorov's elaboration theory is quoted as well as Shannon's theory. The author initially considers the second as more pertinent for biology. Later in the paper a notion of complexity as amount of information is given. This notion is actually based on the first theory and it is described as *covariant to entropy*. Finally, Shannon's theory pops up again in the paper – the more pertinent theory, according to the author, where complexity is *contravariant to entropy* – it is negentropy.

As scientific constructions, both information theories are grounded on fundamental invariants. So it has been since at least Morse's practical invention, with no theory of information transmission. Information is independent of the specific coding and the material support. We can transmit and encode information as *bip-bip*, by short and long hits, as flashes, shouts, smoke clouds etc. by bumping on wood or metal, by electricity in cables – we can do this in a binary, ternary, or other code etc. Information is the *invariant* with respect to the transformation of these coding and material supports: this is its fundamental symmetry. It is also the case in Turing's fundamental invention: the distinction between software and hardware. So, a richer theory of programming was born that was largely based on logic, typed, and typed-free languages, term rewriting systems etc. entirely independent of the specific encoding, implementation, and hardware. The computer's soul is so detached from its physical realization that Descartes dualism is a pale predecessor of this radical and most fruitful split. And when the hardware of your computer is dying, you may transfer the entire software, including the operating system, compilers and interpreters, to another computer. This symmetry by transfer is called *metempsychosis*, we think. Now, it does not apply anywhere in biology.

The DNA is not a code carrying information. There is no way to detach soft content from it and transfer it to another material structure: it cannot be replaced by metal bullets or bumps on a piece of wood. What gets transferred to ribonucleic acid (RNA) and then to proteins is a chemical and physical structure, a most relevant one, as the DNA is an extraordinary *chemical trace of a history*. And it transmits to other chemicals an entirely contingent physicochemical conformation. If a stone bumps against other stones in a river and de-forms them (in-forms them, Aristotle would say), talking of a transmission of information in the scientific invariant sense above has no meaning unless in reference to the Aristotelian sense. No informational invariants can be extracted but the ones proper to the physicochemical processes relative to stone bumping. Life is radically contingent and material: no software/hardware split. The prescientific reference to information, sometimes called *metaphorical*, has had a major misleading role. First, it did not help to find the *right invariants*. The physicochemical structure of cellular receptors, for example, has some sort of generality which yields some stereospecificity [38.43]. Yet, this is still strictly related to common chemistry that has nothing to do with an impossible abstract information theoretic description. The proposal of an invariant that was too abstract and matter-independent did not help in finding the right scientific level of invariance. Or more severely so, it forced exact stereospecificity of macromolecular interaction as a *consequence* of the information theoretic bias.

*Monod*, one of the main theoreticians of molecular biology, claims that the molecular processes are based on the oriented transmission of information [...] (in the sense of Brillouin). In [38.44], he derives from this that the “*necessarily* stereospecific molecular interactions explain the structure of the code [...] a boolean algebra, like in computers” and that “genes define completely the tridimensional folding of proteins, the epigenetic environment only excludes the other possible foldings”. Indeed, biomolecular activities “are a Cartesian mechanism, autonomous, exact, independent from external influences”. Thus, the analysis based on the search for how information could be transmitted forced an understanding inspired by the Cartesian exactness proper to computers. It also conveyed the Laplacian causal structure, Turing would say, proper to information theories. It induced the invention of exact stereospecificity which is *necessary* to explain the boolean coding! That is, stereospecificity was logically, not empirically, derived. Indeed, robust evidence had already shown the stochasticity of gene expression (see [38.27, 45, 46] and [38.47] for a recent synthesis) since 1957 [38.48].

We now know that the protein folding is not determined by the coding (yet, Monod did consider this possibility). Macromolecular interactions, including gene expression, are largely random: they must at least be given in probabilities, as we said, and these probabilities would then depend on the context. No hardware-independent boolean algebra governs the chemical cascades from DNA to RNA to proteins, also because, as we already recalled these cascades depend on the pressure and tensions on the chromatin, the proteome activities, the intracellular spatial organization, the cellular environment, and many other forms of organismal regulations, see for example [38.28, 49].

In summary, the informational bias introduced a reasoning based on Laplacian symmetries, far away from the largely turbulent structure of the proteome, empowered also by chaotic enthalpic oscillations of macromolecules. This bias was far from neutral in guiding experiments, research projects, and conceptual frames. For example, it passed by the role of endocrine disruptors of the more than 80 000 molecules we synthesized and used in the twentieth century, an increasingly evident cause of major pathologies, including cancer [38.50–52]. These molecules were not supposed to interfere with the exact molecular cascades of key-lock correspondences, a form of stereospecificity. The bias guided the work on genetically modified organisms (GMO), which have been conceived on the grounds of the “central dogma of molecular biology” and of Monod’s approach above: genetic modifications would completely guide phenotypic changes and their ecosystemic interactions [38.53].

One final point: Information theories are *code independent*, or they analyze code in order to develop general results and transmission stability as *code insensitive* (of course cryptography goes otherwise: but secrecy and code breaking are different purposes, not exactly relevant for organisms). Information on discrete data is also *dimension independent*: by a polynomial translation one may encode discrete spaces of *any finite dimension* into one dimension. This is crucial to computing since it is needed to define Turing’s universal machine, thus operating systems and compilers.

Biology instead is embedded in a physical world where the space dimension is crucial. In physics, heat

propagation and many other phenomena, typically field theories, strictly depend on space dimension. By *mean field theories* one can show that life, as we know it, is only possible in three dimensions [38.1]. Organisms are highly geometric in the sense that *geometric* implies *sensitivity to coding and dimensions*. In this sense, continuous models more consistently propose some intelligibility: in *natural* topologies over continua, that is when the topology derives from the interval of physical measurement, dimension is a topological invariant. It is a fundamental invariant in physics to be preserved in biology, unless the reader believes that he/she can live encoded in one dimension, just exchanging information like on the tape of a Turing machine. A rather flat universe . . . yet, with no loss of information. But where one has only information, not life.

Missing the right level of invariance and, thus, the explanatory symmetries, is a major scientific mistake. Sometimes, it may seem just a *matter of language*, as if language mattered little, or a matter of informal metaphors, as if metaphors were not carrying meaning, forcing insight and guiding experiments. They actually transfer the conceptual structure or the intended symmetries of the theory they originate from, in an implicit thus more dangerous and unscientific way. Just focusing on language, consider the terminology used when referring to DNA/RNA as the *universal code for life* since all forms of life are based on it. This synchronic perspective on life – all organisms yield these molecules and the basic chemical structure of their interactions, *thus* there is a universal code – misses the historical contingency of life. There is no universality in the informational sense of an invariant code with respect to an independent hardware. Life is the historical result of contingent events, the formation somewhere and somehow of DNA or RNA or both, sufficiently isolated in a membrane, which occurred over that hardware only. Then, the resulting cell reproduced with variation and diversified to today’s biological diversity. Life history has one contingent material origin, then there was a diversification of that matter, of that specific hardware and no other. Invariance, symmetries and their breaking are different from those proper to *information*, in this strictly material, evolutionary perspective.

## 38.5 Theoretical Symmetries and Randomness

In this section, we would like to elaborate on a *thesis*, already hinted at in [38.6]. In physical theories, where the specific trajectory of an object is determined by its theoretical symmetries, we propose that randomness appears when there is a change in some of these symme-

tries along a trajectory and, reciprocally, that changes of symmetries are associated to randomness.

Intuitively, theoretical symmetries allow to understand a wide set of phenomenal situations as equivalent. At the end of the day, the trajectory that a physi-

cal object will follow, according to a theory, is the only trajectory which is compatible with the theoretical symmetries of a given system. Symmetries, in this context, enable to understand conservation properties, the uniqueness of the *entailed* trajectory, and ultimately the associated prediction, if any.

Now what happens when, over time or with respect to a pertinent parameter, a symmetry of the system is broken? A symmetry corresponds to a situation where the state or the set of possible states and the determination of a system does not change according to specific transformations (the symmetries). After the symmetry breaking, the state(s) becomes no longer invariant by these transformations; typically, the trajectory goes to one of the formerly symmetric states and not to the others (a ball on top of a mathematical hill falls along *one* of the equivalent sides). Since the initial situation is exactly symmetric (by hypothesis), all the different *symmetric* states are equivalent and there is no way to single out any of them. Then, in view of the symmetry breaking, the physical phenomena will nevertheless single out one of them. As a result, we are confronted with a nonentailed change: it is a random change.

This explanation provides a physicomathematical meaning to the philosophical notion of contingency as non-necessity: this description of randomness as symmetry breaking captures contingency as a lack of entailment or of necessity in an intended theory. Note that usually the equivalent states may not be completely symmetric as they may be associated to different probabilities, nevertheless they have the same status as *possible* states.

For now, we discussed the situation at the level of the theoretical determination alone, but the same reasoning applies *mutadis mutandis* to prediction. Indeed, we access a phenomenon by measurement, but measurement may be associated to different possible states, not distinguishable individually. Thus, these states are symmetric with respect to the measurement, but the determination may be such that these (nonmeasurably different) states lead to completely different measurable consequences. This reasoning is completely valid only when the situation is such for all allowed measurements, so that randomness cannot be associated to the possible crudeness of an arbitrary specific measurement.

Reciprocally, when we consider a random event, it means that we are confronted with a change that cannot be entailed from a previous observation (and the associated determination). When the possible observations can be determined (known phase space), this means that the different possibilities have a symmetric status before the random event (precisely because they are all predefined possibilities) but that one (or several of them) is singled out by the random event in the sense

that it becomes the actual state. We recognize in this statement the description of a symmetry that is broken during the random event.

Let us now review the main physical cases of randomness:

- Spontaneous symmetry breaking in quantum field theories and theories of phase transitions (from a macroscopic viewpoint) are the most straightforward examples of the conjecture we describe. In these cases, the theoretical determination (Hamiltonian) is symmetric and the change of a parameter leads the systems equilibrium to shift from a symmetric state to an asymmetric one (for example isotropy of a liquid shifting to a crystal with a specific orientation). Randomness then just stems from the *choice* of a specific orientation, triggered by fluctuations in statistical mechanics.
- Classical mechanics can, in spite of its deterministic nature, lead to unpredictability as a consequence of the symmetrizing effect of measurement on one side (there are always different states which are not distinguished by a measurement), and a determination that leads those states to diverge (which breaks the above symmetry). This reasoning applies to chaotic dynamics but also to phase transitions where, from a strictly classical viewpoint, fluctuations below the observation determine the orientation of the symmetry changes.
- In classical probabilities applied to *naive* cases such as throwing a dice or to more sophisticated frameworks such as statistical mechanics, our reasoning also applies. When forgetting about the underlying classical mechanics the probabilistic framework is a strict equivalence between different possibilities, except for their expected frequencies which may differ: those are given by the associated probabilities. In order to theoretically define these probabilities, some underlying theoretical symmetries are required. In our examples, the symmetries are the symmetry between the sides of a dice and for statistical mechanics, the symmetry between states with the same energy for the microcanonical ensemble. From a strictly classical viewpoint, these symmetries are assumed to be established on average by the properties of the considered dynamics. In the case of dice, it is the rotation, associated with the dependence on many parameters which leads to a sufficient mixing, generating the symmetry between the different sides of the dice. In the case of statistical mechanics, it is the property of topological mixing of chaotic dynamics (a property met by these systems by definition). This property is assumed in order to justify the validity of

statistical mechanics from the point of view of classical mechanics. In both cases, a specific state or outcome corresponds to a breaking of the relevant symmetry.

- In quantum mechanics, the usual determination of the trajectory of a state is deterministic, randomness pops out during measurement. The operator corresponding to the measurement performed establishes a symmetry between its different eigen vectors, which also correspond to the different outcomes corresponding to the eigen values. This symmetry is partially broken by the state of the system which provides different weights (probabilities) to these possibilities. The measurement singles out one of the eigen vectors which becomes the state of the system and this breaks the former symmetry.

We can conclude from this analysis and these examples that randomness and symmetry breaking are tightly associated. We can put this relationship into one sentence: *A symmetry breaking means that equivalent directions become no longer equivalent and precisely because the different directions were initially equivalent (symmetric) the outcome cannot be predicted.* As discussed elsewhere [38.6, 54], we assume that theoretical symmetries in biology are unstable. It follows that randomness, understood as associated to symmetry breaking, should be expected to be ubiquitous; however, this approach also leads to propose a further form of randomness. In order to show that randomness can be seen as a symmetry breaking, we needed to assume that the set of possibilities was determined before the event. In biology, the instability of the theoretical symmetries does not allow such an assumption in general. On the

opposite, a new form of randomness appears through the changes of phase spaces and this randomness does not take the form of a symmetry breaking *stricto sensu* inasmuch as it does not operate on a predefined set. In other words, these changes cannot be entailed but they cannot even be understood as the singling out of one possibility among others – the list of possibilities (the phase space) is not pre-given.

In brief, theoretical symmetries in physics enable to single-out a specific trajectory in a phase space, formed by a combination of observables. Thus, a symmetry breaking corresponds to the need of one or several supplementary quantities to further specify a system on the basis of already defined quantities (which were formerly symmetric and thus not useful to specify the situation). In biology, instead, the dynamic introduces new observable quantities which get integrated with the determination of the object as the latter is associated with the intended quantities and symmetries. This dynamic of the very phase space may be analyzed a posteriori as a symmetry breaking. Thus, randomness moves from within a phase space to the very construction of a phase space, a major mathematical challenge.

# 39. Experimentation on Analogue Models

Susan G. Sterrett

Analogue models are actual physical setups used to model something else. They are especially useful when what we wish to investigate is difficult to observe or experiment upon due to size or distance in space or time; for example, if the thing we wish to investigate is too large, too far away, takes place on a time scale that is too long, does not yet exist or has ceased to exist. The range and variety of analogue models is too extensive to attempt a survey. In this chapter, I describe and discuss several different analogue model experiments, the results of those model experiments, and the basis for constructing them and interpreting their results. Examples of analogue models for surface waves in lakes, for earthquakes and volcanoes in geophysics, and for black holes in general relativity, are described, with a focus on examining the bases for claims that these analogues are *appropriate* analogues of what they are used to investigate. A table showing three different kinds of bases for reasoning using analogue models is provided. Finally, it is shown how the examples in this chapter counter three common misconceptions about the use of analogue models in physics.

The array of analogue models used in science is extensive; an attempt to comprehend their range, in size and kind, would have to be abandoned sooner or later. The imagination, intellectual ingenuity, and technical expertise that have been expended in conceiving, constructing, and using these various disparate models, each requiring a methodology of construction and deployment appropriate to its nature and use, are dizzying.

Analogue models have been devised and used in physics for quite some time: one of the most common analogies in physics, the analogy between sound and light, was invoked in the mid-nineteenth century to build a sonic analogue of the Doppler effect for light, which was then used to investigate and establish results for both sound and light [39.1–3]. The analogy was later invoked in the twentieth century to explain Vavilov–Cerenkov radiation, also known as Cerenkov

radiation [39.3,4]. Cerenkov radiation is the electromagnetic radiation emitted when an electron travels in a medium faster than the speed that light travels in that medium. In his Nobel lecture, *Cerenkov* explained [39.4]:

“This radiation has an analogy in acoustics in the form of the so-called shock waves produced by a projectile or an aeroplane travelling at an ultrasonic velocity (Mach waves). A surface analogy is the generally known bow wave.”

More recently, in the twenty-first century, physicists have developed, loosely speaking, analogue space-time and analogue gravity [39.5–7]. Although the initial proposals for analogue models for space-time were based on an analogy between light and sound, once the idea of exploring analogue models of gravity began attract-

ing more interest, a variety of analogue models based on different analogies were proposed [39.8]. Thus the idea of an analogue based on the analogy between light and sound was expanded to many different kinds of analogues. *Faccio* points out a commonality that can be seen across all of them, though: All of them can be “re-connected to some form of flowing medium” [39.8, p. v]. *Visser* elaborates further [39.9]:

“In all the analogue spacetimes, the key idea is to take some sort of *excitation* travelling on some sort of *background*, and analyze its propagation in terms of the tools and methods of differential geometry.”

Arising in part from the interest generated by the work on these analogue models, physicists (*Carusotto* and *Rousseaux*) have formulated the notion of a “generalized Cerenkov emission” process [39.10].

Another analogy commonly drawn in physics is the analogy between electrical circuits and mechanical systems. The analogies date from the nineteenth century; it appears they were first invoked to make mechanical models of electrical circuits, the models being seen as a way of using knowledge about mechanical systems to provide a better understanding of electrical behavior and concepts [39.11, 12]. However, the use of electrical circuits specifically designed to model mechanical systems later became standard:

1. Measurements of the flow of current in an appropriately constructed circuit were used to accurately compute quantities used in the mechanical analysis of the corresponding structure.
2. Varying elements in the circuit corresponded to varying parameters in the mechanical system, so the effect of differences in a design or a system’s initial conditions could be explored.

More generally, electronic circuits were used as analogues of anything that could be formalized as a solution of certain classes of differential equations, and ever more sophisticated machines were developed to deal with ever larger classes of differential equations and

problems ([39.13, 14] and [39.15, p. 222ff]). Other examples of analogues used for computation are mechanical analogues such as the geared devices built in the seventeenth century [39.16], the soap bubble analogue computers invoking minimization principles that were used to efficiently solve difficult mathematical problems in the twentieth century [39.17] and biological analogue computers of the twenty-first century such as amoeba-based computing (ABC) analogue models [39.18].

Other analogue models used experimentally to carry out serious research could be named in astrophysics, cosmology, statistics, economics, geophysics, electromagnetism, fluid mechanics, fluid dynamics, solid mechanics, solid dynamics, structural engineering, coastal engineering, the behavior of volcanoes, and many other fields.

To be clear, these are actual, physical objects or setups, usually human made, designed to be used as analogue models. The modeling process for employing a physical object or setup as an analogue model includes the identification of a mapping that allows one to correlate something observed or measured in the analog model with something else (its correlative, such as a corresponding quantity) in the thing modeled. The modeling process also includes a justification of the mapping of some sort, usually invoking a principle or equation to establish the mapping. What is modeled is usually another physical object, process, or phenomenon. The model’s limitations in representing certain phenomena in the thing modeled, and any corrections that need to be made due to such limitations, are usually discussed when the analogue model is used for a particular problem. Such qualifications are not meant to undermine or recommend against using the model; they are part of the model and modeling process.

While numerical models implemented on electronic digital computers may have supplanted some of these specific uses, analogue models continue to be used in most of these fields today, and new analogue models and methods of using them continue to be invented and further developed.

## 39.1 Analogue Models: Terminology and Role

### 39.1.1 Analogue Models and Scale Models

It will be helpful to clarify the terminology of *analogue model* and *scale model* as used in this chapter.

#### Analogue Models

The word *analogue* has two connotations relevant in discussions on models: (i) analogous or parallel to; and (ii) continuous, as contrasted with digital. It sometimes

happens that a model is analogue according to both meanings. In this chapter, we will use *analogue* to mean analogous or parallel to. Thus *experimentation on an analogue model* is used to mean *experimentation on something analogous to the thing modeled*. It is important to be clear about what is meant in saying that a model is *analogous to* the thing modeled.

To say one thing is analogous to another is always to say it is so *with respect to* a particular analogy, whether

or not this is made explicit; there may be many different possible analogies one could draw between two physical things or processes. Thus, just as it does not make sense to ask whether or not one thing is analogous to another without specifying the analogy between them one means to be inquiring about, so it does not make sense to say that one thing is an analogue model of another thing without specifying the analogous relation that is the basis for the correspondences being drawn between the model and what is modeled. Thus, it is implicit in the notion of an analogue model that there is some definite analogous relationship that one means to be referring to, between the model and the thing modeled.

### Scale Models

A *scale model* (in the sense that engineers and scientific researchers use the term *scale model*) can be considered a special case of an analogue model. (Or, conversely, an analogue model can be considered a generalization of the notion of a scale model.) One way of understanding the relationship between analogue and scale models is by considering how the methodology of physically similar systems applies to each of them.

Using the method of physically similar systems, similarity of two systems is established by showing that each member of a certain (nonunique) set of dimensionless parameters that characterizes the behavior of the two systems has the same value in the model as in the thing modeled; in practice exact similarity is often not achievable (Chap. 18). Instead, certain of the dimensionless parameters are prioritized, or one aims for the dimensionless parameters to be only approximately equal. That is, it is said that a system  $S$  and a system  $S'$  are similar with respect to a behavior  $B$  (e.g., kinematically similar, dynamically similar, similar with respect to buckling behavior, similar with respect to electrical flows, and so on) when a set of dimensionless parameters (ratios) that characterizes that behavior has the same values in  $S$  as in  $S'$ . Despite the fact that, in practice, it is often possible to meet this criterion only partially or approximately, the concept of physically similar systems whose similarity is established by dimensional analysis (via establishing equality of the relevant dimensionless parameters), which was originally developed to provide a basis for making use of scale model experiments, still forms the foundation for the use of analogue models and has the virtue that it does not, as most other methods do, require complete knowledge of the equations and conditions that determine the behavior  $B$  of interest [39.19].

Now, to see the point that a scale model is a special case of an analogue model: each dimensionless parameter is a ratio, so it is only the value of a quantity *in relation to* other quantities that determines the value

of the dimensionless parameters used to establish similarity between two systems  $S$  and  $S'$ . To use a simple example, it is Mach number (the ratio of the velocity of a flow or a moving object to the velocity of sound in the medium at the fluid conditions that obtain at a certain time), and not the value of a quantity such as a velocity itself that indicates whether flow is supersonic or subsonic. The Reynolds number (density  $\times$  velocity  $\times$  length, divided by viscosity) is generally indicative of the flow regime (laminar, transitional, or fully developed (turbulent) flow). People often use the term *scale model* when thinking about scaling *linear* dimensions in particular, and thus are thinking in terms of *ratios of lengths* rather than some other (dimensionless) ratio; then, the point about sameness of ratios becomes a point about sameness of ratios of lengths, and hence about the significance of geometrical similarity to the occurrence of some phenomenon. That is, for two systems  $S$  and  $S'$ , *if all we are interested in is a feature or behavior that depends solely on ratios of linear dimensions, then geometrical similarity between model and thing modeled suffices for an object to serve as an analogue model of the thing modeled*. This is a special case of a physically similar system in which the relevant dimensionless parameter is a ratio of lengths [39.20]. A *scale model* used in architectural layout is a paradigm example of this kind of similarity, and can be considered a special case, even a degenerate case, of a physically similar system.

Unfortunately, the architectural model as a paradigm of a scale model has become so closely associated with the very idea of a scale model that it can interfere with understanding how broadly the concept of *scale model* applies. The concept of *scale model* is not limited to scaling of a linear dimension alone; other quantities can be scaled too [39.20]. Despite this, the term *scale model* is often used in the more restricted sense of scaling the linear dimension of the situation.

Even when restricting the meaning of *scale model* to the scaling of linear dimensions, it is certainly not necessary that a scale model be smaller in size than what it models, nor even that a scale model have the same geometrical proportions as what it models. Scale models of very small things have been built which are larger than what they model, so as to permit ease in manipulation and observation (e.g., a scale model of a cell); and full-size scale models used for prototype testing are common as well (e.g., to test airflow patterns around, or heat convection associated with, a certain shape). Even in full-size scale model testing, the method of physical similarity is applicable in designing the experimental conditions to be applied, and in interpreting the results of the experiment [39.20, 21]. The use of distorted scale models calls for some explanation.

### Distorted Scale Models

Distorted scale models, which are scale models that fail to be geometrically similar to the situation modeled (by design, and in a certain very specific way) [39.21], have been used in scale modeling for over a century; an example may illustrate the nature of, and reason for using, such models.

One example of a distorted scale model is a physical model of Lake Superior [39.22] that was “built to satisfy the Froude number and Rossby number requirements of dynamic similitude.” (The Froude number is indicative of the ratio of inertial forces to the gravity forces of flow, and is important in studies where surface waves are important; the Rossby number is indicative of the ratio of inertial forces to the Coriolis force.) The model was used to generate quantitative results: the coriolis force (in the actual Lake Superior) was modeled by rotating the laboratory model about a vertical axis, and the lake bottom in the model was *warped* so as to provide the correct scaled depth while the model was rotating [39.22, p. 25]. The wind flow over the lake was modeled in the laboratory model using a blower with an air distributor. The researchers’ experimentation on this analogue model of Lake Superior involved blowing *wind* over it in different directions; they recorded the results in the analogue model by “photographing aluminum particles spread on the water surface” [39.22].

The plan view and side view of the model are shown in Figs. 39.1 and 39.2, respectively. The model is a scale model, yet it is not geometrically similar to Lake Superior; the researchers explain: “Because of the large ratio of horizontal to vertical distances in Lake Superior, the model was [intentionally made so as to be] vertically distorted” [39.22]. The fact that the vertical linear dimensions of the model are scaled differently than the horizontal linear dimensions are scaled is, of course, taken into account when the corresponding quantities to be associated with the actual Lake Superior are calculated from the values of the quantities observed in the model. The ratio of time in the laboratory model to time in the actual Lake Superior is 1/9480, so that “1 day in the prototype is equivalent to 9.1 s in the laboratory model,” for instance.

Such distortion of the vertical dimension in modeling ship performance at sea or fluid behavior in canals is common, but they are not the only use of distorted models. One particularly complex hydraulic model that used distortion was constructed and used to study the impact that large woody debris in a stream had in reconfiguring the creek bed itself [39.23]. More recently, the use of distorted laboratory models in investigating the structural response of (flexural) plates has been evaluated analytically and judged to provide a reliable means of laboratory investigation [39.24].

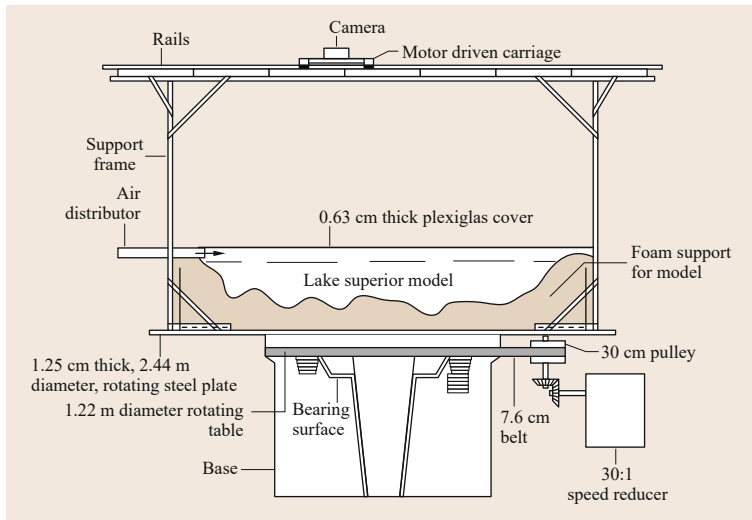

**Fig. 39.1** Plan view of Lake Superior distorted model; the ratio of horizontal distance in the laboratory model to horizontal distance in the actual Lake Superior is 1/300 000 (after [39.22])

### 39.1.2 The Role of Analogue Models in Philosophy of Science

The wide variety of analogue models currently used in serious scientific research mentioned in the beginning of this chapter is not, however, reflected in the discussions of analogue models one finds in the history and philosophy of science literature. When analogue models are mentioned in philosophy of science, they are usually seen as curiosities suitable for illustrative, entertainment or pedagogical purposes, rather than as a serious research methodology. When, on occasion, their role in serious scientific research is recognized, it is usually for a role played in the science of a past era, and often for a qualitative or heuristic purpose at that.

An indication of the extent of confusion and ignorance about analogue models and scale models that exists in mainstream philosophy of science is found in the account in the entry entitled *Models in Science* found in one of the most prominent encyclopedias of philosophy, coauthored by two leading philosophers of science, *Roman Frigg* and *Stephan Hartmann*. Scale models are not included under analogical models in that chapter, and it is claimed that “[t]ypical examples [of scale models] are wooden cars or model bridges” [39.25]. There is no recognition in the article of the notion of physically similar systems or any other methodology of scale models, in spite of the fact that methods of dimensional analysis applied to scale models are the topic of count-

**Fig. 39.2** Side view of Lake Superior distorted model, “Because of the large ratio of horizontal to vertical distances in Lake Superior, the model was vertically distorted.” The ratio of vertical distance in the laboratory model to vertical distance in the actual Lake Superior is 1/1000 (after [39.22])

less books and papers in a wide variety of journals in physics and other scientific disciplines. Instead, the topic of the methodology of scale models is dismissed with the misguided reasoning that [39.25]

“Scale models seem to be a special case of a broader category of representations that Peirce dubbed icons: representations that stand for something else because they closely resemble it.”

and that “no theory of iconicity for models has been formulated yet.” Likewise, the philosopher *Ronald Giere*, widely recognized in philosophy of science for championing the recognition of the role of models in science, uses examples such as “Watson’s original tin and cardboard model of DNA” and “Rutherford’s solar system model of the atom” as examples of scale models and analogue models, respectively ([39.26] and [39.27, p. 747]). Two well-known discussions in philosophical venues that specifically address experimentation on laboratory water tank analogue models [39.28, 29] do not discuss the foundations of the approach used by researchers who actually employ those models, that is, dimensional analysis and the method of physically similar systems.

Hence there is little help to have from the mainstream philosophical literature as far as understanding bases for the scientific reasoning involved in actual experimentation on analogue models by researchers. To be fair, there are a few works that do make some philosophical points about the methodology, the assumptions and the limitations of various bases for experimental methodologies employing analogue models, but they seem unconnected, in that the mainstream discussions in philosophy of science that ought to take note of them seldom do so (Chap. 18 and [39.30–37]). The emphasis

in this chapter will be on the methodologies employed by the researchers who have effectively used laboratory experimentation on analogue models: our interest here is especially in the basis for the inferences drawn using these analogue models.

### 39.1.3 Analogue Models in History of Science

#### Geophysics

*Analogue Models in Geophysics: An Historical Narrative.* An example typical of narratives that view analogue models in terms of their role in the past is historian *Naomi Oreskes’ From Scaling to Simulation: Changing Meanings and Ambitions of Models in Geology* [39.38]. According to her narrative, physical scale models were used in the nineteenth and early twentieth century, but in the latter part of the twentieth century [39.38, p. 93]:

“The word model took on a different meaning: a computer simulation. For earth scientists, this is the dominant meaning it holds today.”

The main storyline in her narrative has to do with the cause of shifts in epistemic goals of geologists in the late twentieth century. Our interest in this chapter is simply in the methodology of the analogue models employed. As Oreskes indicates, the method of physically similar systems was applied to the question of how to scale experimental analogue models for the behaviors of interest in studying geologic structure in the 1930s by *Hubbert*, in *Theory of Scale Models as Applied to the Study of Geologic Structures* [39.39]. It is a means of obtaining *quantitative* results about something by taking measurements on an analogue physical model of it.

*Hubbert* cites Galileo's *Two New Sciences*, then works by Newton, Stokes, Helmholtz, and Reynolds [39.39, pp. 1516–1517]. *Hubbert* also describes work done by Koenigsberger and Morath applying physical similarity to geology [39.39, p. 1518]. Prior to that, many people had built small tabletop models to investigate geological processes, but there was good reason to be skeptical about the validity of these small models; there was a need, *Hubbert* said, for [39.39, p. 1463]:

“an objective criterion to enable one to determine what the correct properties of a model should be for the best similarity, when the properties of the original are known, or whether it is even possible to build a correct model from available materials.”

Koenigsberger and Morath did “the earliest explicit application of the method of dimensional analysis to tectonic structures” that was in 1913 [39.39, p. 1518]. So, *Hubbert* stresses, what he is advocating is not new. *Hubbert* did not use the more mathematically concise and elegant method of physically similar systems that Buckingham presented in 1914 and which is described elsewhere in this volume (Chap. 18), but he did use the theory of dimensional analysis, systematically developing and carefully elaborating the dimensionless ratios associated with providing geometrical, kinematical, and geometrical similarity between the model and what is modeled by it. Finding the requirement of dynamic similarity too strict to be practical in many cases, he then goes on to discuss the kinds of approximations that *are* appropriate in special cases. He considers special cases in which inertial forces are very small, ones in which gravitative forces are negligible, and ones in which resistive forces are negligible, explaining which criterion can be violated without affecting the results too much in each case.

As have so many others who have seen themselves as advocates of the method, that is, as urging the use of the method of physical similarity to handle previously unsolved problems in their profession, *Hubbert* sounds almost evangelical in his advocacy [39.39, p. 1519]:

“[...] the evidence is in that in remote parts of the world the geological professional is already awakening to the importance of so powerful a tool as that afforded by the method of dimensional analysis and correctly made scale models, for the solving of problems that have not yielded satisfactorily to methods of attack previously employed.”

The reasons geophysics needed to use scale models were very much the same as the reasons scale models were being used in other areas such as mechanics and hydrodynamics: the phenomena “are so complicated as

a whole as to render complete mathematical analysis difficult or impossible” [39.39, p. 1460]. Then:

“where mathematical analysis is inadequate, and where for one reason or another direct experimentation is precluded, the best remaining alternative is to construct and study a scale model.”

Writing in 1937, he cites the fields of aerodynamic, hydraulic, mechanical, and electrical engineering for their success, then notes that [39.39, p. 1461]:

“The geological problems of mountain making and of diastrophism in general are peculiarly of the type that do not lend themselves readily to analysis, and the size of the elements involved place them beyond the range of direct experimentation. In this case also there remains the alternative of studying such phenomena by means of experiments performed upon properly built small scale models.”

In the preface to a later paper *The Strength of the Earth*, in which he resolved an apparent paradox in geophysics by appealing to physical similarity, *Hubbert* explained the value of the approach [39.40]:

“By means of the principles of physical similarity, it is possible to translate geological phenomena whose length and time scales are outside the domain of our direct sensory perception into physically similar systems within that domain.”

He shows the value of developing the characteristics of the materials that would be needed to make a physically similar laboratory model, and shows that even the knowledge of what the physically similar laboratory model would be like is informative. For the purpose of resolving the apparent paradox, understanding scaling relations for the case of the earth is all that is needed [39.40, p. 1653]:

“We learn that the resemblance of the behavior of rocks on a length scale of thousands of miles and a time scale of millions of years is not to that of rocks with which we are familiar but rather to that of the viscous liquids and weaker plastics of our personal experience.”

However, the fact that such qualitative lessons can be drawn does not obviate the need for building the models to learn about tectonics in many cases, and even in the same paper in which *Hubbert* makes the general observation just quoted, he reviews various experimental scale laboratory models that had been built using the method of physical similarity [39.40, p. 1653].

Translating geological phenomena occurring *outside the domain of our direct sensory perception* into that domain is of course extremely significant in the

field of geophysics, due to the large sizes and long time scales involved. Given that philosophy has so seldom included this method of experimentation among serious scientific reasoning, the attention Oreskes gives to Hubbert's work on applying physical similarity to geophysics, though not her main point, is a valuable rarity in the literature of history and philosophy of science.

**Analogue Models in Geophysics: The Case of Volcanology.** One area of geophysics where physical similarity has been employed is volcanology. There are different kinds of volcanoes; volcanoes can differ in configuration and in the mechanisms by which they were formed, for instance. Further, the configurations are seldom static: a given volcano's configuration can change during the process that is of research interest (e.g., eruption, spreading). Some processes take place over time periods that are very short, involving very high velocities, and others take place over long time periods, for example, slow changes between eruptions. Concurrent processes are often studied separately in order to understand the mechanisms involved. Sometimes the study focuses on the peculiarities of a specific volcano, and sometimes the subject of the investigation is about general processes and not specific to any volcano. Thus no single example of an analogue model from volcanology is likely to be representative. An example of the use of physical similarity that illustrates how its application can involve very different analogue models of the same volcano is the use of various scaled experiments of different mechanisms involved in the ongoing evolution of Mt Etna in Italy, especially volcano spreading and dike propagation.

To investigate the process of volcanic spreading, cones of sand on layers of sand and silicone were used [39.41]. Volcanic spreading is a long-term process and it involves more than one factor, but the effect of the weight of the volcano on the substratum is one of them. Identifying what the model does not do is part of explaining the model, and the researchers state up front that

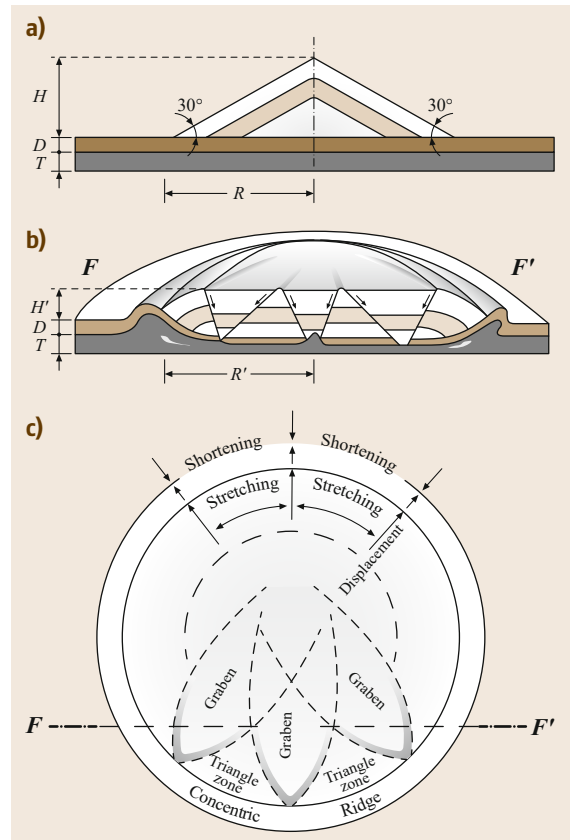

“Our experiments do not model the effect of the intrusive complexes; they cannot be used as exact scale analogs of volcanoes where the intrusive complexes give the dominant contribution to deformation [...]”

citing other experiments that do so. They add: “[...] our experiments do not model the effect of subsidence due to crustal flexure under the load of volcanic edifices” and note that effect *is* in fact important for some specific volcanoes and kinds of volcanoes. Their model considers the volcano already cooled, so they are not modeling thermal effects in the experiment, either. Nor,

they add, do they take into account “any contribution of magma forces to the destabilization process” [39.41].

Their explanation of the value of an analogue model of volcano spreading that neglects so many mechanisms is that it can show a relation between the mechanism they wish to model and an effect that can be observed in both the model and the thing modeled. Figures 39.3 and 39.4 show the schematic and photographic views of the experiment. Drawing on previous results by others, they use dry sand in the small laboratory model as an analog of brittle rocks in the actual Mt Etna volcano [39.41, p. 13808]. The spreading in the model (analogue volcano) experiment takes less than a day; a record of the experiment is made using overhead time lapse photography of the surface of the spreading sand cone [39.41, p. 13807].

The model is constructed by taking the approach of preserving the dimensionless ratios important to the behavior of spreading, as best they can, and prioritizing

**Fig. 39.3a–c** Schematic of experiment of spreading volcano, from initial state of laboratory model to 10 h from initial state. (a) Initial stage (cross section); (b) state after deformation (cross section); (c) state after deformation (top view) (after [39.41])

**Fig. 39.4a,b** Analogue volcano made of sand, from initial state (a) to end of spreading experiment 10 h later (b). From Merle and Borgia [39.41], who find the pattern in the end state above remarkably similar to pattern in actual volcano shown in Fig. 39.5

some ratios over others. The choice of dimensionless parameters and ratios here is not done from scratch by analysis of the specific problem they are investigating, but draws on Hubbert's analysis of these kinds of problems in geophysics. One interesting aspect of this experiment is that some of the ratios change significantly during the experiment itself. Table 39.1 shows the dimensionless variables used. (A note about the notation in the chart in Table 39.1: Although the Greek letter  $\Pi$  is used to denote dimensionless variables there, not all dimensionless variables indicated in Table 39.1 have the same role as a dimensionless  $\Pi$ -group or a dimensionless parameter as that term is commonly used in dimensional analysis (Chap. 18 and [39.33, 34]).

**Table 39.1** Average dimensionless numbers for experiments in actual volcano (*Field*) and in laboratory analogue volcano (*Experiment*) (after [39.41]). Because the configuration changes dramatically during the volcano spreading experiment, some of these ratios change in value during the experiment. Each experiment is characterized in terms of the values these dimensionless variables take on for that experiment

Dimensionless variable	Definition	Value	
		Field	Experiment
$\Pi_1$	Height/radius of volcano	0.15–0.2	0.58 → 0.18
$\Pi_2$	Brittle substratum/height of volcano	0–1.5	0.1 → 0.22
$\Pi_3$	Brittle/weak substratum	0–15	1 → 2
$\Pi_4$	Volcano/substratum density	1–1.4	1
$\Pi_5$	Gravitational/viscous forces	790	1200
$\Pi_6$	Frictional/viscous forces	82–327	160
$\Pi_7$	Inertial/viscous forces	$10^{-20}$	$10^{-12}$

**Fig. 39.5** Summit of Mt. Etna volcano as a digital elevation model (after [39.41], courtesy of Macedonio and Pareschi, University of Pisa)

The analogue spreading volcano experiment is run using different substratum layers (brittle layer only, brittle layer and ductile layer, ductile layer only) and a buffering solid boundary that buttresses the cone. The experiments are characterized in terms of the values of the dimensionless variables [39.41, p. 13809]. The authors remark on the ability of such simple experiments to model features of the natural volcano that had not been modeled before.

More recently, a completely different mechanism suspected to be occurring in the same volcano (although this *same* volcano, Mt Etna, had erupted in the meantime, including flank (side) eruptions) was modeled by an experiment that modeled a very different kind of mechanism: magma emplacement in the volcano [39.42]. In this model, a viscous material was injected into a cone of granular material. An aerial view of Mt Etna is shown in Fig. 39.6. The experimental apparatus for the laboratory analogue model used to study the consequences of magma emplacement is shown in Fig. 39.7.

The experimental apparatus and methods used produce measurements of high precision. The size of the model, the materials used in the model, and the scaling of quantities of interest are developed using dimensional analysis, again citing the work of *Hubbert* [39.42, Section 3.2].

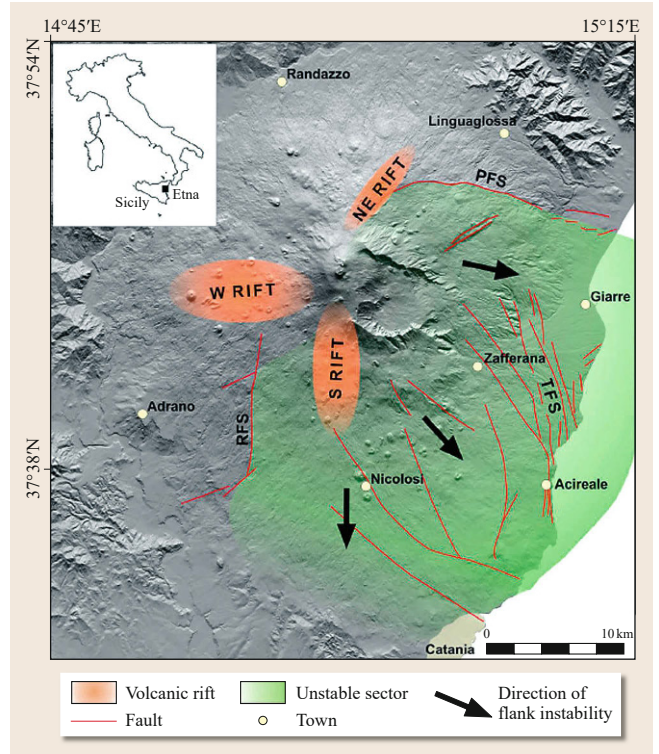

The research into the mechanisms at work in the Mt Etna volcano using analogue volcanoes is of more than theoretical interest, as thousands of deaths have already resulted from Mt Etna's eruptions. Predicting the future is certainly of interest in the employment of this analogue model; the safety of many could depend upon an understanding of how this specific volcano behaves. The authors note that the use of an analogue model to precisely model the displacements of a specific volcano *quantitatively*, as was done in their study, is a new use of analogue models in volcanology, and that this work could lead to an *advanced generation of analog models* that could be compared with those of the actual volcano, and could aid simulation studies [39.42, pp. 18–19].

*Analogue Models in Geophysics: The Lessons of History.* Oreskes' narrative, though a welcome rarity in mentioning the historical role of physical similarity, contains a statement about the role of analogue models that could mislead readers into thinking that (or reinforce existing prejudices that) physical analogue models are dispensable in geophysics. As this is a rather common misconception in philosophy of science today, it is useful to confront it here. Oreskes writes [39.38, p. 113]:

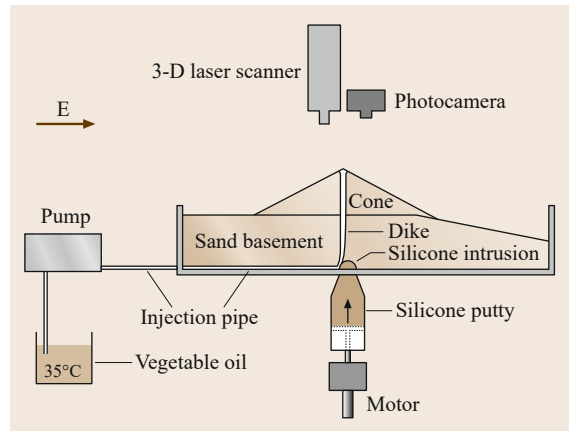

“If one could calculate the required properties of materials in a scale model, then there was actually no need to build the model itself. One could simply calculate the property of interest.”

It is not clear what is the basis of such a claim could be; building and running experiments with analogue models have been shown to be important in many cases in geophysics from *Hubbert's* day all the way up to the present. *Oreskes* continues: “In principle, a computer simulation can be used in precisely the same manner as a mimetic physical model to demonstrate circumstances capable of producing known effects” [39.38, p. 113]. This statement gives pride of place to computer simulation in geophysics, which is not deserved. The “in principle” qualification, which is actually an extremely significant qualification, needs to be given sufficient weight.

First, it needs to be emphasized that experimentation on analogue models has *not* been supplanted by computer simulations; it is surprising how often the misconception that they have been is voiced. Granting that sophisticated computing methods implemented on

**Fig. 39.6** Mount Etna volcano, aerial view. The green area is unstable. The fault systems are indicated by RFS, PFS, and TFS (after [39.42])

**Fig. 39.7** Experimental apparatus used to model magma emplacement by the injection of silicone putty or vegetable oil into an analog volcano (after [39.42])

digital computers are now used for many of the tasks for which analogue models were at one time used, this still does not mean that analogue model experiments are now dispensable. In many cases – perhaps even in most cases – a great deal more knowledge would be needed

in order to construct a computer simulation than would be needed to construct and use an analogue model experimentally in order to yield new knowledge. This is clearly the case in geophysics. Computer simulation is often preferred for reasons of cost and adaptability, but it cannot be considered a satisfactory substitute for experimental analogue models in general. Analogue models can be extremely expensive, due to the laboratory personnel and facilities involved in constructing, instrumenting, and carrying out experiments on models with a high degree of precision. Yet, even costly analogue models are still used to this day, as they often reveal phenomena that a computer simulation built using current knowledge does not. This has been as true in other areas such as aeronautics as it has been in geophysics and physical earth sciences: the demise of the wind tunnel has been predicted quite a few times over the last century, but, in spite of such predictions, wind tunnels are still considered indispensable today. So, too, are the analogue models – some quite costly – used in geophysics today.

Second, it needs to be emphasized that most computer simulations *rely upon* information gained by observation and experimentation, especially experimentation on analogue models. The current practice, in geophysics as in so many other fields, is to use both kinds of models in conjunction; over the long term, each methodology can help inform and improve the other ([39.42] and [39.43, p. 1317]). But there is an asymmetry: while analogue model experiments can be and in the past were performed without benefit of computer simulations, most computer simulations relied heavily on knowledge gained from analogue model experiments – whether today’s users of such sophisticated computer packages realize it or not. One practical benefit of computer simulations that accounts for their popularity and widespread use is the ease with which a model can be modified. The advantage of cost and adaptability of computer simulations led to their adoption in cases where the mechanisms were well understood, and this was followed by over-reaching claims about what computer simulations were capable of replacing. That these claims were over-reaching is seen in retrospect; we can now see that, in geophysics as in many other fields, experimentation on analogue models has not only *not* been replaced, but still *holds an irreplaceable role* in investigation.

*Role of Analogue Models vis a vis Numerical Computer Simulation.* These points about the role of analogue models – that is, their use in conjunction with, rather than their displacement by, numerical simulation computer methods in the post-computer era – is readily seen by looking at actual examples of recent re-

search using analogue models. Many examples would serve for this; here we shall look at the details of an example from a recently published (2014) investigation carried out by researchers at Caltech and the University of California and published in a major venue (*Journal of Geophysical Research: Solid Earth*): the experimental investigation of strong ground motion due to thrust fault earthquakes [39.43].

In this investigation, the topic is not the geometry of the changes caused by the earthquakes, but the rupture velocity. Previously, there had been a question of whether the rupture proceeds below or above the velocity at which the seismic shear wave propagates; though observations that supershear ruptures had occurred in natural earthquakes began piling up, their existence went against well-established belief. According to *Gabuchian et al.* [39.43], the role of analogue laboratory models in the discovery and acceptance of the occurrence of a high-speed “rupture velocity” that *does* exceed this critical velocity was profound: they write that [39.43, p. 1317]:

“it was the experimental discovery of supershear ruptures occurring repeatedly and reproducibly under highly instrumented and controlled laboratory conditions [...] that stimulated the recent flurry of theoretical activities on the subject.”

They report that the theoretical activities were themselves changed in important ways as a result of the laboratory results; [39.43]

“it motivated seismologists to remove [certain speed restrictions], to revisit a number of historic earthquake events, and to reexamine irregular field observations in search for such a phenomenon.”

*Gabuchian et al.* argue that analogue experiments are crucial in developing and validating numerical models [39.43], and that, even more importantly, they are [39.43, p. 1317]:

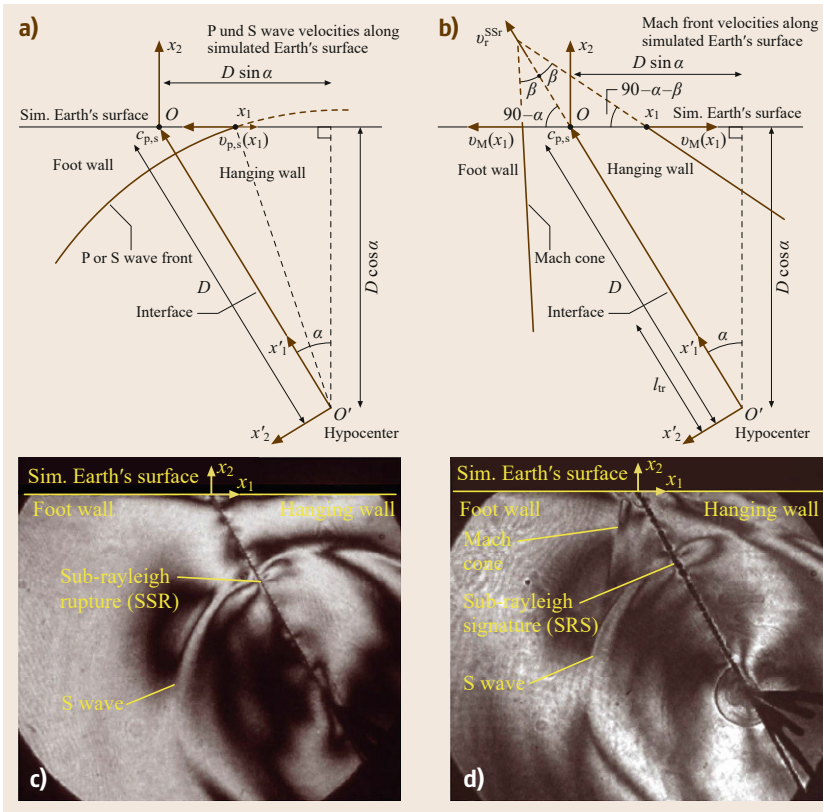

“the only way to provide fresh observations of previously unknown phenomenon (discovery) that can then be investigated in numerical models and in seismological data. Indeed, many of the effects of dip-slip faults [...] were predicted by the analog foam rubber models of *Brune* [39.44]. Thus, laboratory experiments, numerical models, and seismic observations can be used together and iteratively to more fully investigate the physics of faulting.”

*Gabuchian et al.*’s earthquake investigation [39.43] uses an analog material called homalite, which is a high-density photoelastic polymer material. The material is prepared and the setup instrumented in such a way that it provides a high-precision model of lab-

**Fig. 39.8** Experimental specimen made of homalite (a high-density photoelastic polymer material). A dynamic rupture is triggered at the interface; the upper surface on the right side of the interface serves as a *simulated earth's surface* (after [39.43])

**Fig. 39.9** Photoelastic images of experimental results. Panels (a) and (b) are schematic drawings for sub-Rayleigh (a) and supershear ruptures (b). Panels (c) and (d) are photoelastic images of sub-Rayleigh (c) and supershear events (d). A dynamic rupture is induced on the diagonal surface so that the propagation of the rupture in the homalite specimen can be studied. The Mach cone is clearly visible in the *right hand image* (after [39.43])

oratory earthquakes, with respect to the quantities measured. The results are also visually accessible. Many analogue models in geophysics use materials more like the material modeled, as in the volcanic spreading example. The use of a photoelastic polymer such as homalite in which shocks are caused thermally or electrically – rather than being mechanically induced – reflects both the recent development of new laboratory techniques and the recognition that fundamentally dif-

ferent processes may need to be studied now in order to understand the consequences of the phenomena of *dynamic fracture*. Experimental reproducibility is addressed in their studies, too [39.43, Section 4.3]. The interest here is definitely not limited to explaining the past, but in using analogue models to understand the future as well as the past.

A sketch of the experimental specimen used in Gabuchian et al. experiments is shown in Fig. 39.8.

As indicated in Fig. 39.8, one of the surfaces of the specimen serves as a simulated *earth's surface*. The design and sizing of the specimen involved some mathematical analysis; avoiding reflected waves and buckling were two requirements that had to be met. The photoelastic images revealing the difference between the experimental results in the subcritical and supercritical cases are very striking and shown in Fig. 39.9. We shall not go into the details of the results here, except to point out the Mach cone in the

supercritical case (on the right-hand side of Fig. 39.9), and that one can visually compare the photoelastic image of the supercritical case to that of the photoelastic image of the subcritical case (left side of Fig. 39.9).

The significance of this research for our purposes is that, as described above, this research using analogue volcanoes shows a significant feature, or phenomenon, that was not uncoverable using existing methods of analyzing earthquakes [39.43].

## 39.2 Analogue Models in Physics

Analogue models are “a constant presence in the world of physics and an invaluable instrument in the progress of our knowledge of the world that surrounds us,” in the words of the editors of a recent (2013) collection on the use of analogue models in contemporary theoretical physics [39.8], though, as they point out, it “would be impossible to give a comprehensive list of these analogue models” [39.8, p. v]. One especially interesting example in theoretical physics is the use of analogue models of space-time briefly mentioned in the opening of this chapter. A variety of such analogue models have been proposed, including analogues that employ surface waves, Bose–Einstein condensates, graphene sheets, optical fibers, optical glass, and laser pulse analogues. Some of these have so far only been used in probing questions about gravity and space-time theoretically, but some have also been used to actually construct analogue models in the laboratory [39.8].

### 39.2.1 Lessons from the Nineteenth Century

The use of analogue models in investigating cosmology, for example, analogue space-times, or analogue gravity, may seem quite distant from the more familiar analogue models in geophysics and nineteenth century mechanics, but, conceptually, it actually looks like a most natural outgrowth of them. In the late nineteenth century, while engineers were developing similarity methods to improve their designs of and predictions about ships and structures, physicists explicitly employed analogies to help them think through theory and come up with experiments about light, heat, sound, electricity, and magnetism. One of the most well known of these was the analogy between light and sound that was based on the fact that both were waves; another was the analogy between fluid, heat, and electrical currents that was based on the fact that the partial differential equations describing all three such *flows* were of the same form.

### 39.2.2 Sound as an Analogue of Light: The Power of Experimentation on Analogues

The analogy between light and sound was especially fruitful in the development of the correct understanding of the Doppler effect. (The Doppler effect is the change in frequency observed due to relative motion between the source of a wave and an observer. If the relative motion between source and observer is toward each other, the observed frequency increases; if the relative motion between source and observer is away from each other, then the observed frequency decreases.) To put it more precisely, the relevant factor is the ratio of the velocity of the relative motion between observer and source to the velocity  $c$ , where  $c$  is the velocity of sound for a change in pitch, or the velocity of light for colour shift. Because the velocity of light is so high, the velocity of motion required to create an observable change in pitch is much, much less than that required to create an observable change in colour [39.3, p. 18]. Mach devised and carried out laboratory experiments in which changing the relative motion between the observer and the sound source resulted in changes in observed frequency [39.2], concluding in 1860 that “the fluctuation in the pitch is dependent on no other circumstance than the direction and speed [of the source] with respect to the observer” ([39.1] and [39.3, p. 18]).

Could the laboratory experiments using sound be considered an analogue for light in a serious scientific sense? Eventually, Mach became convinced that they could be; in 1878 he published an article on it, no longer hesitant about extending the Doppler principle from his experiments on sound to the realm of optics. The Doppler effect for light, he argues, follows from the characteristics of light that are common to both sound and light waves. He does not need to assume that light is a mechanical wave in order to extend

his results from sound to light. The characteristics that light and sound have in common that are relevant to applying the Doppler principle are things such as being propagated in time with a finite velocity, having spatial and temporal periodicity, and being able to be algebraically summed. This characterization does not assume the existence of a medium for light. Mach considers the experiments on sound to be confirmatory for light, and argues that on the basis of them he can conclude with confidence that the Doppler principle applies to light [39.1, 3].

To lay out the reasoning that Mach eventually uses in claiming that his experiments on the Doppler effect for sound waves in the laboratory are confirmatory of the Doppler effect for light propagation in astronomy: His theory is that it is the relative motion of wave (or signal) source and observer that is responsible for the Doppler effect. Mach identifies the characteristics common not only to light and sound, but also to all oscillatory motion, that he believes are sufficient for the occurrence of the Doppler effect. He shows that any oscillatory motion having these characteristics will give rise to the Doppler effect, according to his line of reasoning. The mechanism does not matter; he is explicit about this point, in part because he wishes to emphasize that the existence of the Doppler effect for sound does not depend on features of the medium of transmission. Mach then experimentally confirms that, as his reasoning predicts, the Doppler effect arises for sound in a laboratory setup that allows him to manipulate the relative motion of signal source and observer. Based upon the fact that light has in common with sound those characteristics he has shown are responsible for giving rise to the Doppler effect according to his line of reasoning, he concludes that the experimental confirmation of his experiments for sound in the laboratory applies to light in astronomical observations [39.3]. As we shall see, this kind of approach using analogue models is very much like approaches still in use in physics today.

### 39.2.3 Water as an Analogue of Electricity: Limitations of Generalizing from Analogues

The nature and limits of analogical reasoning, including reasoning about experiments on analogues, was also a concern of nineteenth century physics. In a paper entitled *On Discontinuous Movements Of Fluids* (which is discussed in more detail in Chap. 18, in this volume), Helmholtz points out both the invaluable role that analogue models can fulfill, and the limitations they may display.

As for the limitation of analogical reasoning on the basis that two things instantiate the same equation,

*Helmholtz* notes that “the partial differential equations for the interior of an incompressible fluid that is not subject to friction and whose particles have no motion of rotation” are precisely the same as the partial differential equations for “stationary currents of electricity or heat in conductors of uniform conductivity” [39.45]. Yet, he notes, even for the same configurations and boundary conditions, the behavior of these different kinds of currents can differ [39.45, p. 58]. The explanation he gives is that in some situations, “the liquid is torn asunder,” whereas electricity and heat flows are not. Based upon observations, the difference in behavior between fluid currents on the one hand and electrical and heat currents on the other is due to “a surface of separation” that exists or arises in the case of the fluid.

*Helmholtz* identifies another method [39.46, p. 68]:

“In this state of affairs [the insolubility of the hydrodynamic equations for many cases of interest] I desire to call attention to an application of the hydrodynamic equations that allows one to transfer the results of observations made upon any fluid and with an apparatus of given dimensions and velocity over to a geometrically similar mass of another fluid and to apparatus of other magnitudes and to other velocities of motion.”

The method Helmholtz is referring to, which he presented in this now-classic paper (originally published in German in 1873), thus differs from deducing predictions from theory. The method he presents there does *make use of* the fact that the same equation applies to both situations to provide a basis for using one situation as an analogue for another. However, Helmholtz derives the dimensionless parameters that must be made the same between analogue model and what is modeled. The topic is discussed in more detail in Chap. 18. What Helmholtz describes is a special case of a scale model, for he specifies that the bodies are to be geometrically similar, and involve fluids to which the hydrodynamic equations apply. This is a use of an analogue model in which the basis for drawing the analogy, although it *makes use of the fact* that there is an equation instantiated by analogue and thing modeled, *does not rely on that fact alone*: there are dimensionless parameters that must be held the same between analogue and thing modeled.

This kind of concern about basing the use of an analogue model on the fact that the analogue model and what it models both instantiate the same equation is reflected in critiques of their use in physics today. The concern Helmholtz raised in the nineteenth century (about the surfaces of separation that arise in fluid flow) regarding the limitations of analogues between differ-

ent kinds of flow (heat, electrical, hydrodynamic) arises today not only when there is a difference in material or what is flowing, but also when the scales between laboratory model and what is modeled are so different that one cannot assume that the same forces or mechanisms are at work in analogue model and what is modeled.

Whether the physicists using analogue approaches in twenty-first century physics realize it or not, the new methods they are developing and the concerns they are raising about them have precursors in the nineteenth century.

### 39.2.4 Some Recent Results Using Analogue Models

The use of analogue models of space-time in the twenty-first century involves drawing analogies between flows of various sorts, too. However, the interest does not seem to be historically continuous with the nineteenth century efforts.

#### Unruh's 1981 *Experimental Black-Hole Evaporation?*

The current interest in analog models of gravity is usually traced to a paper by William Unruh published in 1981. In that very short paper, *Unruh* addressed what he called “one of the most surprising discoveries of the past ten years”: black hole evaporation. He noted that [39.47]

“experimental investigation of the phenomenon would seem to be virtually impossible, and would depend on the highly unlikely discovery of a small black hole (a relic of the initial stages in the life of the universe perhaps) of the earth.”

However, he said, “a physical system exists which has all the properties of a black hole as far as thermal radiation is concerned, but in which the physics is completely understood” [39.47].

The physical system he referred to was a sound wave propagated in supersonic flow. He restricted consideration to cases of “the background fluid smoothly exceeding the velocity of sound” which, he notes, can be assured by the use of “a suitably shaped nozzle” [39.47, p. 1352, n. 7]. Indeed, such a “suitably shaped” nozzle exists; the DeLaval nozzle (Fig. 39.10) was invented

Fig. 39.10 DeLaval nozzle (after [39.48, p. 380])

in the nineteenth century for steam applications, and is used in rocket design and many other applications today.

This insightful invention can be used to create conditions for smooth supersonic flow (i.e., a region in which flow is supersonic but a shock wave does not occur) [39.48, p. 380].

Normally, in a pipe or convergent (decreasing cross-sectional area) nozzle, once flow reaches the critical flow, or *choked* conditions, the velocity of the flow at the throat of the nozzle does not increase, even if the pressure upstream increases. However, if the convergent nozzle has an appropriately designed divergent nozzle attached to its outlet, it is possible for the velocity of the flow to increase in the divergent (increasing area) portion of the nozzle, after passing through the throat (minimum area) of the nozzle. The striking thing about this situation (as many engineers are aware) is that changes in the downstream pressure do not affect the rate of flow in the nozzle. Considering the phenomenon in terms of pressure signals, one way to think of this is that the information that the pressure downstream has changed (i.e., a pressure signal or pressure pulse) cannot travel back upstream to the throat of the nozzle [39.49]. This feature of flow in a DeLaval nozzle is depicted in Fig. 39.11.

This physical situation is an analogue model, in that, as *Unruh* put it: “The model of the behavior of a quantum field in a classical gravitational field is the motion of sound waves in convergent fluid flow” which, he added [39.47, p. 1353]:

“forms an excellent theoretical laboratory where many of the unknown effects that quantum gravity could exert on black hole evaporation can be modeled [...] the phonons emitted are quantum fluctuations of the fluid flow and thus affect their own propagation in exactly the same way that graviton emission affects the space-time on which the various relativistic fields propagate.”

He had some doubts about how detectable the emission would be in that physical system, though.

Fig. 39.11 Scheme of a DeLaval nozzle showing important features of flow behavior (after [39.49, p. 89])

### Reasoning About Analogues of Gravity Before and After 1981

Visser notes that, actually, notions of analogues of gravity “have, to some extent, been quietly in circulation almost since the inception of general relativity itself” citing Walther Gordon’s introduction of “a notion of *effective metric* to describe the effect of a refractive index on the propagation of light” and “notions developed in optics to represent gravitational fields in terms of an *equivalent refractive index*” [39.6]. *Max Born’s* sonic analogue of the kinematics of special relativity might be cited as another example of sorts [39.50, p. 251], also quoted and discussed in [39.3]:

“[...] if we use sound signals to regulate the clocks, Einstein’s kinematics can be applied in its entirety to ships that move through motionless air. The symbol  $c$  would then denote the velocity of sound in all formulae. Every moving ship would have its own units of length and time according to its velocity, and the Lorentz transformations would hold between the systems of measurement of the various ships. We should have before us a consistent Einsteinian world on a small scale.”

Nonetheless, Unruh’s short 1981 paper is regarded as marking a new era in the revival of analogue notions of gravity, although the thinking concerning the analogue involved in it has progressed since then. Whereas, in the 1981 paper, Unruh had proposed an analogue involving sound traveling in a fluid flowing through a nozzle, by 2002, *Schutzhold* and *Unruh* [39.51] proposed “gravity waves of a flowing fluid in a shallow basin” as an analogue to study black holes in a curved space-time. The surface wave setup permitted manipulations not available in the earlier proposal, due to being able to alter the depth of the water. The reasoning *Schutzhold* and *Unruh* use here appeals to “similar equations”, that is, that the behavior of interest in the analog and the behavior of interest in what the analogue models are described by equations of the same form [39.51, emphasis added]:

“Analogues, which obey similar equations of motion to fields around a black hole raise the possibility of demonstrating some of the most unusual properties of black holes in the laboratory. This is the basic idea of the black and white hole analogs [...] originally proposed by Unruh [in 1981] [...]. The sonic analogs established there are based on the observation that *sound waves in flowing fluids are (under appropriate conditions) governed by the same wave equation as a scalar field in a curved space-time*. The acoustic horizon, which occurs if the velocity of the fluid exceeds the speed of sound within the

liquid, acts on sound waves exactly as a black hole horizon does on, for example, scalar waves.”

However, there is also reasoning about aspects of the analogue model (surface waves in fluid) that is *not* part of the analogy, in a way that aims to show how the fuller knowledge we have about the analogue model might be drawn upon [39.52, p. 2908]:

“In the case of a fluid, one knows that the fluid equation of motion is inapplicable at high frequencies and short wavelengths. At wavelengths shorter than the interatomic spacing, sound waves do not exist and thus the naive derivation of the temperature of [sonic analogues of black] holes will fail. But unlike for black holes, for [sonic analogues of black] holes, the theory of physics at short wavelengths, the atomic theory of matter, is well established. For black holes, a quantum theory of gravity is still a dream. Thus, if one could show that for [sonic analogues of black] holes the existence of the changes in the theory at short wavelengths did not destroy the existence of thermal radiation from a [sonic analogue of a black] hole, one would have far more faith that whatever changes in the theory quantum gravity created, whatever nonlinearities quantum gravity introduced into the theory, the prediction of the thermal radiation from black holes was robust.”

This is basically an attempt to identify the *relevant characteristics* of a system of which the thermal radiation is a consequence. The approach is reminiscent of Mach’s approach in investigating the Doppler effect: if features other than the relative motion of source and observer did *not* make a difference to the existence of the Doppler effect, that would increase confidence (or show to those who were sceptical) that the Doppler effect depended only on the relative motion of source and observer. In this case (sonic analogues of black holes), if features *other than those related to instantiating the equation* that the black hole and the sonic analogue for it had in common seemed *not* to make a difference to the existence of a certain effect, then one’s confidence that the effect followed in virtue of a system instantiating the equation would be strengthened. But it could go the other way, too [39.52, p. 2908]:

“On the other hand, if the introduction of the atomicity of matter invariably destroyed the thermal radiation for [sonic analogues of black] holes, one would strongly suspect that the thermal nature of black holes would not survive the complications introduced by quantum gravity.”

Unruh had shown concern from the start that Hawking’s derivation of black hole evaporation relied upon

assumptions he describes as *absurd*. There was thus value in being able to sort out which features or characteristics of the situation are actually responsible for the Hawking effect. Visser had argued [39.53] that Hawking radiation is a kinematic effect independent of dynamics; In Schutzhold and Unruh's 2002 paper, they remark on what this means for the value of analogue models of gravity [39.51]:

“Although the kinematics of the waves propagating within the black and white hole analogs are governed by the same equation as those in a curved space-time, the dynamics of the effective metric itself are not described by the same laws as gravity (i. e., the Einstein equations) in general. In this way the analogs allow one to separate the dynamical effects of gravity (following from the Einstein equations) from more general (kinematic) phenomena.”

Our interest here is in the methodologies that are used to underwrite the use of analogue models to serve as models of what they are used to model. However, it is worth noting that this use of analogue models – that is, using them to help sort out what the phenomenon of interest is dependent upon for its existence – is a valuable help that analogue models can provide when there is dispute about the dependency. It is not a new kind of reasoning, of course, for we saw that Mach used it in his experiments on the Doppler effect, especially to argue against a view held by others (e.g., Petzval) that the phenomenon arose from features of the medium of transmission. Nor does reasoning about sorting out dependencies necessarily require the use of analogue models or experimentation; mathematicians often show that a result can be proven with fewer assumptions than

currently known proofs, without resorting to laboratory experiments to do so.

#### *Sorting out Dependencies: Measurements of Stimulated Hawking Emission in an Analogue System.*

When Hawking radiation was finally measured in an analogue model of a black hole, it was for exactly this benefit – sorting out dependencies – that it was especially valued, and the interest was in observing the existence of the phenomenon. Unruh argued for his view that the result of the experiment counted as a genuine measurement of Hawking radiation in 2010; there are also comprehensive reports on the experiment by the experimental team headed by *Silke Weinfurter* et al. [39.54, 55]. The laboratory setup is shown in Fig. 39.12 [39.54, Figure 8.2]: a region of high-velocity flow, including (surface wave) horizons, is created by placing a streamlined obstacle in the water flume [39.54, Figure 8.4], as seen in Fig. 39.13.

Against this flow, long waves are propagated, which become blocked and converted into short waves, thus creating a laboratory analogue of the behavior of interest [39.55, p. 120312–2]:

“It is this blocking of the ingoing waves that creates the analogy with the white hole horizon in general relativity. That is, there is a region that the shallow water waves cannot access, just as light cannot enter a white hole horizon. Note that while our experiment is on white hole horizon analogs, they are equivalent to the time inverse of black hole analogues.”

*Rousseaux* illustrates the effect occurring in nature: Fig. 39.14 below, of a white hole formed where a river enters the sea, is one such example from his work [39.56]. Other examples are fluid being poured into a sink, and a whale's *fluke-print* [39.56, p. 99]:

“As a whale swims or dives, it releases a vortex ring behind its fluke at each oscillation. The flow induced on the free surface is directed radially and forms an oval patch that gravity waves cannot enter [...].”

In the 2011 paper by Weinfurter et al., *Measurement of Stimulated Hawking Emission in an Analogue*

**Fig. 39.12** Experimental apparatus in Weinfurter et al.: Analogue model of Hawking emission (after [39.54]): (1) holding reservoir, (2) pump and pump valve, (3) intake reservoir, (4) flume, (5) obstacle, (6) wave generator, (7) adjustable weir

**Fig. 39.13** Obstacle in Weinfurter et al. experiments (after [39.54]): (1a) and (1b) curved parts motivated by airplane wing; (2) flat aluminum plate to further reduce flow separation; and (3) flat top aluminum plate to reduce wave tunneling effects

**Fig. 39.14** White holes in nature. Where a river enters the sea, the sea waves may be *blocked* (after [39.56])

*System*, the authors note that they already had numerical studies indicating that “the [Hawking] effect is independent of short-wavelength physics” [39.55]. The motivation for experimentation on the analogue model is that, were they to be able to show that there was thermal emission in their physical setup, this would “indicate the generic nature of the Hawking thermal process.” This is because the water tank/flume physical system “exhibits turbulence, viscosity, and nonlinearities”; their argument seems to be that the existence of thermal emission *in spite of* these would show that the process is a feature that follows from the wave kinematics of the physical setup, not forces arising due to these other features of the setup. And, if that were true, the result would be a very general one, applying to waves of any sort.

The measurement result is not as simple as providing the value of a quantity; the researchers identified a certain dimensionless parameter having to do with the ratio of the amplitudes of the waves that were absorbed to those that were emitted, which is important in

describing thermal (Hawking) emission, and they investigated how it scaled with frequency. This was a check that what they were observing did have the character of the theorized emission, that is, this ratio scaled with frequency in just the way one would expect thermal (Hawking) emission to.

The role of the results from the analogue model do not have their significance as stand-alone results; as Weinfurter et al. point out, there are certainly other, theoretical reasons for suspecting the thermal emission to be independent of quantum gravity or Planck-scale physics. There are other reasons for departing from the view Hawking had when he first discovered it, that is, for abandoning the view that thermal emission was “a feature peculiar to black holes” [39.54, p. 179], notably *Visser’s* work in 1998 mentioned above, in which he argued that Hawking radiation is a “purely kinematic effect” that is “generic to Lorentzian geometries containing event horizons” [39.53, 57]. The experimentation on an analogue model demonstrated how to create and measure such thermal emission in a laboratory setup with classical waves, lending support to the theoretical conclusions that the phenomenon is a far more general feature of waves in systems of a certain sort. *Weinfurter* et al. close the paper in which they report their results with an indication of even more valuable work that experimentation on analogue models of black holes might do [39.55]:

“It would still be exciting to measure the spontaneous emission from a black hole. While finding small black holes to test the prediction directly is beyond experimental reach, such measurements might be achievable in other analogue models, like Bose–Einstein condensates, or optical fibre systems. [citing such models being developed by others.]”

### 39.3 Comparing Fundamental Bases for Physical Analogue Models

Analogue models are often described in terms of an equation that both a physical model and what it models have in common; on such an account, an analogue model is described as one of two physical setups instantiating a certain equation. Common examples are a hydraulic system and an electrical system (each of which can serve as an analog model of the other), or an oscillating electric circuit modeling an oscillating mechanical device. This is certainly one kind of basis for an analogue model. However, as the discussions in this chapter drawing on actual scientific practice indicate,

instantiating the same equation is not always the basis used to develop, justify, and reason using analogue models. The actual logic involved is often far more sophisticated, and sometimes does not require as much knowledge about the phenomenon one wished to bring about as the approach of exhibiting an equation that is instantiated by both the model and the thing modeled does. Gathering together the insights above, along with points made in the sources cited, three kinds of bases for analogue models can be identified. These are depicted in Table 39.2. Besides the account just men-

**Table 39.2** Three bases for experimentation on a physical analogue model

Basis for analogy between physical analogue model and thing modeled	Knowledge relied upon
<p>1. Equation in common The equation governing a quantity or phenomenon in the model is the same equation governing the corresponding quantity or phenomenon in what is modeled, although the quantities in the equation refer to different physical things, processes, or systems when used to describe the model and what is modeled. Experimentation on the analog model (e.g., flow currents in a fluid body) is used to inform the researcher about what will happen in the analogous setup modeled (e.g., electrical currents in an electrically conducting body), or vice versa.</p>	<p>In the example of a fluid body as an analogue of an electrically conducting body, the <i>knowledge relied upon</i> includes the partial differential equation for fluid flows governing the behavior of flow currents in the analog model, the analogous equation for electrical current in the electrically conducting body, and that they can be put in the same form so as to permit drawing correspondences between the fluid quantities (e.g., flow velocity, pressure) and electrical quantities (e.g., current, voltage). Note: Behavior of analogue model and thing modeled can diverge. Key example: Helmholtz's <i>On Discontinuous Movements Of Fluids</i> [39.45] in which a surface of separation arises in the case of fluids, but not in the case of electrical flows – even though the partial differential equation takes the same form for both flows. Nevertheless, there are cases for which this discontinuity is known not to arise (the pressure does not become negative in the case of interest). Which cases are which is one piece of knowledge relied upon in using this kind of basis for the analogue model.</p>
<p>2. Relevant characteristics in common Characteristics essential to behavior of interest are the same in the model as in the thing or systems modeled. Sometimes the features are derived from equations and/or analyses of mechanisms.</p>	<p>Relies upon knowledge as to which characteristics are essential to the behavior of interest. Examples: (a) <i>E. Mach</i> identified characteristics essential a wave that did not depend upon the existence of a medium of transmission and showed the Doppler effect due to relative motion of source and observer was a consequence of these features, then verified by experiments on analogue model [39.1–3] (b) <i>S. Weinfurter</i> et al. identified classical features of Hawking process that did not depend upon quantum gravity or Planck-scale physics (e.g., wave pair formation), showed Hawking radiation a consequence of these features of waves, and then subsequently verified the phenomenon by experiment on the analogue model [39.54, 55]</p>
<p>3. Physically similar systems A (nonunique) set of dimensionless parameters that characterize the system with respect to a certain kind of behavior is identified; similarity of system behavior between <math>S</math> and <math>S'</math> is established when these parameters have the same value in <math>S</math> as in <math>S'</math> (see Chap. 18, this volume)</p>	<p>Relies upon knowledge as to which quantities (e.g., viscosity, density) are relevant to the behavior of interest. (Generally this is <i>less</i> information than required in 1. above) (Note: There is also reliance on the basic assumption that the behavior is rule-governed, in that it is assumed that there is a relation (possibly unknown) between the quantities relevant to the behavior of interest, and that the relation(s) can be expressed by a physical equation.)</p>

tioned, which is listed below as *equation in common*, there are two others: *characteristics essential to the behavior of interest are the same in the model as in the thing or system modeled*; and *physically similar systems*.

### 39.3.1 Three Kinds of Bases for Physical Analogue Models

These three kinds of bases are listed below and the points made about them are organized in Table 39.2.

#### Equation in Common

When the basis for the analogy between the analogue model and what is modeled is an appeal to the fact that an equation governing a quantity or phenomenon in the model is the same equation governing the corresponding quantity or phenomenon in the thing modeled, we will say the basis is having an *equation in common*. The equation may refer to different physical things, processes, or systems in the analogue model than in what is modeled.

To illustrate with an example using a hydraulic circuit as an analogue of an electrical circuit, experimentation on the analogue model (e.g., hydraulic setup) is used to inform the researcher about what will happen in the analogous setup modeled (e.g., the electrical circuit). The knowledge relied upon in constructing and using the model is the partial differential equation of fluid flow governing the hydraulic flow behavior in the analogue model, the analogous equation for electrical current in the electrical circuit, and that they can be put in the same form so as to permit drawing correspondences between the fluid quantities (e.g., flow velocity, pressure) and electrical quantities (e.g., current, voltage).

This kind of basis has a potential vulnerability: the behavior of analogue model and thing modeled can diverge. A key example of this is due to *Helmholtz' On Discontinuous Movements of Fluids* (1868) in which a "surface of separation" [39.45, p. 59] arises in the case of fluids, but not in the case of electrical flows – even though the partial differential equation takes the same form for both flows [39.45]. Nevertheless, there are cases for which the discontinuity Helmholtz cites is known not to arise (i.e., the pressure does not become negative in the case of interest). Which cases are which is one piece of knowledge relied upon (or, sometimes, explored) when using this kind of basis for the analogue model.

#### Relevant Characteristics in Common

When the basis for the analogy between the analogue model and what is modeled is the fact that the charac-

teristics essential to the behavior of interest are the same in the model as in the thing or system modeled, we will call it a case of *relevant characteristics in common*.

Sometimes the relevant characteristics are derived from equations and/or analyses of mechanisms, so the knowledge relied upon may involve some of the same information that is relied upon in the *equation in common* approach; it depends upon the reasoning the researcher uses to decide which characteristics of the situation are relevant. Sometimes a researcher may employ an approach based on partial knowledge (i.e., less knowledge than that needed to solve the problem) – but the partial knowledge may be enough to identify what the characteristics relevant to producing the behavior of interest are. Or, the partial knowledge may be enough to show that an analogue model and what it models will display the same behavior of interest, so that experimenting on the analogue is informative about how what it models will behave. Some of the scaling arguments used in developing the analogies underwriting models of analogue gravity are examples of this, as in *Rousseaux's* discussions of the differences between shallow and deep water tank analogue models [39.56]. *Rousseaux's* scaling arguments are based upon dimensional analysis, though he does not lay out and solve the problem as one of physically similar systems.

Other examples of this sort are Ernst Mach's work on the Doppler effect and work by *Weinfurter et al.* on identifying the classical features of the Hawking process: E. Mach identified characteristics essential to being a wave that did not depend upon the existence of a medium of transmission (spatial and temporal periodicity, finite velocity, can be algebraically summed) and showed the Doppler effect due to relative motion of source and observer was a consequence of these features, which he then verified by experiments on an analogue model [39.1, 3]. *Weinfurter et al.* identified classical features of the Hawking process that did not depend upon quantum gravity or Planck-scale physics (e.g., wave pair formation), then showed Hawking radiation a consequence of these features of waves, and subsequently verified by experiment that the analogue of Hawking radiation occurred on the analogue model [39.54, 55].

#### Physically Similar Systems

When employing the method known as *physically similar systems*, a (nonunique) set of dimensionless parameters that characterizes the system with respect to a certain kind of behavior is identified using the method of dimensional analysis; similarity of system behavior between  $S$  and  $S'$  is established when these parameters have the same value in  $S$  as in  $S'$  (see Chap. 18, this volume). The knowledge relied upon for this method

is the knowledge as to which quantities are relevant to the behavior of interest. Generally this is *less* information than is required in the *equation in common* method. In a much more fundamental sense of reliance, the researcher is also relying on a basic assumption made

implicitly in much of scientific research: that the behavior is rule-governed, in that it is assumed that there is a relation (possibly unknown) between the quantities relevant to the behavior of interest, and that the relation can be expressed by a physical equation.

## 39.4 Conclusion

The discussion presented here, of a few selected examples of analogue models and the investigation of the different bases for their use, should help put to rest three common misconceptions about the use of analogue models in physics today.

*First, the misconception that analogue models are a thing of the past:* As the examples discussed above indicate, analogue models are not a thing of the past. In fact, there are new areas of application and new kinds of analogue models being developed; the recent surge in development of analogue models in general relativity is one striking example [39.5, 57]. Yet, the use of some of these models in the twenty-first century does have precursors in the nineteenth century.

*Second, the misconception that analogue models serve merely illustrative or pedagogical purposes.* Many of the examples described above are cases of serious investigative research. This is so even when the main benefit of the model is gaining a better qualitative understanding of the mechanisms at work. *Rousseaux* remarks that the investigation of analogue gravity “through the prism of water waves theory has broadened our definition of a horizon” [39.56, p. 106]. In geophysics, experimentation on analogue models has sometimes brought about an appreciation of mechanisms that might be at work and ought to be investigated, which is a kind of discovery [39.43].

*Third, the misconception that numerical methods along with high-speed digital computers can always provide whatever an analogue model could provide.* This is the most pernicious and deep-seated of the three misconceptions. It betrays a fundamental misunderstanding of the logic behind analogue models. Such statements are probably based on assuming that the basis for analogue models is having an equation in common. As Table 39.2 indicates, there are other bases for using analogue models than having an equation, and it is not the case that an analogue model can in principle always be replaced by an equation: the method of dimensional analysis and physically similar systems often requires less information than the method of finding an equation that is instantiated by both the analog model and what it models does. (That is why similarity methods are sometimes called partial information meth-

ods [39.58].) More importantly, even when one does have such an equation, and cites it as the basis for the analogy between analogue model and what is modeled, the role of the equation is to establish a correspondence between items in the analogue model and what it models. Even if one has the means to solve that equation numerically on a digital computer, there is no guarantee that the numerical solution of the equation will reveal every phenomenon that might be observed in the analogue model. It has been the case many times that the use of an analogue model shows a phenomenon that the numerical solution of the equation had not, no matter how many colorful visuals and graphics the computer program is capable of producing. Analogue models do need to be examined to determine when they are and are not appropriate for a certain investigation, but so, of course, do equations and numerical simulations. The fact that the use of analogue models in various fields has been revived (after supposedly being eliminated from those fields), often for new applications and employing new technologies, reflects something that is becoming increasingly clear: sometimes analogue models really are irreplaceable.

*Acknowledgments.* Thanks to Matt Walhout for suggesting, many years ago, that I might find William Unruh’s work on sonic analogues of black holes of interest. Later, in April 2011, I had the good fortune to attend Unruh’s lecture *Measurement of Hawking Radiation in an Analog System* and the discussion afterward, at the University of Pittsburgh.

Thanks also to the organizers of the conference *Philosophy of Scientific Experimentation III* (PSX3), for financial support to present the talk this paper is based upon *Experimentation on Analogs* at PSX3 on October 5, 2012, at the Department of Physics, University of Colorado, Boulder. I benefitted from comments by, and discussion with, the other participants of PSX3 on the many papers related to analogy, including James Mattingly’s talk *Experimental Cosmology*, which also discussed experimentation on an analogue model (using Bose–Einstein condensates).

Another paper on the topic of the same experiments on sonic analogues of black holes, as are discussed in

this paper, was presented at the Philosophy of Science Association Biennial meeting in late 2014. As that presentation by Dardashti (and the subsequent publication of a related paper by Dardashti et al. *Confirmation via Analogue Simulation: What Dumb Holes can tell us*

*About Gravity* (2015)) occurred more than 2 years after I submitted and presented *Experimentation on Analogues* at PSX3 in October 2012, the talk on which my article for this volume is based, their commentary on those experiments is not discussed here.

# Models of Chemical Structure

## 40. Models of Chemical Structure

William Goodwin

Models of chemical structure play dual crucial roles in organic chemistry. First, they allow for the discovery and application of *laws* to the complex phenomena that chemists hope to understand. Second, they are a source of novel concepts that allow for the continuing development of structure theory and theoretical organic chemistry. In chemistry, therefore, the centrality and significance of models to the scientific enterprise is manifest and furthermore chemistry is a relatively clear, useful, and interesting context in which to consider more general philosophical questions about the nature and role of models in science.

One of the most important and influential trends in the philosophy of science over the last 50 years has been the increase in both the attention paid to the concept of a model and the employment of this concept in philosophical reflection on the nature and dynamics of science. This trend has been usefully described and analyzed by many philosophers (see for instance: [40.1–3]). Without trying to be exhaustive, in this paper I plan to identify a few of the most significant philosophical insights that have emerged out of this increased interest in scientific models and then to reflect on these insights in the context of chemistry, which has been relatively neglected in the philosophical literature. I hope to show both that in chemistry the centrality and significance of models to the scientific enterprise is manifest, and that chemistry is a relatively clear, useful, and interesting context in which to consider more general philosophical questions about the nature and role of models in science.

Models have been characterized in many different ways in the philosophical literature, but for the purposes of this paper it will suffice to think of them as instruments for representation that are not primarily linguistic. The important contrast is with the linguistic statements of a theory (in the logical sense). So the double helix model of DNA represents DNA molecules not because it is a statement in a language that describes this molecule, but because it is a physical object with

certain similarities to the objects that it is intended to represent. Likewise, the billiard ball model of a gas is an image of an interacting system (or the abstract idea of such a system) along with, perhaps, a narrative about how to understand this image, which can be used to represent a gas for certain purposes. Many types of objects, other than statements, have been thought of as models (including mathematical structures, abstract objects, and fictional objects). Given the diversity of things that models might be, it seems best to summarize the central insight behind the relatively recent philosophical interest in models as follows: Representational instruments that are not primarily linguistic are crucial to understanding the nature and development of science.

This central insight has been developed in a variety of ways, but I want to focus on two of them. First, models are crucial to the dynamics of science – how scientific representations, theories, experiments and concepts change over time in response to feedback from the world. And second, models are crucial to science’s capacity to confront complexity – its ability to have useful things to say about real world and/or complex systems. Models, being nonlinguistic entities, help philosophers to get a grip on these aspects of science at least in part because they are representationally rich, that is, they are not limited in their representational capacities (as purely linguistic representations would be) by the arbitrary associations between their component

symbols and aspects of the world. In the case of the dynamics of science, the rich representational capacities of models both supply (or allow for) new features that can be exploited in the models' representational role and thereby act as an incubator for novel concepts. Similarly, models can act as intermediaries between theory and complex real world phenomena because their richer resources allow for representation of the more concrete and local features crucial to understanding such phenomena.

Chemistry, like any large and diverse field of scientific inquiry, is replete with models of many different sorts. Much of the modeling in chemistry is of the standard sort discussed in the philosophical literature – that is, a response to the problem of getting abstract mathematical theories to apply to complex real world phenomena. There has been interesting philosophical work on the form that this sort of modeling takes in chemical contexts [40.4–6] and [40.7] for example; however in this paper I want to focus on what is, I think, a distinctively central and important role for modeling in chemistry. Chemistry, at least large parts of it, is concerned with representing the structures of the substances it studies. For the most part, chemists do not use linguistic resources to represent structure; instead, they build models. Sometimes, like Watson and Crick and most students of organic chemistry, they build physical models, but most frequently they use diagrammatic representations like structural formulas. While there are often linguistic components to such formulas (letters for the atoms, for example), the representational resources of these diagrams are not limited to the arbitrary relations between their component signs and predicates or terms in the current language of the theory. Furthermore, much of importance of these models for both the dynamic development of chemistry and for facilitating the application of chemical theories to concrete, real world cases derives from these extra linguistic representational resources.

Structural formulas (Fig. 40.1), which were initially developed over the course of the nineteenth century, are the centerpiece of a research program that has been immensely successful ([40.8] for a summary of the development of structural formulas). The guiding strategy of this research program, articulated by Aleksandr Butlerov in 1861, was to have one structural formula for

Fig. 40.1 A structural formula for caffeine

each chemical compound, and then to explain the chemical properties of these compounds by determining, “the general laws governing the dependence of chemical properties on chemical structure” [40.9, p. 256]. Structural explanations of chemical properties (and some physical properties as well) have been central to chemistry – particularly organic chemistry, on which I shall focus – ever since. A structural explanation of a chemical property proceeds by identifying the structural features of a compound that are responsible for some (usually contrastive) chemical fact. These structural features are typically general features of the compound as represented in its models, i.e., in its structural formula, which might also be realized by other structural formulas or models as well. In other words, structural patterns identifiable in the models are correlated with chemically significant facts (usually, these days, differences in energy or stability). It is these structural correlations that have ended up playing the role of the *laws* that Butlerov imagined. Thus the *laws* of structural chemistry are formulated in terms of something like chemically significant patterns in the models; in this sense, then, in structural chemistry the laws piggyback on the models. The models don't just interpret or concretize the laws, they make them possible in the first place. Understanding the complex chemical facts of organic chemistry depends, at the most basic level, on building structural models of chemical compounds.

Structural chemistry has not been a static research program. Over the course of its 160 year development, there have been immense changes in chemists' understanding of structure. And not surprisingly, these changes have been reflected in the models used to represent that structure. In the course of this continuous refinement – the back and forth between conceptions of structure and representations of it – models of structure have played a crucial role as a source of new general structural features. In other words, features of the models not originally used in their representational role are reinterpreted as representationally significant in order to explain or account for new theories or experimental facts. Additionally, even after a new aspect of *chemical structure* has been recognized and represented in the models, there still remains the daunting task of making that structural feature experimentally and synthetically relevant (making it useful) and models have also supplied some of the very local structural concepts that allow for the experimental and theoretical development of whole new subfields. Thus, just as models are crucial for structural chemistry to discover and apply laws to the complex phenomena it studies, so too are these models crucial as a source of the novel concepts necessary for the continued development of structure theory and theoretical organic chemistry.

## 40.1 Models, Theory, and Explanations in Structural Organic Chemistry

Structural formulas are the central representational tool used in the explanations and predictions of the theory of organic chemistry. These formulas play many representational roles in organic chemistry, including the role of denoting expressions for chemical kinds. In this role, they serve as descriptive names for these kinds, individuating them according to their composition, bond connectivity and (aspects of their) stereochemistry. Because they can be put (roughly) into one-to-one correspondence with the kinds that they purport to denote, they are also able to act as *stand-ins* for these chemical compounds ([40.10–12] for more on the roles of structural formulas as both names and models in organic chemistry.). When acting as stand-ins for chemical kinds, structural formulas can be *manipulated to teach us things about themselves*, and the things learned about these models can, in many cases, “be transferred to the theory or to the world which the model represents” [40.2, p. 33] ([40.13] for examples of how models acted as paper tools in the early development of organic chemistry.). That is to say that chemists can learn from their models by exploring the implications of (or for) abstract theory in the concrete contexts of particular chemical kinds and often this exploration takes the form of the manipulation of structural models. To bring out some of the interconnections between models of structure, theory, and the explanations in structural chemistry I am going to briefly consider the theory of resonance, which is a modification of structure theory developed in the first half of the twentieth century that is still central to organic chemistry today.

Though it was developed prior to any generally accepted account of the nature of chemical bonding, structure theory has had to evolve in the face of changing theoretical accounts of the nature of the chemical bond. This is to be expected given Butlerov’s aspiration for structural formulas; namely, that they explain the chemical and physical properties of the compounds that they depict. As the theoretical understanding of what a bond was changed, so to did the depictions of chemical bonds in structural formulas, and this was crucial to leveraging the revised understandings of bonding into new structural explanations of chemical or physical properties. The theory of resonance is one important way (and was historically the first broadly accepted way) that the quantum mechanical character of chemical bonding is recognized and applied within structural organic chemistry.

Even before the development of quantum mechanics, in response to the explanatory demands placed on chemical structures, several modifications of structure theory were suggested that [40.14, p. 2]:

“considered it possible for the true state of a molecule to be not identical with that represented by a single classical valence-bond structure, but to be intermediate between those represented by two or more different valence-bond structures.”

These suggested modifications were motivated by cases where a chemical compound did not behave as it would have been expected to behave given its representation using a single structural formula but where, by thinking about the compound as a mixture intermediate between two or more such formulas, the behavior could again be accounted for in structural terms. *Pauling*, in his seminal *Nature of the Chemical Bond* [40.15], laid out the theory of resonance by employing quantum mechanics to rationalize and systematize (but not to deduce), the use of multiple structures to represent individual chemical kinds and then went on to demonstrate the broad usefulness of this theory in organic chemistry.

The theory of resonance is interesting, from the point of view of the role of structural models in chemistry, for two related reasons. First, it was the manipulation of valence bond structures (which are structural formulas that explicitly depict the bonding electrons of the constituent atoms) that first revealed the possibility of explaining recalcitrant chemical and physical phenomena by thinking of chemical kinds as appropriately represented by a combination of distinct structural formulas. Facts in the world of the model – that multiple different valence bond structures were plausible for a given chemical kind – were used to suggest modifications designed to improve the explanatory power of structure theory. Furthermore, these facts about the structural models (multiple possible valence bond structures for a given kind) were systematized and rationalized using the theory of quantum mechanics so that the delocalization of bonding electrons (which is the central implication of quantum mechanics for chemical bonding) could be recognized and exploited in organic chemistry. Manipulations of the model supplied the vehicle for making quantum mechanics first applicable to structural organic chemistry. In this sense, then, the structural models mediated between the theory (quantum mechanics) and the world. Secondly, and similarly, it is the actual exploration of the range of available valence bond structures that often proves crucial to the use of the theory of resonance in generating the structural explanations that are useful in organic chemistry. In a typical case of an explanation invoking resonance, none of the individual structural formulas making up a resonance hybrid allows for the explanation of all of the chemical or physical properties of interest. In-

stead, more standard structural analysis is applied to some of the individual component formulas of the resonance hybrid, and then the behavior of the chemical kind as a whole is understood as some proportional mixture of the structural prediction based on its component structures. In other words, without the more complex depiction of a chemical kind allowed by resonance theory, it would not be possible to successfully supply structural explanations of its chemical or physical behavior. Getting the structural *laws* to apply to some chemical kinds requires a more complex model of their structure – their depiction as a resonance hybrid. Explorations in the world of the model uncovering potential significant resonance structures mediate between the theory (structure theory) and the world by allowing for the successful application of this theory to complex cases to which it would otherwise not be useful.

In order to see how the theory of resonance allows structural formulas to mediate between more general structure theory and experimental facts, it will be useful to consider some of Pauling's work on the structure of proteins. Proteins are polymers of amino acids formed when the carboxyl group of one amino acid reacts with the amino group of another forming an amide linkage called a peptide bond. As a result, there is a recurring structural pattern in proteins: tetrahedral carbon atoms (bonded to the R-groups of the amino acids) joined by amide groups (-NH-CO-). Amide groups are therefore a fundamental structural component of proteins; however, in order to predict the behavior of these groups, and thus to outline the basic structural features of proteins, it is not sufficient to consider only one of the structural formulas that can be used to represent them. Instead amide groups, at least in Pauling's treatment, were thought of as a resonance hybrid of two component structural formulas, and their structural behavior was anticipated to be a sort of weighted average of the behavior predicted by the structure theory for these individual structural formulas.

The most important feature of the amide linkage from the point of view of predicting the structure of proteins is that the carbon and nitrogen of the amide linkage lie in a single plane with the two tetrahedral carbons that they connect. *Pauling* regarded the planarity of the amide group as, "a sound structural principle" concluding that a "structure in which the atoms of the amide group are not approximately coplanar should be regarded with skepticism" [40.16, p.19]. Though he provided substantial experimental confirmation of the planarity of the peptide bond, it was the theoretical arguments for this principle that invoked the theory of resonance. An amide linkage is typically represented by a structural formula in which there is a single bond between the nitrogen and the carbonyl carbon, which

is itself double bonded to oxygen. However, another possible structural formula for the amide linkage has a double bond between the carbon and the nitrogen while there are three unshared electron pairs around the oxygen (resulting in a net formal charge of  $-1$  on the oxygen) and no unshared pairs around the nitrogen (resulting in a formal charge of  $+1$ ). The theory of resonance indicates that the first, and more typical, structure should be the most significant contributor to the overall structure of the amide linkage, but that the second structure might also be important to consider (Fig. 40.2).

The most salient difference between these two structures is where the double bond is located, either between carbon and oxygen or between carbon and nitrogen. Pauling argued based on experimental measurements of the bond lengths in some simple peptides (by x-ray crystallography), that in the actual peptide linkage (on average) the relative contribution of these two structures was 60% for the typical structure and 40% for the secondary structure. These numbers were based on the fact that the measured C-O bond length in the peptide bonds was longer than typical double bonds between carbon and oxygen (in cases where no alternative resonance structures were available) but also shorter than typical single bonds between C and O. Similarly, the measured C-N bond length was shorter than typical single bonds, but longer than typical double bonds between these atoms. If he supposed that the relative contributions of the two structures were 60% and 40% respectively, and thus that the C-O bond was 60% double and 40% single, while the C-N bond was 40% double and 60% single, then the predicted length of the bonds closely matched the measured values.

Once Pauling had argued that the second resonance structure with a double bond between carbon and nitrogen was an important contributor to the overall structure of the linkage, it followed from standard structural theory that the peptide linkage should be essentially planar. Double bonds do not allow free rotation; that is, you have to break the bond (costing a lot of energy) in order to rotate around the axis of the bond. The energetic cost of rotation around the double bond is the reason that double bonds lead to stereoisomerism (there are distinct chemical compounds, with different structural formulas, that reflect different arrangements of substituents around a double bond). Since the C-N bond in

Fig. 40.2 Resonance structures of the peptide bond

the peptide linkage was 40% of a double bond, Pauling was able to estimate that the energetic cost of rotating around this bond would be about 40% of the bond energy of a typical double bond between these atoms. Furthermore, he was able to estimate the strain energy of deviations from planarity, concluding: “we can calculate strain energies of about 0.9 kcal/mole for 10° distortion of the amide group” [40.16, p. 14]. This effectively meant that large deviations from planarity in peptide linkages would be very energetically expensive and would therefore constitute a “highly unusual steric relationship” [40.16, p. 16].

Pauling’s analysis of the structure of peptide linkages shows both what structural accounts of chemical phenomena look like, and how resonance theory allowed structural analysis to be applied to a broader range of chemical facts. The measured bond lengths of the amide linkages in peptides do not correspond to the average bond length that one would expect based on the typical representation of the amide linkage using structural formulas (with typical CO double bonds and typical CN single bonds). In order to provide a structural explanation for this deviation from expected values, Pauling needed to find some recurring structural feature of the amide linkage that could explain it. What he found, by manipulation of the formulas, is that such amide linkages could be represented by another structural formula, one obtained by redistributing the valence electrons (and thus moving around the bonds). According to the principles of resonance

theory, this alternative structure was energetically plausible and should be regarded as a potential contributor to the overall structure of the amide linkage. However, a structural analysis of this second structure by itself would also not explain the experimental bond lengths. Instead, only by regarding the actual structure as intermediate between the two resonance structures, did an explanation of the observed bond lengths become possible. Exploration in the world of the model, then, was crucial to providing a structural account of the observed bond distances. Furthermore, the success of this explanation gave Pauling confidence that his resonance structures provided a reasonable representation of the peptide bond, and thus that he could apply a structural analysis to this representation in order to make a significant structural prediction about all proteins. Again this prediction (the planarity of the peptide bond) was based on giving a weighted analysis of the various accessible resonance structures. Without the detour through the range of plausible resonance structures, explored by the chemist through manipulations of structural formulas, neither the original explanation, nor the extremely significant prediction that Pauling made about the structure of proteins would have been possible. (Now there are other ways of taking into account the implications of quantum mechanics on chemical bonding, and these can also presumably support the same explanations and predictions; but the historical fact is that Pauling, who basically initiated the study of protein structure, used resonance theory.)

## 40.2 Structures in the Applications of Chemistry

In addition to their role supporting the explanations and predictions of structural organic chemistry, structural formulas and/or models also play a crucial role in applying the theory of organic chemistry to the solution of synthesis problems. Synthesis problems are the guiding application of the theory of organic chemistry. Of course not all organic chemists are working to synthesize compounds, but this is the characteristic goal around which the field developed, and it is possible to understand the theoretical structure of the field as reflecting this goal. That is, an important reason that the explanations of organic chemistry take the form that they do – looking for structural accounts of chemical phenomena, for example – is because this approach facilitates the solution of synthesis problems [40.17, 18]. Synthesis problems have a common form, and the intellectual challenges that they present derive from this form. By understanding the basic form of synthesis problems, and the basic strategies developed for solving

these problems, it is possible to appreciate the central importance of the sorts of structural analysis undertaken in the typical explanations and predictions of organic chemistry. As seen in the last section, explorations in the world of the model, and thus the role of structural formulas as models, can be crucial to providing the structural analyses of organic chemistry. However, the role of structural formulas and models in solving synthesis problems is not limited to their support of structural explanations or predictions. Instead they play additional roles in delimiting the array of possible synthetic approaches and evaluating the plausibility of those approaches.

A synthesis problem begins with a target molecule. The chemist’s goal is to come up with a method for making this target molecule by a sequence of chemical reactions that begins with compounds that chemists already know how to make. Often, no chemist has ever synthesized the target molecule before, though it may

be a natural product that is synthesized by some biological systems. The first step in solving such a problem is to get a clear idea about the structure of the target molecule. Since organic molecules are individuated by their structures, this amounts to insisting that the synthesis problem is well defined – it has a clear goal. Once the structure of the target is settled, the synthetic chemist must come up with some way to leverage knowledge about the outcomes of lots of chemical reactions run on different (typically simpler) compounds into a strategy for making the target compound, which, presumably, no chemist has ever experimented with before. It is crucial, therefore, for the synthetic chemist to exploit some notion of structural similarity. Structural patterns identified in the target indicate which known reactions might be plausibly employed in its synthesis. Furthermore, because the structural patterns identified in the target are in a novel context, the chemist must have some way of accounting for, or anticipating, the way that the structural context influences the behavior of known reactions (characterized and understood in simpler structural contexts). This is what the structural accounts (explanations and predictions) of theoretical organic chemistry do.

One way to think about the process of coming up with a synthesis for a target compound is through the process of retrosynthetic analysis [40.19]. Retrosynthetic analysis works backwards from the target molecule, systematically investigating all of the ways that one might produce the target molecule by a known chemical reaction (these are characterized by the structural patterns on which they operate, for instance, by the functional groups that they begin with and that they produce). All of the reactants that might produce the target molecule by one of these known reactions are then subjected to the same process, generating their own lists of possible second-order reactants. This process is repeated until it generates a path terminating in compounds that can already be synthesized. Given that there are thousands of known reactions, many of which might apply to a complex target molecule, the branching array of possibilities generated by such a process – the retrosynthetic tree – is immense and must be systematically pruned into a plausible synthetic plan. (I have described this process in significantly more detail, with concrete examples, in [40.20, 21].)

The pruning of the retrosynthetic tree, following Corey's conception, takes place in stages. In the first stage, strategic pruning, the synthetic chemist analyzes the target compound in order to identify the sources of synthetic complexity in it. By identifying these sources of complexity, the chemist can focus on paths in the retrosynthetic tree that reduce synthetic complexity and that, therefore, are more likely to terminate in com-

pounds that have already been synthesized or are easy to make. Assessing the sources of synthetic complexity in a target molecule amounts to using a set of heuristic principles, grounded in both the collective experience of synthetic chemists and the theory of organic chemistry, to identify particular bonds or atoms whose structural environment will make them particularly difficult to create. The relative difficulty of dealing with these sources of complexity can also often be estimated, giving the synthetic chemist, in the end, a clear focus on branches of the retrosynthetic tree that eliminate the largest source of complexity. Though this can result in a drastic narrowing of the possible synthetic paths that need to be explored, strategic pruning must be followed up by plausibility assessment, where the possible paths removing the largest source of complexity are evaluated for their relative structural plausibility. As I characterized the retrosynthetic tree, the possible reactions that might produce a structure were characterized based on the presence of some structural feature in the target. Any reactions that might produce that product were part of the tree. However, not all of these reactions are actually plausible because, for example, the target has other structural features that would interfere with the success of that particular reaction. And even among those that are plausible, the synthetic chemists will want to decide which path or paths are most likely to work and to generate the fewest complications downstream. These assessments again depend on analyzing how a reaction, understood and characterized in some other, simpler structural context, would perform in the complex local circumstances of the target molecule. After plausibility assessment comes the final stage of synthetic design, which is optimization, where precise ordering of synthetic steps is worked through and control steps are added. These control steps are added in order to eliminate complicating factors identified by a careful structural analysis of the synthetic route. They work by adding chemical groups to synthetic intermediates in the proposed path that either eliminate the influence of complicating structural factors or promote the formation of desired products. These control groups can then be removed after they have done their job. Often the precise ordering of the synthetic path can influence which control groups are needed, and vice-versa, so the overall optimization of the synthetic route must involve both of these considerations.

This brief sketch of the process of designing a chemical synthesis has made it clear, I hope, that close structural analysis of the both the target molecule and the potential intermediates is crucial to the process. The possible reactions resulting in the target molecule (or some intermediate) guided by structural similarity to the products of known reactions is what generates

the array of potential precursors at each stage in the generation of the retrosynthetic tree. This exploration of possible reactants and reactions, and the array that it generates, all take place in the world of the model – in fact, the molecules depicted by these structural formulas may never have existed. The possible reactants must be deduced based on the reaction being considered, and this can be done by exploring what reacting structures would, upon application of the considered reaction, result in the target molecule; the reactions must be worked through backwards in the world of the model to generate potential precursors. Similarly, the strategic pruning of the array of possible reactions depends on investigating the detailed local environments of particular atoms or bonds in the model of the target molecule. Rules of thumb about the relative difficulties of producing these atomic arrangements or bonds (based in part on what the reactant structures would have to be if they were generated by certain procedures) guide the synthetic chemist to particular routes in the retrosynthetic tree. Recurring structural features identified in the local environment of the model of the target molecule provide the basis for the application of these rules of thumb, and thus for the large-scale decisions

about synthetic strategy. Both plausibility analysis and optimization depend on determining how generically characterized reactions would be likely to perform in the complex local environment of the target molecule or intermediates. Often the typical explanations (and/or predictions) of organic chemistry can be used to figure out how individual structural features would affect the reaction. But in complex environments there are often multiple relevant, and potentially competing, structural features at play. To make sensible choices about strategy in these cases, synthetic chemists can either attempt to theoretically discriminate the plausibility of potential pathways, or to modify the structure to make its behavior more predictable using control steps. All of this takes place in the world of the model, using whatever theoretical principles are applicable in that local environment, to analyze and make sensible decisions about what synthetic pathways might work in the lab. Synthetic design is thus a process that, from beginning to end, involves manipulating, exploring, deducing possible precursors and analyzing structural models. Theory can be brought to bear on the problem only through its application to, and analysis in the context of, particular structural models.

### 40.3 The Dynamics of Structure

In this last section, I want to describe two ways that structural models have contributed to the development of the research program of structural chemistry by supplying new structural concepts. In the first case, models of structure had features that were not initially recognized to be representationally significant but which, when interpreted as significant, could be used to explain anomalous results. Chemists did not abandon the structural research program when they encountered unexpected experimental results; instead, they modified their models of structure, taking features readily available in the model and attributing new representational significance to them. General features carried around in the models were appropriated in order to modify the conception of chemical structure in the face of new experimental results. In the second case, particular structures supplied foothold concepts that allowed for experimental results to be brought to bear on these newly representationally significant features of structural formulas. Particular structures are cognitively richer than general types of models or abstract theories; they have all sorts of features that might turn out to support important inferences about the target system. In this example, chemists isolated particular cases where the significance of this new structural element was clear,

used very local concepts to explain and predict in those cases, and then generalized from there. Thus features identified in particular structures were appropriated to develop and articulate the experimental consequences of this new aspect of chemical structure. Models of structure do play an important role in the dynamics of science by supplying concepts or features that can be appropriated to modify or develop a research program. Visual representations of structure, and models of structure more generally, act as incubators for the concepts essential to modifying and teasing out the experimental consequences of chemical structure.

One of the most dramatic changes in chemists' conception of structure occurred during the middle third of the twentieth century with the gradual realization that the *conformations* of molecules, and not just their bond connectivity, had a crucial role to play in understanding their physical and chemical behavior. A conformation is, roughly, any of the three-dimensional arrangements of atoms in space resulting from rotations around single bonds in a molecule. The development of the theory of conformations (typically called conformational analysis) occurred when features of structural formulas that had originally not been thought to have any representational significance, the 3-D arrangement of bonds or

its 2-D depiction, was recognized to represent something about the compounds that the formulas denote. With these new features available, new concepts were crafted to organize the phenomena and then articulated throughout the domain. Though it is somewhat artificial, in order to relate the development of conformational analysis to the themes of this paper, it can be understood to have occurred in two phases. First, the prior understanding of structural formulas had to be found to be insufficient, and the three-dimensional arrangement of bonds recognized to accommodate those insufficiencies. Second, once the three-dimensional orientation of bonds had been seen to be significant, the consequences of the newly enhanced conception of structure had to be developed and articulated.

### 40.3.1 Recognizing the Importance of Conformations

At the end of the nineteenth century, structural formulas (roughly) allowed for the generation of one distinct formula for each known, distinguishable chemical compound. The formulas used at this time included not just single bonds between adjacent atoms, but also occasional double bonds. Double bonds allow for *geometrical isomers* in which the same groups are connected to the four available positions in a double bond in two different ways. Similarly, there are two distinct ways of orienting four distinct groups around a carbon. As a result, given the number of *asymmetric double bonds* and the number of *centers of asymmetry* one could compute, using a formula due to Van't Hoff, the number of stereoisomers to be expected. This formula worked because: "It was based on the concept of *restricted* rotation about double bonds and of *free* rotation about single bonds" [40.22, p. 299]. Rotation around single bonds had to be free because otherwise one would have expected many more distinguishable isomers. In order for structural formulas to accurately map onto the results of isomer counting experiments, certain features of the models of organic molecules had to be regarded as representationally significant. For example, structural formulas had to distinguish the two distinct ways that groups can be oriented about a double bond because these represented two distinguishable compounds. At the same time, however, the experimental facts demanded that other features of the formulas not be taken to be representationally significant. The fact that there were lots of ways to produce formulas with the same bonding and orientation (differing by what we would now think of as rotations around single bonds) was explicitly not taken to be significant in the resulting structural formulas. When it came to individuating chemical compounds, the various physical models

or structural formulas that could be generated by rotations about single bonds were distinct without being different. The possibility of rotational variants was an incidental feature of the symbol system that needed to be ignored when deducing the experimental facts from the models. They were not taken to reflect significant features of the target system.

Chemical structures are not frozen in time, however, and chemists aspired to add to the array of chemical and physical features that could be explained in terms of them. Chemists knew (or thought they did) that the many distinct models producible by rotations about single bonds weren't important for the individuation of chemical compounds, and thus for isomer counting experiments, but that left it open whether these differences might be employed to explain other sorts of experimental results. In fact, given the rich array of distinctions available in the models as yet uncorrelated with differences in the compounds they depicted, these distinctions would seem to have been ripe for exploration should new experimental results force modifications of the models.

Eventually, new experimental results did force such modifications. There are at least two distinct sorts of evidence that put pressure on the idea of free rotation about single bonds. First were failed isomer counting experiments, beginning in 1922, in which chemists were able to distinguish optically active forms of (unusual) compounds where, if all rotation about single bonds had been free, there should not be any such forms. More precisely, so long as all rotational variants around single bonds were regarded as indistinguishable, structural formulas did not predict the existence of distinct optically active forms, but optically distinct forms there were. The second sort of evidence came from discrepancies between the observed and measured entropy of ethane. These discrepancies "could only be explained by a barrier to free rotation about the two methyl groups" [40.22, p. 299]. These new experimental results were accommodated, eventually, by changing the representational significance of the models. Most fundamentally, the fact that a model has lots of rotational variants was now regarded as an explanatorily significant fact. Many of those differences between models of structure that had been irrelevant became differences that could correspond to differences in the energy or stability of the represented compound. For example, the distances between the *atoms* in the model (or suggested by the structural formula) became a feature used to connect differences in structure to differences in the energy or stability of the represented compound. It is because of differences in the distance relationships between the depicted atoms that rotational variants have different energies.

By imagining the atoms of a molecular *model* or *structural formula* to be interacting (either by attraction or repulsion) in a manner that varied according to the distance between them, the chemists looking to revise earlier interpretations of *chemical structure* could explain both why the rotations of ethane would be restricted and why there might be optically distinct forms of some strategically bulky organic molecules. This required the idea of nonbonding interactions between the atoms in the compound and the addition of this idea was nontrivial, depending for its plausibility on the dawning awareness of the nature of the chemical bond. But once this idea was in place, not only could the new experimental results be explained, but the success of Van't Hoff's formula could be preserved as approximately true. Most of the time, the newly postulated nonbonding interactions would be insufficient to allow for distinct forms of chemical compounds to be isolated. Sometimes, however, such distinctions would show up in physical properties that Van't Hoff hadn't been concerned to explain (like the entropy of ethane). And occasionally, in structurally rationalizable exceptional cases, these distinctions would result in failed isomer counting experiments. Instead of there being free rotation about single bonds, now the rotation about single bonds was just substantially freer than rotation about double bonds, except in certain special circumstances.

The significance of nonbonded interactions in ethane and in dramatically rotation-restricted organic molecules suggested that such interactions would also be significant to the physical properties of organic molecules in general. Thinking in terms of such nonbonding interactions required interpreting chemists' representations of structure, including structural formulas, to be significant in new ways. However, perhaps because "there was no technique available to demonstrate the phenomenon experimentally" [40.22, p. 299] this more general significance was not systematically explored until after the Second World War. Still, by this point, the rotational variants of structural formulas or physical models had demonstrated their usefulness by explaining several different sorts of novel experimental results (entropy measurements and failed isomer counting experiments) and had therefore earned their place as representationally significant.

### 40.3.2 Using Conformations in Organic Chemistry

Though this newly significant feature of chemists' structural models had been used to explain unexpected experimental results, it had not yet been integrated into the mainstream practice of organic chemists and used to generate results of its own. This began to change when

Odd Hassel published his systematic investigations of the conformations of cyclohexane and its derivatives. Cyclohexane is an ideal experimental system for investigating the significance of conformations because, as investigation of a model will quickly show, there are only three conformations of this system (what are now called the *chair*, *boat*, and *twist-boat*), out of the infinite number that are theoretically possible, that have no angle strain (Fig. 40.3). In an earlier application of structural formulas as models ([40.10, 20], for a description of this work), chemists had shown that angle strain (or deviations from the standard tetrahedral bonding angles) was an important factor in the stability of rings. This meant that when trying to understand the behavior of cyclohexane, it was principally these three conformations that needed to be considered because all others would be energetically unfavorable. Hassel not only showed that the *chair* conformation was the most stable, but was also able to establish that the relevant nonbonded interactions were repulsive, because the chair form maximizes the distances between atoms in the ring.

Exploring a careful drawing of a chair conformation, or better yet a physical model of it, quickly reveals that there are two distinct types of bonds emanating from the carbon ring. In an obvious case of using models to introduce new conceptual distinctions, these are now called axial and equatorial bonds, according to whether they are parallel to the axis of symmetry of the molecule or in an equatorial belt around it. Furthermore, it is also clear that substituents attached axially are closer to the other atoms in cyclohexane than are substituents attached equatorially. As a result, substituted cyclohexanes generally prefer to have their substituents equatorial since this minimizes the nonbonding repulsive interactions. Hassel's work showed how the conformational preferences of cyclohexane derivatives could be rationalized using repulsive nonbonding inter-

Fig. 40.3 (a) Chair form of cyclohexane. (b) Boat form of cyclohexane

actions in a way that had strong experimental support. Furthermore, he not only isolated a structural type in which the energetic implications of conformational differences were clear, but he also provided structural concepts (axial versus equatorial positions on the ring) useful in explaining the relative energies of structures of this type.

It was Barton who established the importance of conformational analysis in explaining and predicting the chemical behavior of synthetically important organic molecules. He did this by recognizing that steroids are instances of the structural type carefully studied by Hassel. The steroid nucleus consists of three cyclohexane rings fused to a five-membered ring. Because “the ring fusions of the steroid nucleus fix the conformation of the whole molecule” [40.22, p. 302] there are basically two different significant conformations of the steroid nucleus. In both of these conformations, all three of the cyclohexane rings are fixed in the *chair* form. So just as with cyclohexane itself, the significance of conformations for the behavior of steroids can be understood by considering just a few of the infinitely many possible conformations. Better still, following Hassel, the axial and equatorial substituents in the steroid nucleus can be distinguished and their relative stability rationalized in terms of repulsive non-bonded interactions.

Barton next showed how differences in the relative stability of steroids based on the conformational location of their substituents could be used to explain the chemical behavior of these molecules. Most simply, in a chemical reaction known for mechanistic reasons to result in the most stable product, one can often predict which of several candidate steroids will be preferred. Similarly, if one knows something about either the steric requirements or the geometry of the transition state, then one can often deduce which steroid will react more quickly or which product will be preferred in a reaction under kinetic control. What Barton did (originally in [40.23]) was to show that “an enormous literature of stereochemical fact” [40.22, p. 302] about steroids could be systematically and consistently interpreted using the conformational analysis of the steroid nucleus. He went through a variety of different results previously reported in the steroid literature and showed that the differences in rates or product distribution were what would be expected based on the conformational analysis of the steroid nucleus. This established by a sort of consilience of inductions that, at least in the case of steroid chemistry, conformations had an important role to play in understanding chemical behavior.

Between Hassel and Barton, not only had conformations proved themselves to be useful in explaining

significant chemical behavior, but also a set of structural circumstances (and concepts) had been articulated that allowed chemists to clearly discern the implications of conformation. With these resources in place, chemists were able to begin to apply these concepts in synthesis and experimental design. For example, once chemists understood why certain substitution patterns of the steroid nucleus were more stable than others, they could begin to exploit this knowledge in designing synthetic reactions. Barton describes how the tendency for adjacent diaxial substituents to rearrange into the more stable diequatorial form led to “a convenient route for shifting an oxygen function from one carbon atom to the adjacent carbon” [40.22, p. 304]. Similarly, because the conformation of the steroid nucleus was well known and restricted, it could be used to investigate the mechanisms of chemical reactions by effectively locking the substrate in a reaction into a particular geometry. For example, steroids were useful in establishing that “the phenomenon of neighboring group participation demands a conformational interpretation (diaxial participation)” [40.22, p. 304]. These, and other cases of application, depend on being able to recognize a set of structural circumstances in which conformational analysis is straightforward because it can be directly related back to cases that have already been successfully analyzed.

Of course, chemists were not content to apply conformational analysis just to cyclohexane and steroids. Instead, conformational analysis was articulated, from this base, along several different avenues. In the first place, it was applied to other molecules containing cyclohexane subunits, such as triterpenoids and oleanolic acid [40.22, p. 305]. Quantitative approaches were developed and this allowed for precise predictions of energy differences between conformations in these sorts of systems. Eventually, the structural limits of this approach were probed by identifying situations in which molecules with cyclohexane subunits did not behave as expected. New concepts, such as *conformational transmission* were then introduced to account for these deviations from expectation. These were refinements in the application of conformational analysis to the same basic type of system in which its clear consequences were originally discerned. Additionally, attempts were made to extrapolate the same basic approach used in analyzing cyclohexane to unsaturated six-membered rings and heterocyclic compounds. This is a case of pushing the approach into new territory. It required adapting the concepts used in the cyclohexane case to these structurally similar but importantly different new cases. New issues had to be confronted, such as how to account for the conformational implications of electron pairs. Eventually, conformations became one of the central tools

used to understand the behavior of biologically relevant molecules.

Once the rotational variants of structural models were recognized to be significant, chemists still faced the daunting task of organizing and sorting these infinite structural variations into categories that could be inferentially connected with experimental results, and eventually lead to new experiments. This was not done in a top-down way, by somehow deducing the implications of nonbonded interactions and conformations for chemical reactions. Instead, successfully doing this depended on finding a particular case where the conformational implications were clear and then generalizing and articulating from there. The concepts used to connect conformations with experiment came, initially, from considering cyclohexane. Models of cyclohexane played a crucial role in both the recognition of these concepts and their connection to experiment.

Cyclohexane was focused on because chemists already knew, from manipulation of models, that it had just a small number of strain-free conformations. This feature of cyclohexane is not shared with most other organic compounds, but it was crucial to its role in revealing the power of conformational analysis. Examination of these conformations showed that the chair

form maximized interatomic distances, which led to the conclusion that the relevant nonbonded interactions were repulsive. Additionally, inspection of the chair form led to the important distinction between axial and equatorial positions about the ring, which was subsequently linked with important energy differences between structural variants of cyclohexane (including, ultimately, steroids). These conformational features of cyclohexane are also not features shared by most molecules. The concept of an axial or an equatorial substituent simply doesn't apply in most molecules, but this concept turned out to be crucial is deducing the chemical consequences of conformations. The distinctions between conformations that were actually used in order to connect this new aspect of chemical structure with experiment were available only in concrete representations of a particular structure. Models of cyclohexane are rich with discernible differences not previously identified as significant in chemical explanations. These previously neutral features supplied the concepts that eventually got connected with experimental results. It was then by generalizing, adapting, and articulating these foothold concepts that the broad applicability and novel applications of conformations were developed.

## 40.4 Conclusion

I hope to have established that models of structure, typically in the form of structural formulas, are essential tools for chemists. They mediate between theory and phenomena, providing the platform on which theoretical principles are both recognized and applied. They also facilitate application, as seen in the use of the theory of organic chemistry in solving synthesis problems by – in addition to its role in explanation and prediction – providing for the possible reaction pathways, strategic evaluations, plausibility assessments,

and optimization that are crucial to synthetic design. Furthermore, structural models have also played important roles as sources of the concepts that chemists use to adapt their models to both theoretical and experimental developments. In sum, structural models are the keystone of the success of structural chemistry, not only because they are crucial to its theoretical content and application at any particular time, but also because of their contribution to its continued viability as a research program.

# Models in Ge

## 41. Models in Geosciences

Alisa Bokulich, Naomi Oreskes

The geosciences include a wide spectrum of disciplines ranging from paleontology to climate science, and involve studies of a vast range of spatial and temporal scales, from the deep-time history of microbial life to the future of a system no less immense and complex than the entire Earth. Modeling is thus a central and indispensable tool across the geosciences. Here, we review both the history and current state of model-based inquiry in the geosciences. Research in these fields makes use of a wide variety of models, such as conceptual, physical, and numerical models, and more specifically cellular automata, artificial neural networks, agent-based models, coupled models, and hierarchical models. We note the increasing demands to incorporate biological and social systems into geoscience modeling, challenging the traditional boundaries of these fields. Understanding and articulating the many different sources of scientific uncertainty – and finding tools and methods to address them – has been at the forefront of most research in geoscience modeling. We discuss not only structural model uncertainties, parameter uncertainties, and solution uncertainties, but also the diverse sources of uncertainty arising from the complex nature of geoscience systems themselves. Without an examination of the geosciences, our philosophies of science and our understanding of the nature of model-based science are incomplete.

### 41.1 What Are Geosciences?

The geosciences (sometimes also referred to as the Earth sciences) cover a very broad spectrum of disciplines including geology, paleontology, hydrology (the distribution and movement of water, on the surface and underground), glaciology (the study of ice and glaciers), climate science, oceanography, geophysics (the internal structure of the Earth, its gravitational and magnetic fields, plate tectonics, and volcanology), and geomorphology (how surface landscapes change over time). There is significant overlap between these different sub-

fields because the various subsystems of the Earth are not isolated from one another and are often interacting in complex ways. Usually, the geosciences are understood as ending where biological systems begin, but given, for example, the great relevance of plants for the hydrological cycle (e.g., ecohydrology) and erosion phenomena (e.g., biogeomorphology), as well as the great relevance of human activity in altering the climate, landscapes, and oceans, this division is becoming increasingly difficult to maintain [41.1].

Although the geosciences have traditionally focused on the Earth, the conceptual and disciplinary divides between studies of the Earth and studies of other planets are also breaking down. For example, the wealth of new information coming from the space program (e.g., the Mars Rovers, HiRISE images from the Mars Reconnaissance Orbiter, and images of various planets and moons from the Cassini-Huygens spacecraft and the New Horizons Pluto mission) has helped to generate the field of *planetary* geomorphology in addition to terrestrial (Earth) geomorphology. Planetary geomorphology includes the study of landscapes on not only planets, but also on moons (such as Saturn’s moon Titan, which has the largest dune field in our Solar System) and other large celestial bodies (such as the Comet 67P which was determined by the Rosetta-Philae lander module to have water).

The phenomena that geoscientists investigate are extremely complex and can span a vast range of spatial and temporal scales. Hence, idealized models play a central role in all of the geosciences. These models are used for a variety of purposes, including both prediction and explanation. They are used not only for basic scientific research (theoretical tools for advancing insight and understanding) but also for planning purposes, policy, and hazard mitigation. Models are used to fore-

cast a wide range of phenomena of human interest, such as earthquakes, volcanic eruptions, landslides, flooding, the movement of groundwater and spread of contaminants, and coastal erosion.

The geosciences are one of the most rapidly growing areas of interest in scientific modeling. This is led, in large part, by the tremendous amount of attention and resources that have been invested recently in climate modeling. Climate science is not unique, however, and many of the methodological issues found there are in fact widespread among the Earth sciences. Although, traditionally, philosophers of science have largely neglected the geosciences, leaving it a philosophical terra incognita [41.2], it is increasingly being recognized that our picture of the nature of science is inadequate if we do not take this research in the geosciences into account.

A complete review of all the relevant work in the diverse domains of the geosciences – and all the conceptual and methodological issues in modeling that arise within these different fields – is not possible in a single chapter. We provide here an overview of philosophical perspectives on this research that we hope will encourage more scholars to explore these topics further. The sections are organized primarily by the relevant conceptual and methodological issues.

## 41.2 Conceptual Models in the Geosciences

Conceptual models are the first step one takes before creating a more formal model (i. e., either a physical or numerical model). It is conceptualization of the key processes operating in the system of interest and the interactions between the components in the system. A conceptual model can simply take a narrative form or it can be an elaborate diagram. Typically, however, conceptual models can yield only qualitative predictions.

Some of the earliest models in geomorphology were conceptual models. Two historically important examples of conceptual models are Grove Karl Gilbert’s (1843–1918) *balance of forces* conceptual model and William Morris Davis’s (1850–1934) *cycle of erosion* conceptual model. In 1877, Gilbert introduced a conceptual model of a stream that appealed to physical concepts such as equilibrium, balance of forces, and work to explain the tendency of a stream to produce a uniform-grade bed. *Gilbert* describes his conceptual model as follows [41.3, p. 112]:

“Let us suppose that a stream endowed with a constant volume of water is at some point continuously supplied with as great a load as it is capable of car-

rying. For so great a distance as its velocity remains the same, it will neither corrade (downward) nor deposit, but will leave the grade of its bed unchanged. But if in its progress it reaches a place where a less declivity of bed gives a diminished velocity, its capacity for transportation will become less than the load and part of the load will be deposited. Or if in its progress it reaches a place where a greater declivity of bed gives an increased velocity, the capacity for transportation will become greater than the load and there will be corrasion of the bed. In this way a stream which has a supply of *débris* equal to its capacity, tends to build up the gentler slopes of its bed and cut away the steeper. It tends to establish a single, uniform grade.”

As *Grant et al.* note [41.4, p. 9]:

“Gilbert’s greatest and most enduring contribution to conceptual models in geomorphology [...] was the application of basic principles of energy and thermodynamics to the behavior of rivers. He did so with clarity of expression and an absence of math-

ematics that appeals directly to intuition, logic, and analog reasoning.”

Note that Gilbert’s model provides the conceptual foundation on which a numerical model, giving an equation to describe the balance of these forces, could be constructed, though he himself does not take this further step.

Another seminal conceptual model in the history of geomorphology is Davis’s cycle of erosion [41.5]. Davis was a professor of geology at Harvard University; in an 1899 article entitled *The geographical cycle*, he established a framework for thinking about modeling in geomorphology [41.6, p. 481]:

“All the varied forms of the lands are dependent upon – or, as the mathematician would say, are functions of – three variable quantities, which may be called structure, process, and time.”

The evolution of a landscape may be understood as a cycle, which begins with a *peneplain* (a low relief plain) near a base (e.g., sea) level, is followed by rapid uplift leading to a youthful stage of rugged topograph, in

which streams become established, and then a mature stage of tectonic stability in which those streams widen and gradually erode the landscape back down toward the base level. Finally, there will be an *old age* stage, involving low-relief landscapes with hills where mountains used to be. This then becomes eroded back to the peneplain stage until tectonic activity resumes and the cycle begins again. He used this idea to explain, for example, the features of the Appalachian mountains. It was a qualitative and explanatory conceptual model: it sought to explain and provide qualitative predictions for various features of a landscape.

For Davis, the conceptual model was the end point of his research; in recent years, most geoscientists have sought to quantify these sorts of processes. Thus, conceptual models can be seen as either the final product (an end in itself), or as a preliminary step in the process of creating a physical or mathematical model. In the case of mathematical models, there are two levels of modeling at which questions can be raised: Is the fundamental conceptual model adequate? And has that conceptual model been adequately represented or captured by that particular choice of mathematical equations?

## 41.3 Physical Models in the Geosciences

Until the mid-twentieth century, most conceptual models in the geosciences were realized as physical models. Physical models, also sometimes referred to as *hardware* or *table top models*, are a (usually, but not always) scaled-down version of the physical system of interest. In the geosciences, the systems of interest are typically large-scale, complex, open systems that are not amenable to experimental manipulation. A physical model allows a geoscientist to bring a version of the landscape into the laboratory, manipulate various variables in a controlled way, and explore hypothetical scenarios.

One of the central questions for geologists in the late nineteenth century was the origin of mountains (a subject known as orogenesis, from the Greek word *oros* meaning mountain). A popular orogenic theory in the nineteenth century was that mountains resulted from an overall contraction of the Earth, which was thought to be a consequence of the nebular hypothesis, first proposed by *Immanuel Kant* [41.7] and *Pierre-Simone Laplace* [41.8]. To explore this hypothesis, the Swiss geologist Alphonse Favre (1815–1890) built a physical model involving layers of clay on a piece of stretched rubber, which was then released and the resulting structures were observed. The ability of this

model to successfully reproduce some of the features of mountains led Favre to conclude that it supported the *plausibility* of the hypothesis [41.9, p. 96]. It was, what we would today call, a “how-possibly model explanation” (see Chap. 4, Sect. 4.4).

One of the great challenges for physical modeling in the geosciences, however, is that the relevant pressures, temperatures, durations, etc., of geological processes are largely beyond our reach. This limitation was recognized in the nineteenth century by the French geologist and director of the *École Nationale des Mines*, Auguste Daubrée (1814–1896), who notes (*Daubrée* [41.10, p. 5], [41.11] quoted in *Oreskes* [41.9, p. 99]),

“[T]he equipment and forces that we can set to work are always circumscribed, and they can only imitate geological phenomena at the scale [...] of our own actions.”

In order to make further advances in physical modeling in the geosciences, it was realized that the relevant forces and processes would have to be appropriately scaled in the model. The quantitative mathematical theory by which such scaling could be achieved, however, would not be developed until the work of M. King Hub-

bert (1903–1989), an American oil company geologist, in the late 1930s and 1940s.

Hubbert's work provided [41.9, p. 110]:

“the first fully quantitative treatment of the question how to choose the physical properties of materials in a model to account for the much smaller scale and time frame as compared with nature.”

Hubbert's 1945 paper begins by noting the paradox that has long perplexed the geologic sciences: How could an Earth whose surface is composed of hard, rigid rock have undergone repeated deformations as if it were composed of a plastic material, as field observations of mountains and strata suggest? He notes that this paradox is a result of failing to adequately consider the concept of physical similarity, which like geometric similarity in a map, requires that *all* the relevant physical quantities (not just lengths, but densities, forces, stresses, strengths, viscosities, etc.) bear *constant ratios* to one another [41.12, p. 1638]. He notes that when the strengths are appropriately scaled, the resulting strength of the rock on a human scale is “comparable with that of very soft mud or pancake batter” [41.12, p. 1651]. So, for example, since the elastic properties of solids depend on the strain rate, scale models that operate orders of magnitude faster than terrestrial processes need to use materials that are orders of magnitude weaker than terrestrial rocks [41.9, p. 113]. Hubbert's work on scaling not only helped explain the puzzling field observations, but also provided the key to more adequate physical modeling.

Physical models can be classified by how they do or do not scale down. At one extreme there are *life size* (1 : 1) replica models of the system of interest. Sometimes such 1 : 1 physical models are a localized study of a particular process, such as *Bagnold's* [41.13] use of a wind tunnel to study how grains of sand saltate form ripples. However, a full-scale physical model can also be an entire complex system, such as the Outdoor Streamlab at the University of Minnesota. In this full-scale model of a river segment, water and sediment flow down an artificial river system where the sediment is collected, measured, and recirculated to a sediment feeder. Although such replica models are able to avoid some of the problems arising from scaling issues (discussed below), they still involve simplifications and *laboratory effects* that can affect the reliability of the conclusions drawn for their real-world counterparts. More generally, however, many of the systems that geoscientists are interested in (e.g., mountain ranges and coastlines) are simply too large to be recreated on a 1 : 1 scale; hence, this type of physical model is typically not feasible.

Scale models are physical models that have been shrunk down according to some scale ratio (scale mod-

els can in principle be enlarged versions of their real-world counterparts, though this is not typical in the geosciences). For example, a 500 m-wide real river may be represented by a 5 m-wide scaled physical model, in which case the scale is 1 : 100. As Hubbert realized, simply shrinking a system down by some factor, however, will rarely preserve the necessary dynamical relations [41.14, p. 4]:

“A true scaled model requires perfect geometric, kinematic, and dynamic similitude, something that cannot be achieved when using the same fluid as in the real world system due to equivalent gravitational and fluid motion forces.”

Further complicating accurate scale modeling is the fact that different hydrodynamic processes are occurring at different spatial scales, and different physical effects can become dominant at those different scales too. For example, when scaling down one might substitute a fine sand for a pebbly gravel, but then cohesive forces can become dominant in the model when they are negligible in the target. These are examples of what are known as *scale effects*, when the force ratios are incomparable between the model and target. In such cases, one might need to substitute a liquid with a different viscosity or a different bed material into the model to try to overcome these scaling limitations – an example of how modelers sometimes deliberately get things more wrong in the model in order to get the conclusions to come out more right.

More often, the physical models are *distorted scale models*, where not all factors are scaled by the same ratio. The San Francisco Bay model, which is a table-top working hydraulic model of the San Francisco bay and Sacramento–San Joaquin River Delta system built by the US Army Corps of engineers, is an example of a geometrically distorted scale model, with the horizontal scale ratio being 1 : 1000, while the vertical scale ratio is only 1 : 100, and the time scale being 15 min to one day (for a philosophical discussion of this model see *Weisberg* [41.15]). Relaxing scale requirements further get what are sometimes referred to as *analog physical models*, where one reproduces certain features of a target system without satisfying the scale requirements. These are typically seen as physical systems to be investigated in their own right for what they can teach us about certain physical processes, rather than miniature versions of some specific real system [41.14, p. 5].

Physical models have their own strengths and weaknesses. The strengths, as mentioned, involve bringing a version of the system of interest into the laboratory as a closed system that is amenable to experimental manipulation and control. One does not need to have a mathematical representation of the system in order

to explore its behavior. The weaknesses, or limitations, of physical models predominantly fall into two classes: *laboratory effects* and *scale effects*. Laboratory effects are those that occur in the laboratory system but not in the real-world counterpart. These can be related to model boundary conditions (sometimes literally the wall or edge of the table) where the behavior can drastically change, unrealistic forcing conditions, or the omission of causally relevant factors in the model. Scale effects refer to problems in maintaining the correct re-

lations between variables when they are scaled down. This can lead to certain forces (e.g., cohesive forces) becoming dominant in the model that are not dominant in nature. More generally, these laboratory and scale effects are yet another example of the problem of external validity: Does the model accurately reflect the behavior of the system in the real world? This problem is pervasive among the sciences, and physical models are no more immune to it, despite dealing with the same physical stuff as their target.

## 41.4 Numerical Models in the Geosciences

Numerical models are mathematical models that represent natural systems and their interactions by means of a system of equations. These equations are typically so complex that they cannot be solved analytically, and so they have to be solved by numerical methods (such as finite difference or finite volume methods) that provide an approximate solution, or the equations need to be substituted with alternative algorithms, such as cellular automaton models. Numerical models are often implemented on a computer in a simulation that shows how the model will behave over an extended period of time, with some sort of graphical output to visualize that behavior (for a review of some of the philosophical issues in computer simulations see *Winsberg* [41.16]). This has enabled geoscientists to do something that they were generally unable (and often unwilling) to do in the past: to expand the goals of the geosciences to include forecasting and prediction as well as explanation.

In the context of the geosciences, there are many different kinds of numerical models, which can be categorized in different ways. The British geomorphologist *Kirkby* et al. [41.17], for example, distinguish the following four broad types of numerical models:

1. Black-box models
2. Process models
3. Mass–energy balance models
4. Stochastic models.

As *Kirkby* et al. explain, *black-box models* are models where “the system is treated as a single unit without any attempt to unravel its internal structure” [41.17, p. 16]. *Tucker* [41.18] gives as an example of a black-box model what is known as *Horton’s laws* of river network topology. The law predicts the average number of branching stream segments of a certain order (roughly size or width). It was discovered by Robert Horton in 1945 from purely empirical analyses of stream basins, but gives no insight into why this so-called law would

hold (it is not a law in the traditional sense, in that it does not hold universally). Black-box models are phenomenological models that involve a brute fitting to the empirical data. Although such models give no insight or understanding of the internal processes, they can be useful for making predictions.

At the other extreme of numerical modeling are *process models*, which try to describe the internal mechanisms giving rise to the empirical relations. *Tucker* explains, while [41.18, p. 687]:

“a black-box model of soil erosion would be based on regression equations obtained directly from data [...] a process model would attempt to represent the mechanics of overland flow and particle detachment.”

In between these two extremes are what *Kirkby* et al. [41.17] have called *grey-box models*, where some mechanisms may be known and included, but the rest is filled by empirical relations.

An important class of process models are landscape evolution models (LEMs). LEMs are numerical models in which the evolution of the landscape is related to the key underlying physical processes. These include, for example, the physical and chemical processes of rock weathering leading to rock disintegration and regolith production (*regolith* is a generic term referring to loose rock material, such as dust, soil, and broken rock, that covers solid rock), gravity-driven mass movement/landsliding, and water flow/run off processes (e.g., represented by the St. Venant shallow-water equations, which are a vertically integrated form of the Navier–Stokes equations). Each of these processes is represented mathematically by a *geomorphic transport function* (GTF), which get linked together to form the LEM. LEMs are often constructed as a software framework within which a variety of different component processes (represented by a particular choice of GTFs or equations), arranged in a partic-

ular configuration, can be implemented. Examples of such LEMs include the channel-hillslope integrated landscape development (CHILD) model, developed by Tucker et al. [41.19], and the cellular automaton evolutionary slope and river (CAESAR) model developed by Coulthard et al. [41.20]. These LEMs can simulate the evolution of landscapes on scales ranging from 1 to 500 km<sup>2</sup> and temporal scales ranging from days to millennia.

Often a component of LEMs, but sometimes presented as a model on their own, are *mass-balance models* (or *energy-balance models*). Mass-balance models use the fact that mass–energy is conserved to develop a continuity equation to describe the movement of mass (or energy) between different *stores*. A store could be anything ranging from water in lake, the population of a species in ecosystem, the energy stored as latent heat in an atmospheric column, the carbon mass in a tree, to the depth of soil at a point on a hillslope [41.18, p. 688]. An example of a mass-balance numerical model is a glacier model that describes the relation between ice accumulation and ablation (by melting and sublimation) at a given point of time under certain climate conditions [41.21]. Similarly, an energy-balance model in glaciology would be one that calculates the energy (heat) fluxes at the surface of the glacier that control melting and affect mass balance.

Climate science is a field of the geosciences in which both energy-balance and process numerical models have been developed to a high level of sophistication. Energy-balance models represent the climate of the Earth as a whole, without detailed information about processes or geographical variation. General circulation models (GCM) go a step further in explicitly representing atmospheric and oceanic processes. The most recent generation of climate models are Earth system models (ESM), which additionally include information about the carbon cycle and relevant biogeochemical processes. More specifically, ESMs are a composite of a large number of coupled models or *modules*, including an atmospheric general circulation model, an oceanic general circulation model, an ice dynamics model, biogeochemistry modules for land and ocean (e.g., for tracking the carbon cycle), and a software architecture or framework in which all these modules are integrated and able to communicate with each other. Developing and running GCMs and ESMs require a large number of collaborating scientists (scores to hundreds), significant supercomputing time, and millions of dollars. Because of the resource-intensive nature of such modeling projects, there are currently only a few dozen of them, and their outputs are periodically compared in intercomparison projects (e.g., coupled model intercomparison project

(CMIP5) [41.22]). (For more on coupled models and intermodel comparison projects, see Sect. 41.9 below.) At present, GCMs and ESMs typically have a spatial resolution of 100–300 km; to fill this gap at the finer level of resolution, regional climate models (RCMs) have been developed for various locations.

While the trend in climate modeling has been toward increasing the complexity of these models with ever more process modules being added, there has recently been an interesting debate about whether a fundamentally new approach to climate modeling is required (for an excellent review and assessment of the leading proposals see Katzav and Parker [41.23]). More generally the trend toward ever more complex models in the geosciences has led to what Naomi Oreskes calls the *model-complexity paradox* [41.24, p. 13]:

“The attempt to make models capture the complexities of natural systems leads to a paradox: the more we strive for realism by incorporating as many as possible of the different processes and parameters that we believe to be operating in the system, the more difficult it is for us to know if our tests of the model are meaningful.”

In opposition to this trend, many geoscience modelers have started developing what are known as *reduced complexity models*, which are motivated by the idea that complex phenomena do not always need complex models, and simpler models may be easier to understand and test. A simpler model may also be run more often, and with more different parameters, making it more amenable to sensitivity analysis (see Sect. 41.6.3 below).

In the context of geomorphology, reduced complexity modeling is often defined in contrast with what is termed *simulation* modeling (*simulation* here refers not to models that are run as a computer simulation, but rather models that try to simulate or mimic all the details of nature as closely as possible). While simulation models try to remain grounded in the fundamental laws of classical mechanics and try to represent as many of the processes operating, and in as much detail, as is computationally feasible, reduced complexity models represent a complex system with just a few simple rules formulated at a higher level of description. As physical geographers Nicholas and Quine note, emphasis added [41.25, p. 319]:

“In one sense, the classification of a model as a *reduced complexity* approach appears unnecessary since, by definition, all models represent simplifications of reality. However, in the context of fluvial geomorphology, such terminology says much about

both the central position of classical mechanics within theoretical and numerical modeling, and the role of the individual modeler in defining what constitutes an acceptable representation of the natural environment.”

One of the first successful reduced complexity models in geomorphology was a cellular automata-type model of a braided river (i. e., a river with a number of interwoven channels that shift over time) that used just two key rules [41.26]. This model was heralded as a paradigm shift in geomorphic modeling [41.27,

p. 194]. As Brad Murray, one of the proponents of this approach, argues, knowing how the many small-scale processes give rise to the large-scale variables in the phenomenon of interest is a *separate* scientific endeavor from modeling that large-scale phenomenon (Murray [41.28]; see also Werner [41.29]). Although reduced complexity models may seem like caricatures of their target systems, they can be surprisingly successful in generating realistic behaviors and providing explanatory insight (for further philosophical discussion of reduced complexity models and this case, see Bokulich [41.30] and Murray [41.31]).

## 41.5 Bringing the Social Sciences Into Geoscience Modeling

The geosciences are considered a branch of the physical sciences, being concerned with the chemistry and physics of the Earth, its history, and (more recently) its future. As such, the geosciences are typically thought of as excluding the domains of both the biological sciences and social sciences. Maintaining these artificial divisions, however, has increasingly become difficult. As Oreskes argues [41.1, p. 247]:

“Many, perhaps, most, significant topics in Earth science research today address matters that involve not only the functioning of physical systems, but the interaction of physical and social systems. Information and assumptions about human behavior, human institutions, and infrastructures, and human reactions and responses are now built into various domains of Earth scientific research, including hydrology, climate research, seismology and volcanology.”

For example, hydrological models that attempt to predict groundwater levels on the basis of physical considerations alone, can be inadequate for failing to include possible changes in human groundwater pumping activity, an external forcing function that can have dramatic effects on the physical system.

Climate science is another domain of the geosciences in which the need to incorporate the social sciences (specifically patterns and projections of human behavior involving, e.g., emission scenarios and deforestation practices) is evident. The Intergovernmental Panel on Climate Change (IPCC) has attempted to incorporate these social factors by three separate working groups, the first on the physical basis and the others on the social and policy dimensions, each issuing separate reports, released at different times. But, as Oreskes notes, the social variables are not just relevant to the

social–policy questions, but to “the work that provides the (allegedly) physical science basis as well” [41.1, p. 253].

Increasingly geoscientists are being called upon to not only use their models to predict geoscience phenomena, but also to perform risk assessments and to communicate those risks to the public. Given that geoscientists are typically not trained in risk assessment, risk policy, or public communication, the results can be troubling. Oreskes recounts the high-profile case of the 2009 earthquake in central Italy that killed 309 people, and for which six geophysicists were sentenced to six years in prison for involuntary manslaughter in connection with those deaths. Although the international scientific community expressed outrage that these seismologists were being charged with failing to predict the unpredictable, the prosecutor, as reported in *Nature* painted a different picture (Hall [41.32, p. 266]; quoted in Oreskes [41.1, p. 257]):

“‘I’m not crazy’, Picuti says. ‘I know they can’t predict earthquakes. The basis of the charges is not that they didn’t predict the earthquake. As functionaries of the state, they had certain duties imposed by law: to evaluate and characterize the risks that were present in L’Aquila.’ Part of that risk assessment, he says, should have included the density of the urban population and the known fragility of many ancient buildings in the city centre. ‘They were obligated to evaluate the degree of risk given all these factors’, he says, and they did not.”

Oreskes concludes from this case [41.1, p. 257]:

“[s]eismology in the twenty-first century, it would seem, is not just a matter of learning about earthquakes, it is also about adequately communicating what we have (and have not) learned.”

Whether it is communicating the risks revealed by geoscience models or incorporating social variables directly into geoscience models, geoscientists are under increasing pressure to find ways to model these hybrid geosocial systems.

In some areas, such as geomorphology, agent-based models (ABMs) (which are common in fields such as economics) are starting to be used. ABMs consist of a set of agents with certain characteristics, following certain rules of self-directed behavior, a set of relationships describing how agents can interact with each other, and an environment both within which, and on which, the agents can act. As *Wainwright and Millington* note [41.33, p. 842]:

“Despite an increasing recognition that human activity is currently the dominant force modifying landscapes, and that this activity has been increasing through the Holocene, there has been little integrative work to evaluate human interactions with geomorphic processes. We argue that ABMs are a useful tool for overcoming limitations of existing [...] approaches.”

These ABM models, with their simplistic representation of human behavior, however, face many challenges, including not only difficulties in integrating the different disciplinary perspectives required to model these hybrid geosocial systems, but also issues of model evaluation.

## 41.6 Testing Models: From Calibration to Validation

### 41.6.1 Data and Models

Empirical data was long assumed to be the objective and unimpeachable ground against which theories or theoretical models are judged; when theory and data clashed, it was the theory or model that was expected to bend. Beginning in the early 1960s, however, philosophers of science including *Kuhn* [41.34, pp. 133–134], *Suppes* [41.35], and *Lakatos* [41.36, pp. 128–130] began to realize that this is not always the case: sometimes it is reasonable to view the theory as correct and use it to interpret data as either reliable or faulty. In a 1962 paper called *Models of Data*, *Suppes* argued that theories or theoretical models are not compared with raw empirical data, but rather with models of the data, which are a cleaned up, organized, and processed version of the data of experience. The production of a data model can involve, among other things, *data reduction* (any data points that are due to error or noise, or what are otherwise artifacts of the experimental conditions are eliminated from consideration) and *curve fitting* (a decision about which of several possible curves compatible with the data will be drawn).

This same insight has been recognized by scientists as well. The ecological modeler *Rykiel*, for example, writes, “Data are not an infallible standard for judging model performance. Rather the model and data are two moving targets that we try to overlay one upon the other” [41.37, p. 235]. Similarly *Wainwright and Mulligan* argue that the data of measurements are an abstraction from reality depending on timing, technique, spatial distribution, scale, and density of sampling. They continue [41.33, p. 13]:

“If a model under-performs in terms of predictive or explanatory power, this can be the result of inap-

propriate sampling for parametrization or validation as much as model performance itself. It is often assumed implicitly that data represents reality better than a model does (or indeed that data is reality). Both are models and it is important to be critical of both.”

A similar point has been made by the historian *Paul Edwards* [41.38] in his book on the development of climate modeling. There he traces in detail the changing meaning of *data* in meteorology and atmospheric science, noting how the existing incomplete, inconsistent, and heterogeneous data had to be transformed into a complete and coherent global dataset, with large numbers of missing gridpoint values interpolated from computer models in a process known as “objective analysis” [41.38, p. 252]. *Edwards* further argues that even the data obtained from measuring instruments is model-laden. He notes, for example, that [41.38, pp. 282–283]:

“meteorology’s arsenal of instrumentation grew to include devices, from Doppler radar to satellites, whose raw signals could not be understood as meteorological information. Until converted – through modeling – into quantities such as temperature, pressure, and precipitation, these signals did not count as data at all.”

The importance of recognizing this model-ladenness of data is vividly illustrated in *Elizabeth Lloyd’s* [41.39] recounting of the high-profile case in which it was claimed in a US congressional hearing that data from satellites and weather balloons contradicted climate model evidence that greenhouse warming was occurring. In the end, the climate models were vindicated as more reliable than the data. *Lloyd* concludes

from this case that we need to move towards a more complex empiricist understanding of the nature of data.

The data from measurements can, for example, be skewed by the fact that measurements are local, and yet the model might require a more global value (especially when there is significant heterogeneity), or more generally that measurements can only be made at one scale, and yet have to be extrapolated to another scale. Hence, when using data to parameterize, calibrate, or validate a model (see below) it is important to be aware of the limitations of the *data model* as well, and pay attention to any biases or errors that may have been introduced during the collection and processing of that data.

In some areas of the geosciences, such as paleontology, models have even been used to correct biases in available data. For example, one aim of paleontology is to gather information about the deep-time history of biodiversity (ranging from the Cambrian explosion to the various mass extinctions) on the basis of the observed fossil record. The conditions under which fossils are formed, preserved, and revealed are not only rare, but highly contingent and uneven with respect to space, time, and type of organism. Hence, there is arguably a strong detection (or sampling) bias in the observations. While some have taken the paleodiversity curves constructed from these fossil observations as a literal description of ancient biodiversity, others have argued that observed paleodiversity is a composite pattern, representing a biological signal that is overprinted by variation in sampling effort and geological drivers that have created a nonuniform fossil record [41.40, 41]. Before any evolutionary theories can be tested against the data of the fossil record, these data need to be corrected to extract the relevant biological signal from other confounding factors. Thus, for example, “many vertebrate paleodiversity studies have relied on modeling approaches (e.g., multivariate regression models) to ‘correct’ data for uneven sampling” [41.40, p. 127]. Of course, how the data are to be properly corrected, including which models of possible drivers and sources of bias are included in the multivariate analysis yielding the corrected data, involves substantial theoretical assumptions. As *Kuhn* noted years ago, observations are not “given of experience”, but are “collected with difficulty” [41.34, p. 126].

The model-ladenness of data has led philosophers such as *Giere* to claim that “it is models almost all the way down” [41.42, p. 55] – a conclusion *Edwards* [41.38] argues is strongly supported by his historical analysis of the nature of data in meteorology and atmospheric science. Others, such as *Norton* and *Suppe*, have taken this conclusion even further, arguing that it is models *all* the way down. They write [41.43, p. 73]:

“Whether physically or computationally realized, all data collection from instruments involves modeling. Thus raw data also are models of data. Therefore, there is no important epistemological difference between raw and reduced data. The distinction is relative.”

However, saying that all data is model-laden to some degree does not imply that there is no epistemological difference, nor that all models are epistemically on par [41.44, pp. 103–104]. One of the most underdeveloped issues in this literature on data models is an analysis of what makes some data models better than others, and under what sorts of conditions data models should – or should not – be taken as more reliable than more theoretical models.

#### 41.6.2 Parametrization, Calibration, and Validation

In mathematical modeling, one can distinguish variables, which are quantities that can vary and are to be calculated as part of the modeling solution, and parameters, which are quantities used to represent intrinsic characteristics of the system and are specified external to the model by the modeler. Also specified external to the model are the boundary conditions and the initial conditions (the latter describe the values of the variables at the beginning of a model run). Whether something is a variable or parameter depends on how it is treated in a particular model. Parameters need not be constant and can also vary across space, for example, but how they vary is specified external to the model. One can further distinguish two general types of parameters: those related to characteristics of the dynamics of a process and those related to the characteristics of a specific system or location where the model is being applied [41.45, p. 7].

Sometimes parameters can be universal constants (e.g., gravitational acceleration or the latent heat of water), in which case specifying their values is relatively unproblematic (though the process by which the values of constants are initially determined is nontrivial, and as *Chang* [41.46] cogently argues, challenges arise even in so-called basic measurements, such as temperature). More typically in the geosciences, however, the value of a parameter has to be determined on the basis of complex measurements, and even an idealization or averaging of those measurements (such as in the case of the parameter for bed roughness of a stream bed). The process by which input parameters are initially chosen has not been well studied, and is greatly in need of a better understanding. What has been the subject of considerable attention is the problem of calibration: the

adjustment of model parameters in response to inadequate model performance.

In an ideal world, modelers would build a model based on physical principles and the equations that represent them, and then, with the use of appropriate input parameters for physical variables (like temperature, pressure, permeability, equilibrium constants, etc.), build a numerical simulation that accurately reflects the system under analysis. But most models do not do this: for a variety of reasons the match between the model output and available empirical information is often quite poor [41.47]. Therefore, modelers *calibrate* their models: they adjust the input parameters until the fit of the model to available information is improved to a level that they consider acceptable.

There are several concerns that can be raised about this process. One is that parameterized models are nonunique, and there is no way to know which particular set of parameterizations (if any) is the so-called right one; many different parameterizations may produce a given output. (This may be understood as a variation on the theme of underdetermination, discussed further below.) As hydrologist *Beven* notes [41.45, p. 7]:

“parameters are usually calibrated on the basis of very limited measurements, by extrapolation from applications at other sites, or by inference from a comparison of model outputs and observed responses at the site of interest.”

Moreover, because of the variability and uniqueness of many complex systems, parameter values extrapolated from one site may not be appropriate for another. Even if one restricts oneself to a given site, a model calibrated for one purpose (e.g., predicting peak runoff) may be predictively useless for another purpose (e.g., predicting total runoff) [41.33, p. 15]. Indeed, if the chosen parameterization is not an accurate representation of the physical system under consideration, it is likely that the model will not perform reliably when used for other purposes. This helps to explain the observation that many calibrated models fail, not only when used for purposes other than that for which they were calibrated, but sometimes even when used for their intended purposes [41.48].

Once a model has been built and calibrated, many modelers engage in an activity they call model validation, by which they normally mean the testing of the model against available data to determine whether the model is adequate for the purpose in question. Many geoscientists acknowledge that the use of the term *validation* should not be taken to imply that the model is true or correct, but rather only that “a model is acceptable for its intended use because it meets specified

performance requirements” [41.37, p. 229]. *Rykiel* thus argues that before validation can be undertaken, the following must be specified:

- a) The purpose of the model
- b) The performance criteria
- c) The context of the model.

However, many so-called validated models have failed even in their intended use. For example, in a 2001 study, *Oreskes* and *Belitz* showed that many hydrological models fail because of unanticipated changes in the forcing functions of the systems they represent. More broadly, validated models may fail for the following reasons [41.9, p. 119]:

1. Systems may have emergent properties not evident on smaller scales.
2. Small errors that do not impact the fit of the model with the observed data may nonetheless accumulate over time and space to compromise the fit of the model in the long run.
3. Models that predict long-term behavior may not anticipate changes in boundary conditions or forcing functions that can radically alter the system’s behavior.

The idea that a model can be validated has been critiqued on both semantic and epistemic grounds. Semantically, *Oreskes* et al. have noted that the terminology of *validation* implies that the model is *valid* – and thus serves as a claim about the legitimacy or accuracy – a claim that, as already suggested above, cannot be sustained philosophically and is often disproved in practice [41.47, 49]. Hence, a better term than model validation might be *model evaluation*. Even with this change in terminology, however, epistemological challenges remain. In many cases, the available empirical data (e.g., historic temperature records) have already been used to build the model, and therefore cannot also be used to test it without invoking circular reasoning. Some modelers attempt to avoid this circularity by calibrating and validating the model against different historical time periods, with respect to different variables, or even different entities and organisms.

Paleontologists, for example, use biomechanical models to try to answer functional questions about extinct animals based on the structures found in the fossil record (which is a subtle and difficult process, see e.g., [41.50]). These biomechanical models, which are used to make predictions about paleospecies, are validated or tested against data for present-day species. More specifically, *Hutchinson* et al. have used such models to determine how fast large theropod dinosaurs, such as *Tyrannosaurus rex*, could run. They write [41.51, p. 1018]:

“The model’s predictions are validated for living alligators and chickens [...]. [m]odels show that in order to run quickly, an adult Tyrannosaurus would have needed an unreasonably large mass of extensor muscle.”

Such an approach may work in cases where very large amounts of data are available, or where there are clearly distinct domains that may be enlisted. In many areas of the geosciences, however, data is scant and all available data need to be used in the initial construction of the model.

### 41.6.3 Sensitivity Analysis and Other Model Tests

Irrespective of the difficulties of model construction and calibration, models can be highly effective in helping to identify the *relative* importance of variables, through techniques such as sensitivity analyses. Sensitivity analysis – also known (inversely) as robustness analysis – is the process of determining how changes in model input parameters affect the magnitude of changes in the output (for philosophical discussions of robustness analyses see, e.g., *Weisberg* [41.52] or *Calcott* [41.53]; for a comprehensive, technical introduction to sensitivity analysis in a variety of domains see *Saltelli et al.* [41.54]). For example, in the context of the paleontology research on models of *Tyrannosaurus rex* introduced above, *Hutchinson* writes [41.55, p. 116]:

“Because any model incorporates assumptions about unknown parameters, those assumptions need to be explicitly stated and their influences on model predictions need to be quantified by sensitivity analysis [...]. In many models this can be determined by varying one parameter at a time between minimal and maximal values (e.g., crouched and columnar limb poses) and evaluating the changes in model output (e.g., the required leg muscle mass).”

Varying one parameter at a time is known as a *local* sensitivity analysis. However, for some sorts of systems (especially systems in which nonlinearities and thresholds operate), a complicating factor is that model sensitivity to a parameter can also depend on the values of the other model parameters [41.56, p. 141] and [41.33, p. 18]. Hence, in these latter cases, one needs to perform what is known as a *global* sensitivity analysis, where all the parameters are varied simultaneously to assess how their interactions might affect model output [41.57].

Sensitivity analysis is used in nearly all domains of modeling, and it can be an important guide to data

collection: alerting the scientific community to where additional or better empirical information is most likely to make a difference. That is to say, sensitivity analyses can reveal which parameters are most important in a model (and hence should be targeted for additional data collection) and which parameters are relatively unimportant or even negligible. It may thus suggest parameters that should be omitted, which can save on computational time. Sensitivity analyses can also help determine whether a model might be overparameterized, which involves a kind of overfitting to the data that occurs when too many parameters are included and fixed.

Model testing can involve a wide spectrum of different techniques, ranging from subjective expert judgments to sophisticated statistical techniques. *Rykiel* [41.37] has assembled a list of 13 different procedures, which he calls *validation procedures*. However, given the concerns raised above about the term validation and the heterogeneity of the procedures collected in his list, the broader rubric of *model tests* is arguably more appropriate. *Rykiel*’s list is as follows [41.37, pp. 235–237]:

1. Face validity, where experts are asked if the model and its behavior are reasonable.
2. Turing-test validity, where experts assess whether they can distinguish between system and model outputs.
3. Visual validation, where visual outputs of model are (subjectively) assessed for visual goodness of fit.
4. Inter-model comparisons.
5. Internal validity of model.
6. Qualitative validation: the ability to produce proper relationships among model variables and their dynamic behavior (not quantitative values).
7. Historical data validation, where a part of the historical data is used to build the model and a part is used to validate it.
8. Extreme conditions tests, where model behavior is checked for unlikely conditions.
9. Traces: the behavior of certain variables is traced through the model to see if it remains reasonable at intermediate stages.
10. Sensitivity analyses: the parameters to which the model is sensitive are assessed against the parameters to which the system is or is not sensitive.
11. Multistage validation: validation at certain critical stages throughout the model-building process.
12. Predictive validation: model predictions are compared to system behavior.
13. Statistical validation: statistical properties of model output are evaluated and errors are statistically analyzed.

Although, as noted before, the term validation is inappropriate and this heterogeneous list could be usefully organized into different categories, it nonetheless provides a good sense of the broad spectrum of techniques

that modelers deploy in testing and evaluating their models. Each of the procedure on this list can play an important role in the modeling process and is arguably worthy of further philosophical and methodological reflection.

## 41.7 Inverse Problem Modeling

One of the central tasks of geophysics is to determine the properties of the interior structure of the Earth on the basis of measurements made at the surface. The primary method by which this is done is known as *inverse problem modeling*. Most broadly, an inverse problem is defined as that of reconstructing the parameters of a system or model based on the data it produces; in other words, one starts with a set of observational data and then tries to reason back to the causal structure that might have produced it. The inverse problem is contrasted with the *forward problem*, which involves starting with a known model and then calculating what observations or data that model structure will produce. Inverse problems are found across the sciences, such as in finding the quantum potential in the Schrödinger equation on the basis of scattering experiments, diagnostic imaging in medicine using X-ray computer assisted tomography, or, most relevantly here, determining information about the interior structure of the Earth on the basis of travel-time data of waves (e.g., earthquakes). Indeed, the first methods for solving inverse problems were developed in the context of seismology by a German mathematical physicist Gustav Herglotz (1881–1953) and the geophysicist Emil Wiechert (1861–1928).

A fundamental challenge for inverse modeling methods is the problem of underdetermination [41.58, p. 120]:

“[T]he model one aims to determine is a continuous function of the space variables. This means the model has infinitely many degrees of freedom. However, in a realistic experiment the amount of data that can be used for the determination of the model is usually finite. A simple count of variables shows that the data cannot carry sufficient information to determine the model uniquely.”

In other words, the solution to the inverse problem is not unique: there are many different models that can account for any given set of data equally well. This is true for both linear and nonlinear inverse problems [41.59].

One method for trying to constrain this underdetermination is known as the model-based inversion

approach, which involves introducing a second, intermediary model known as the *estimated* or *assumed* model [41.60, p. 626]. The estimated model is used in the forward direction to generate *synthetic* data, which is then compared with the observational data. On the basis of the discrepancy between the two datasets, the estimated model is modified and the synthetic data it produces is again compared in an iterative optimization process. As *Snieder* and *Trampert* note, however [41.58, p. 121]:

“There are two reasons why the estimated model differs from the true model. The first reason is the nonuniqueness of the inverse problem that causes several (usually infinitely many) models to fit the data [...] The second reason is that real data [...] are always contaminated with errors and the estimated model is therefore affected by these errors as well.”

In other words, one must also be aware of errors arising from the data model (as discussed earlier). Different modeling approaches for dealing with inverse problems in geophysics have been developed, such as the use of artificial neural network (ANN) models (see, e.g., *Sandham* and *Hamilton* [41.61] for a brief review).

Recently, a number of philosophers of science have highlighted the philosophical implications of the underdetermination one finds in geophysical inverse problems. *Belot* [41.62], for example, argues that this “down to earth underdetermination” shifts the burden of proof in the realism–antirealism debate by showing that a radical underdetermination of theory by (all possible) data is not just possible, but actual, and likely widespread in the geosciences (and elsewhere). *Miyake* similarly calls attention to the problem of underdetermination in these Earth models and notes that there are additional sources of uncertainty that are not even considered in the setting up of the inverse problem [41.63]. He argues that thinking of these Earth models as a case of what philosophers [41.64] call *model-based measurement* is important for understanding the epistemology of seismology.

## 41.8 Uncertainty in Geoscience Modeling

Geoscientists have paid considerable attention to the problem of model uncertainty and sources of error, but many (if not all) of the sources of uncertainty they identify are not unique to the geosciences. There are different ways in which one can construct a taxonomy of the sources of uncertainty in modeling. One can, for example, organize the sources of uncertainty by the relevant stage in the modeling process. Here, one can group the various uncertainties into the following three categories:

1. Structural model uncertainties
2. Parameter uncertainties
3. Solution uncertainties.

Alternatively, one can also organize the sources of uncertainty in modeling on the basis of various complexities that arise for the sort of systems one is trying to model. This latter approach is taken by geomorphologist *Stanley Schumm* [41.65], who organizes the sources of uncertainty into the following three categories:

1. Problems of scale and place
2. Problems of cause and process
3. Problems of system response.

Each of these ways of thinking about sources of uncertainty in modeling serves to highlight a different set of philosophical and methodological issues.

Uncertainties can be identified at each step of the modeling process. During the construction phase of the model there are a number of uncertainties that can be grouped together under the broad rubric of *structural model uncertainties*. In this category, there are what are termed *closure uncertainties*, which involve uncertainties about which processes are to be included or not included in the model [41.66, p. 291]. There can be uncertainties regarding both which processes are in fact operating in the target system (some processes might be unknown) and which of the processes known to be operating are in fact important to include (we may know that a process is operating, but not think it is relevant). Sometimes whether a process is important, however, depends on what other processes are included in the model, as well as on other factors, such as the relevant spatiotemporal scale over which the model will be applied. As an example of this type of structural model (closure) uncertainty, *O'Reilly et al.* [41.67] discuss the case of early attempts to model stratospheric ozone depletion (that resulted in the unexpected *ozone hole* in the Antarctic, which was discovered in 1985). They write [41.67, p. 731]:

“[B]efore the ozone hole discovery led scientists to rethink their conceptual models, ozone assessments had not considered such multiphase reactions [i. e., heterogeneous chemical reactions] to be important. At the time, gas-phase atmospheric chemistry was much better understood than multiphase chemistry, and heterogeneous reactions were seen as arcane and generally unimportant in atmospheric processes.”

Because these chemical processes were not well understood scientifically and were not recognized as important to this phenomenon, they were left out of the model, leading to a drastic underprediction of the rate at which ozone depletion would take place. More generally, as *Oreskes* and *Belitz* have noted, when modelers lack reliable information about known or suspected processes, they may simply leave out those processes entirely, which effectively amounts to assigning them a value of zero [41.48, 67]. Such closure uncertainties in modeling can thus lead to significant errors.

Second, there are *process uncertainties*, which are concerned with how those processes should be represented mathematically in the model. For many processes in the geosciences, there is no consensus on the right way to represent a given process mathematically, and different representations may be more or less appropriate for different applications. For example, there are different ways that turbulence can be represented in models of river flow, from the greatly simplified to the highly complex [41.66, p. 291].

Third, there are what are more narrowly called *structural uncertainties*; these are uncertainties in the various ways the processes can be linked together and represented in the model. Included in this category are uncertainties associated with whether a component is taken to be active (allowed to evolve as dictated by the model) or passive (e. g., treated as a fixed boundary condition). *Lane* [41.66, p. 291] gives the example of the different ways the ocean can be treated in global climate models: because of water's high specific heat capacity, the ocean responds slowly to atmospheric changes; hence, if used on short enough time scales, the modeler can represent the ocean as a passive contributor to atmospheric processes (as a source of heat and moisture, but not one that in turn responds to atmospheric processes). *Parker* [41.68] also discusses structural uncertainty in climate modeling, with regard to the choice of model equations.

Structural model uncertainties can give rise to *structural model error*, which *Frigg et al.* [41.69] define broadly as a discrepancy between the model dynamics

and target system dynamics. They demonstrate that in a nonlinear model, even a small structural model error can lead to divergent outcomes more drastic than those due to the sensitive dependence on initial conditions characteristic of chaotic systems. In analogy with the well-known butterfly effect, they (following Thompson [41.70]) call this the *hawkmoth effect*. They conclude that the structural model error in a nonlinear model “is a poison pill . . . operational probability forecasts are therefore unreliable as a guide to rational action if interpreted as providing the probability of various outcomes” [41.69, p. 57]. Nonetheless, they note that such models may still be useful for generating insight and understanding.

In addition to these three types of structural model uncertainty (closure, process, and structure uncertainties), another significant source of uncertainty is *parameter uncertainty*. As discussed earlier, models contain both variables (whose values are determined by the model itself) and parameters (whose values must be specified externally by the modeler). In the global circulation or ESMs of climate science, parameters are used, for example, in representations of unresolved processes (such as cloud systems or ocean eddies) that are on a finer-grained scale than that on which the model operates. Ideally, the value of a parameter is determined directly by field measurements, but often this is not possible. In many cases, the parameter is either prohibitively difficult to measure or has no simple field equivalent. The parameters then need to be estimated or calculated on the basis of other models (e.g., as detailed by Edwards [41.38] in his discussion of parameters in meteorology and atmospheric science). Beven [41.45, p. 8] gives the example of the parameter representing soil hydraulic conductivity in hydrology. Measurements of soil hydraulic conductivity are typically made on soil samples in a small area, but are known to exhibit order of magnitude variability over even short distances. Often, however, the model will require a value of hydraulic conductivity over a much larger spatial scale (e.g., the whole catchment area). Hence, substantial uncertainties can arise as one tries to determine an *effective* value for the parameter.

Parameters can also take on different values than their real-world counterparts during the process of calibration or optimization. An example is the bed roughness parameter, which is used to represent the grain size of a river bed affecting the friction and turbulence of the flow. As Odoni and Lane note [41.71, p. 169]:

“it is common to have to increase this quite significantly at tributary junctions, to values much greater than might be suggested by [...] the bed grain size. In this case there is a good justifica-

tion for it, as one-dimensional models represent not only bed roughness effects but also two- and three-dimensional flow processes and turbulence.”

In other words, the bed roughness parameter in the model is used to capture not just the bed roughness, but other effects that act like bed roughness on the behavior of the flow. This is another example of what was earlier called *getting things more wrong in order to get them more right*. More generally, parameter values determined for one model may be calibrated for that particular model structure, and hence not be independent of that model structure or even different discretizations or numerical algorithms of that model structure, and therefore are not transferable to other models without additional error [41.45, p. 8]. Hence, one must be aware of the problem of *parameter incommensurability*, where parameters that share the same name might in fact “mean” different things [41.45, p. 8].

Although they are not strictly speaking parameters, one can also include under this umbrella category uncertainties in the initial conditions and the boundary conditions, which also need to be specified externally by the modeler in order to operate the model. Examples include [41.71, p. 169]:

“the geometry of the problem (e.g., the morphology of the river and floodplain system that is being used to drive the model) or boundary conditions (e.g., the flux of nutrients to a lake in a eutrophication model).”

In order to integrate a model forward in time, one needs to first input the current state of the system as initial conditions. Not only can there be uncertainties in the current state of the system, but also some chaotic models will be very sensitive to such errors in the initial conditions.

The final category of model uncertainties is *solution uncertainties*. Once the model equations are set up, the parameters fixed, and the initial and boundary conditions are specified, the next step is to solve or run the model. Often in geoscience modeling, the governing equations are nonlinear partial differential equations that do not have general analytic solutions. In such cases, one must resort to various discretization or numerical approximation algorithms (e.g., finite difference methods, finite element methods, boundary element methods, etc.) to obtain solutions, which will not be exact (though they can often be benchmarked against analytic solutions). There can also be uncertainties introduced by the way the algorithm is implemented on a computer for a simulation model. Beven notes [41.45, p. 6]:

“[D]ifferent implementations will, of course, give different predictions depending on the coding and degree of approximation. [The] computer code [...] represents a further level of approximation to the processes of the real system.”

In implementing a model on a computer, decisions must be made about the appropriate choice of time steps and spatial discretizations, and these and other solution uncertainties can lead to further sources of error.

In his book *To interpret the Earth: Ten ways to be wrong*, Schumm identifies 10 sources of uncertainty, which he organizes into the three categories of problems of scale and place, problems of cause and process, and problems of system response [41.65]. The first source of uncertainty concerns *time*. Compared to the long-time history over which Earth’s landscapes evolve, the time scale of human observation is extremely short. There can be short-term patterns in geoscience phenomena that are very different from the long-term pattern one is trying to predict or explain; hence, extrapolations from short-term observations may not be reliable (e.g., the short-term wind direction you observe may not be indicative of the prevailing long-term wind direction that predominantly shapes the landscape). Also, different features of a landscape (and the corresponding different processes) can become salient as different time scales are considered. The processes that are most relevant on a short-time scale (such as storm events) may be insignificant on a long-time scale, as well as the reverse (e.g., uplift phenomena are negligible over the short term, but are such stuff as the Himalayas are made of over the long term). Hence, inadequate attention to these issues of time, both in the construction and application of the model, can be a significant source of uncertainty. The second source of uncertainty, *space*, is analogous to these problems of time. For example, to understand how water moves through the ground on a small spatial scale, the type of soil or rock (e.g., its porousness) might be most relevant to model, while on a large scale, the overall topology of the landscape (e.g., whether it is on a steep slope) and whether it has large-scale rills (cracks or channels) might be more relevant. The third source of uncertainty Schumm calls *location*, which relates to the uniqueness of geomorphic systems (e.g., there is a sense in which no two rivers are exactly the same, and hence models developed for one location, might not be applicable to other locations).

In the next cluster, Schumm identifies *convergence* as a fourth source of uncertainty. Convergence is the idea that different processes or causes can produce similar effects. For example, sinuous rills on the Moon look like dried river beds formed by flowing water, but were later concluded to be the result of collapsed lava

tubes [41.65, p. 59]. Hence, one needs to be careful in inferring cause from effect, and in drawing an analogy from the causes of an effect at one location to the causes of a very similar effect at another location. The fifth source of uncertainty, *divergence*, is the opposite of convergence: the same cause can produce different effects. Schumm gives the example of glacio-eustasy, or the change of sea levels due to the melting of glaciers and ice sheets. He explains [41.65, p. 64]:

“With the melting of the Pleistocene continental ice sheets the assumption is that a global sea-level rise will submerge all coastlines. However, the results are quite variable [...] [a]s a result of isostatic uplift following melting of the continental ice sheets.”

Isostatic uplift refers to the rebounding or rise of land masses that were depressed under the massive weight of the ice sheets (this rebound is still ongoing and averages at the rate of a centimeter per year: see, e.g., *Sella et al.* [41.72]). In other words, the melting of glaciers and icesheets can cause sea levels both to rise and to fall (depending on the location): one cause, two different (and opposite) effects.

The sixth source of uncertainty Schumm identifies is what he calls *efficiency*, which he identifies with the assumption that the more energy expended, the greater the response or work done. He notes that this will not generally be the case [41.65, p. 66]:

“When more than one variable is acting or when a change of the independent variable, such as precipitation, has two different effects, for example, increased runoff and increased vegetation density, there may be a peak of efficiency at an intermediate condition.”

He gives as an example the rate of abrasion of a rock by blown sand, which has a maximum abrasion efficiency at relatively low rates of sand feed (presumably due to an interference of rebounding particles with incoming particles).

The seventh source of uncertainty he identifies is *multiplicity*, which is the idea that there are often multiple causes operating in coordination to produce a phenomenon, and hence one should adopt a *multiple explanation approach*. This concept originated in the work of the American geologist Thomas C. Chamberlin (1843–1928), specifically in his method of multiple working hypotheses, a method which he urged was beneficial not only to scientific investigation, but also to education and citizenship. In his 1890 article introducing this method he considers the example of explaining the origin of the Great Lake Basins. *Chamberlin* writes [41.73, p. 94]:

“It is practically demonstrable that these basins were river-valleys antecedent to the glacial incursion, and that they owe their origin in part to the pre-existence of those valleys and to the blocking-up of their outlets [. . .]. So, again, it is demonstrable that they were occupied by great lobes of ice, which excavated them to a marked degree, and therefore the theory of glacial excavation finds support [. . .]. I think it is furthermore demonstrable that the earth’s crust beneath these basins was flexed downward, and that they owe [. . .] their origin to crustal deformation.”

What might initially appear to be a scientific controversy involving rival hypotheses or competing explanations, in fact turns out to be a case where each hypothesis correctly has part of the story. Chamberlin concludes that one benefit of considering diverse explanations for observed phenomena is that it forces the geologist to move beyond hasty or simplistic explanations, and instead to consider the possibility that more than one relevant process has been involved. (For a philosophical discussion of the method of multiple hypotheses in the case of plate tectonics, see *Rachel Laudan* [41.74].)

An example of this from paleontology is the long-standing debate about the cause of the Cretaceous (K–T) mass extinction (in which 70% of all species, including all the (nonavian) dinosaurs, went extinct). The favored explanation of this extinction event is the impact hypothesis: that the extinction was caused by a large comet or asteroid that hit Earth near present-day Chicxulub, Mexico. While the fact that this impact occurred is not in doubt, some scientists question whether the impact hypothesis can explain the gradual and step-wise extinction pattern that is observed in the fossil record. They favor instead an explanation that appeals to massive volcanism and climate change, which was already underway. While often viewed as rivals, these two explanations might be complementary [41.75]. *Schumm* concludes, “if there is more than one cause of a phenomenon, unless all are comprehended, extrapolation will be weak and composite explanations are needed” [41.65, pp. 74–75]. (For a more general philosophical discussion of explanation in the Earth sciences, including a discussion of the explanation of the K–T extinction, see *Cleland* [41.76].)

The final three sources of uncertainty *Schumm* identifies are *singularity*, the idea that landforms, though also having many commonalities, have features that make them unique, and hence respond to changes in slightly different ways or at different rates; *sensitivity*, the idea that small perturbations to a system can have significant effects, especially when a system involves

either internal or external thresholds; and the *complexity* of geomorphic systems, which means they have numerous interconnected parts interacting in typically nonlinear ways. An example of an important threshold in the geosciences is the velocity at which a sediment particle of a given size is set in motion by a particular fluid (e.g., water or wind). This is an example of an extrinsic threshold involving changes in an external variable. There can, however, also be intrinsic thresholds in which there is an abrupt change in a system without there being a corresponding change in an external variable. For example, under constant weathering conditions the strength of materials can be weakened until there is an abrupt adjustment of the system (such as a landslide). Another example of an intrinsic threshold is when a bend or loop in a meandering river will suddenly be cut off by the formation of a new channel. More generally, geomorphic systems often exhibit what are called *autogenic behaviors*, in which there can be a sudden and pronounced change in the system’s behavior or characteristics, not due to an external cause, but rather due to internal feedbacks in the system, in which gradual changes can result in sudden, threshold-like responses (for a discussion see *Murray et al.* [41.77]; for an example of an autogenic behavior discovered in the St. Anthony’s Falls physical model discussed earlier, see *Paola et al.* [41.78]). *Schumm* concludes [41.65, p. 84]:

“The recognition of sensitive threshold conditions appears to be essential in order that reasonable explanations and extrapolations can be made in geomorphology, soil science, sedimentology and stratigraphy, and many environmental and ecosystem areas.”

So far we have reviewed five sources of uncertainty arising during stages of the modeling process and 10 sources of uncertainty arising from the complexity of geoscience systems. A further complication arises from the fact that even models with these sorts of errors can generate predictions that agree reasonably well with observations – a case of getting the right answer for the wrong reason. Hence, on pain of committing the fallacy of affirming the consequent, one cannot deductively conclude that one’s model is right, just because it produces predictions that match observations. More generally, this is related to the fact that more than one model or theory can account for a given set of observations: the data underdetermine the model or theory choice. In the philosophical literature this is known as the problem of underdetermination (e.g., see *Duhem* [41.79], or for contemporary discussion, see *Stanford* [41.80]; for a philosophical discussion of underdetermination in the Earth sciences see *Kleinhaus*

et al. [41.2]). In the geoscience literature the problem of underdetermination is sometimes referred to as the problem of nonuniqueness, or *equifinality* [41.81]. *Beven* and *Freer* write [41.82, p. 11]:

“It may be endemic to mechanistic modeling of complex environmental systems that there are many different model structures and many different parameter sets within a chosen model structure that may be [...] acceptable in reproducing the observed behavior of that system. This has been called the equifinality concept.”

In other words, the data are not sufficient to uniquely pick out a model structure or parameter set. (A similar sort of equifinality was seen in the nonuniqueness of inverse problems discussed earlier.) Moreover, the acceptable parameter sets may be scattered throughout parameter space (i. e., not localized around some optimum parameter set). This problem of equifinality is not

just hypothesized, but has been demonstrated in computer simulations, which are now cheap and efficient enough to allow explorations of the parameter space of models of a variety of geoscience systems.

The problem of equifinality has led *Beven* et al. to develop a method to deal with uncertainty that they call the generalized likelihood uncertainty estimation (GLUE) methodology [41.83]. GLUE involves a kind of Monte Carlo method with a random sampling of the space of possible model–parameter combinations, in which each possible set of parameters is assigned a likelihood function (assessing the fit between model predictions and observations). The idea is not to pick one *best* model–parameter set, but rather to take into account the predictions of all acceptable models (models not ruled out by current data or knowledge), weighted by their relative likelihood or acceptability, in something like a Bayesian averaging of models and predictions. (For a recent review and discussion of objections to the GLUE methodology see *Beven* and *Binley* [41.84].)

## 41.9 Multimodel Approaches in Geosciences

The GLUE methodology is just one of several different approaches that try to use multiple models in concert to reduce uncertainty. The GLUE methodology requires a large number of runs to adequately explore the parameter space. However, this is not typically feasible in computationally intensive models. An alternative approach that can be used with more complex models is the *metamodel* approach (for a review see *Kleijnen* [41.85]). A metamodel is a simplified surrogate model that is abstracted from the primary model and used to aid in the exploration of the primary model and its parameter space. While metamodels have long been used in engineering research, they have only recently started to be applied to models in the geosciences.

*Odoni* [41.86], for example, has applied the metamodel approach to the study of a landscape evolution model (LEM) developed by *Slingerland* and *Tucker* [41.87] known as GOLEM (where GO stands for geomorphic-orogenic). GOLEM has been used, for example, to model the evolution of a catchment landscape of the Oregon Coast Range around the headwaters of the Smith River over a period of 100 000 years. In order to understand how equifinality manifests itself in GOLEM, *Odoni* selected 10 parameters (related to mass movement, channel formation, fluvial erosion, and weathering processes) to vary over a range of values that was determined to be consistent with the location based on published data and calibration. The model outputs used to describe the landscape at 100 000

years include sediment yield, drainage density, sediment delivery ratio, and a topographic metric. Rather than trying to solve the full GOLEM model for the immense number of possible parameter value combinations, *Odoni* derived a metamodel, or set of regression equations, that described each model output as a function of the GOLEM parameters. As he explains, “The parameter space is then sampled rapidly and densely ( $> 1 \times 10^6$  times), using each metamodel to predict GOLEM’s output at each sample point” [41.86, p. i]. In this way metamodels yield a clearer picture of what drives model output (leading to a possible further simplification of the model) and an understanding of where equifinality may be lurking. It is important to note that this equifinality is not just an abstract cooked-up possibility, but a genuine, wide-spread practical problem, making it yet another example of what *Belot* termed down-to-earth *underdetermination*.

More common than both the GLUE and metamodel approaches are classic *intermodel comparison* projects. The most well known here are the large-scale, multi-phase intercomparison projects used by the IPCC in their assessments. The most recent coupled model intercomparison project (CMIP5), for example, compares the predictions of dozens of climate models running the same set of scenarios. The aim of such multimodel ensembles is to “sample uncertainties in emission scenarios, model uncertainty and initial condition uncertainty, and provide a basis to estimate projection uncertain-

ties” [41.88, p. 369]. *Lloyd* has emphasized the strength of such multimodel approaches, arguing that it is “a version of reasoning from variety of evidence, enabling this robustness to be a confirmatory virtue” [41.89, p. 971].

The proper assessment of such intermodel comparisons for robustness and uncertainty reduction involves some subtleties, however (see, e.g., *Parker* [41.90, 91]; *Lenhard* and *Winsberg* [41.92]). Models can, for example, agree because they share some common model structure, rather than indicating model accuracy. As *Masson* and *Knutti* explain [41.93, p. 1]:

“All models of course contain common elements (e.g., the equations of motion) because they describe the same system, and they produce similar results. But if they make the same simplifications in parameterizing unresolved process, use numerical schemes with similar problems, or even share components or parts thereof (e.g., a land surface model),

then their deviations from the true system or other models will be similar.”

In such cases an agreement among climate models does not indicate that modelers are on the right track. It remains unclear how best to conceptualize and assess model independence [41.23, p. 485]. More generally, the spread of an ensemble of models is often taken to approximate the uncertainty in our predictions; however, as *Knutti* et al. [41.94] have argued, these are *ensembles of opportunity*, not systematic explorations of model or parameter space. They suggest a number of ways forward, including having a larger diversity of models to help find constraints valid across structurally different models, and developing new statistical methods for incorporating structural model uncertainty [41.94, p. 2755]. There are many other multimodel approaches used in the geosciences, including *coupled models* and *hierarchical modeling*.

## 41.10 Conclusions

The geosciences provide a rich and fruitful context in which to explore methodological issues in scientific modeling. The problem of understanding and articulating scientific uncertainty has particularly come to the fore in these fields. The complex and multiscale nature of geological and geophysical phenomena require that a wide variety of kinds of models be deployed and a broad spectrum of sources of uncertainty be confronted. Most modelers do not expect their models to give specific, quantitative predictions of the detailed behavior of the systems under investigation. Rather, they are understood as providing a tool by which scientists can test hypotheses (including causal ones), evaluate the relative importance of different elements of the system, develop model-based explanations [41.95, 96], and generate qualitatively accurate projections of future conditions. Indeed, it is precisely by grappling with

these many sources of uncertainty that geoscientists gain insight and understanding into the various processes that shape the Earth, their relative importance and patterns of dependence, and the emergent structures that they produce.

The geosciences, as we have seen, constitute a significant portion of scientific research today. Our philosophies of science and our understanding of the nature of model-based inquiry are inadequate if we do not take this research into account. As we hope this review has made clear [41.44, p. 100]:

“the earth sciences are profoundly important, not only because they challenge conventional philosophical portraits of how scientific knowledge is produced, tested, and stabilized, but also because they matter for the future of the *world*.”

# Models in the

## 42. Models in the Biological Sciences

Elisabeth A. Lloyd

Evolutionary theory may be understood as a set of overlapping model types, the most prominent of which is the natural selection model, introduced by Charles Darwin and Alfred Russel Wallace. Many of the most prominent models today are represented through mathematical population genetics, in which genetical representations of populations evolve over time to produce evolutionary change. I review the variety of evolutionary models – from genic to group to species selection models – and how they are confirmed through evidence today. I discuss both applications to cases where we do not know the genetics, and to animal behavior and evolution.

### 42.1 Evolutionary Theory

Charles Darwin proposed a general type of natural selection model that could explain a variety of particular cases of adaptation to local environments, once details of organismic traits and selection pressure were inserted. Much of evolutionary theory today, though not all, is represented through mathematical models, especially through the models of population genetics, of the evolution of states of a given system, both in isolation and interaction through time. This chapter discusses in detail various ways to describe the evolutionary models that make up evolutionary theory. The main items needed for this description are the model types of natural selection, drift, and so forth, most often described through the definition of a state space, state variables, parameters, and a set of laws of succession and coexistence for the system. Choosing a *state space* (and thereby, a set of state variables) for the representation of genetic states and changes in a population is a crucial part of population genetics theory. Claims about evo-

lutionary models may be confirmed in three different ways:

1. Through fit of the outcome of the model to a natural system
2. Through independent testing of assumptions of the model, including parameters and parameter ranges
3. Through a range of instances of fit over a variety of the natural systems to be accounted for by the model, through a variety of assumptions tested, and including both instances of fit and some independent support for aspects of the model.

#### 42.1.1 The Structure of Darwinian Evolutionary Models

The basic structure of Darwinian evolutionary models is deceptively simple and elegant; such simplicity can yield powerful change over the proposed time spans

encountered by the biological systems involved. For evolution by natural selection, for example, we start with a basic very general model structure that includes a set of assumptions or components [42.1, 2]. *Van Fraassen* has defined *model type* as the description of a structure in which certain parameters are left unspecified, like this [42.3, p. 44].

#### Definition 42.1 Model Type

*Model type* = a structure in which certain parameters are left unspecified [42.3, p. 44].

The classic selection model type concerns a population of varied organisms, and these variations are assumed to be at least partially inheritable. In this population's environment (which is always defined relative to the organism's needs and sensitivities), there are demands and stresses affecting some variants more than others, resulting in differential reproduction. Thus, the basic natural selection model type leads to the change in the population variants' composition and structure over evolutionary time. (For discussion about multilevel selection model types, see *Lloyd* [42.4]).

In 1859, Charles Darwin, in *On the Origin of Species*, proposed his basic abstract selection model type, and other evolutionary model types, and also filled in their details in various cases in various ways in the book and his correspondence; in this manner, he illustrated how to use and apply the models.

#### Definition 42.2 Natural Selection Model Type

Population (with details filled in) \_\_\_\_\_  
 Traits \_\_\_\_\_  
 Genetic basis \_\_\_\_\_  
 Correlation with fitness \_\_\_\_\_  
 Selection pressure, environment \_\_\_\_\_

More specifically, each of the model types serve as formats for explanation; the particular terms or factors in a model type vary in each application, depending on the outcome of the model and various assumed conditions [42.1, 2]. For example, in the *Origin*, Darwin needed evidence for his assumption that wild organisms spontaneously developed heritable variations some of which would be advantageous to their survival and reproduction. Such a general assumption of the existence of useful variations was necessary for a variable in the natural selection model type, which would then be instantiated in specific models by individual cases of variation. Darwin found empirical evidence for this assumption in the animal breeders' information, as he

presents in the *Origin*. (Darwin kept up an avid and long-term correspondence with a number of pigeon breeders, from which he learned detailed information about the vast variety of feather form, pattern, and color, as well as behaviors, which spontaneously arose in their pigeons.) Elsewhere in his correspondence, Darwin also offers evidence to support an empirical assumption of a specific model constructed using the selection model type. In looking at wingless insects that appear on oceanic islands at a higher concentration than elsewhere, Darwin proposed to explain their frequency by a selection pressure of high winds blowing them off the islands, thus favoring insects without wings. He tested this model assumption by comparing an even smaller island to the other islands he was examining earlier: he found, as he predicted, even a higher percentage of wingless insects. His earlier assumption of a selection pressure was thus indirectly confirmed in his proposed model [42.1, pp. 121–122], [42.5, p. 401], [42.6, pp. 226–227]. See Sect. 42.2 for more detailed discussion about the confirmation of evolutionary models. Note that the evolutionary selection models can range from the very abstract, general, model structure with its high level assumptions, through ever more specified models as we identify and fill in the necessary assumptions of selection pressures, types of variation, and evidence for heritability. Ultimately, our ever more detailed specifications of the assumptions result in a fully specified selection model, which anchors the most concrete end of the model-continuum, from most abstract model type to most concrete model [42.7], [42.2, pp. 106–107], [42.1, pp. 118–119].

#### 42.1.2 The Structure of Population Genetic Evolutionary Models

While Darwin's evolutionary models and explanations were nonquantitative, much of evolutionary theory at the beginning of the twenty-first century is represented through mathematical models or equations, especially through the models of population genetics, of the evolution of states of a given system, both in isolation and interaction, through time. This is done by conceiving of the evolutionary model as capable of a certain set of states – these states are represented by elements of a certain mathematical space, the state space [42.5, 6, 8, 9].

#### Definition 42.3 (State Space)

A *state space* is a mathematical space specified by variables capable of a certain set of states; the collection of all possible configurations or states of these variables.

**Definition 42.4 (Data Models)**

*Data models* are simplified structures representing the natural world made up of measurements, observations, or the results of experiments, that is, numbers or values extracted from the real world, many of which are arranged in relations suggested by the theoretical models.

Generally speaking, *models* and *systems* always refer to ideal systems, described theoretically. When the actual biological systems are being discussed, they are called *empirical* or *natural* systems. The variables used in each model represent distinct measurable or potentially quantifiable, physical, or biological magnitudes. Classically, any particular configuration of values for these variables is a *state* of the system, the *state space* being the collection of all possible configurations of the variables.

The theory itself represents the behavior of the system in terms of its states: the rules or laws of the theory (i. e., laws of coexistence, succession, or interaction) can delineate various configurations and trajectories on the state space. A description of the structure of the theory itself therefore only involves the description of the set of models, which make up the theory. In an application of the theory or models to the real world, we consider both *data models* and the idealized models describing idealized systems and their resemblance. *Data models* are simplified structures representing the natural world made up of measurements, observations, or the results of experiments, that is, numbers or values extracted from the real world, many of which are arranged in relations suggested by the theoretical models [42.10].

The ideal systems are usually gradually specified, as described in Sect. 42.1.1, to show a good match or similarity with the data models, to which they are compared during an application of the theory or model type [42.3, 11]. Construction of a model within the theory involves assignment of a location in the state space of the theory to a system of the kind defined by the theory. Potentially, there are many kinds of systems that a given theory can be used to describe – limitations come from the dynamical sufficiency (whether it can be used to describe the system accurately and completely) and the accuracy and effectiveness of the laws used to describe the system and its changes.

**Definition 42.5 (Dynamical Sufficiency)**

The concept of *dynamical sufficiency* concerns what state space and variables are sufficient to describe the evolution of a system given the parameters being used in the specific system.

Thus, there are two main aspects to defining a model. First, the state space must be defined – this involves

**Fig. 42.1** A three-dimensional Cartesian coordinate system, with axes  $x$ ,  $y$ , and  $z$  (after [42.12])

choosing the variables and parameters with which the system will be described, e.g. in Fig. 42.1; second, coexistence laws, which describe the structure of the system, and laws of succession, which describe changes in its structure, must be defined.

**Definition 42.6 (Coexistence Laws)**

Laws representing compatible states of the state variables.

**Definition 42.7 (Laws of Succession)**

Laws representing progressive changes of states of a system.

**Definition 42.8 (Parameters)**

Values that are not themselves a function of the state of the system. Unvarying values.

Defining the state space involves defining the set of all the states the system could possibly exhibit. Certain mathematical entities – in the case of many evolutionary models, these are vectors – are chosen to represent these states. The collection of all the possible values for each variable assigned a place in the vector is the state space of the system. The system and its states can have a geometrical interpretation: the variables used in the state description (i. e., state variables) can be conceived as the axes of a Cartesian space.

The state of the system at any time may be represented as a point in that space, located by projection on the various axes. The family of measurable physical magnitudes, in terms of which a given system is defined, also includes a set of parameters. *Parameters* are values that are not themselves a function of the state

**Fig. 42.2** Genotype space with genotypic coordinates  $AA$ ,  $Aa$ , and  $aa$  (after [42.13])

of the system. Thus, a parameter can be understood as a *fixed value* of a variable in the state space – topologically, setting a parameter amounts to limiting the number of possible structures in the state space by reducing the dimensionality of the model.

Laws, used to describe the behavior of the system in question, must also be defined in a description of a model or set of models. Laws have various forms: in general, coexistence laws describe the possible states of the system, while laws of succession describe changes in the state of the system.

Let us discuss in, more detail, the description of the evolutionary models that make up current evolutionary theory. The main items needed for this description are the definition of a state space, state variables, parameters, and a set of laws of succession and coexistence for the system. Choosing a *state space* (and thereby, a set of state variables) for the representation of genetic states and changes in a population is a crucial part of population genetics theory. (Population genetics models are a most technical, but not necessarily a *core*, part of evolutionary theory itself (but see *Thompson* [42.6]).

*Paul Thompson* suggests that the state space for population genetics would include the physically possible states of populations in terms of genotype frequencies. The state space would be “a Cartesian  $n$ -space where  $n$  is a function of the number of possible pairs of alleles in the population” [42.6, p. 223]. We can picture this geometrically as  $n$  axes, the values of which are frequencies of the genotype, as in Fig. 42.2.

The state variables are the frequencies for each genotype. Note that this is a one-locus system, that is, we take only a single gene locus and determine the dimensionality of the model as a function of the number of alleles at that single locus.

Another type of single locus system, used less commonly than the one described by *Thompson*, involves using single gene frequencies, rather than genotype frequencies, as state variables. Some of the debates about *genic selectionism* center around the descriptive, dynamical, and parametric adequacy of this state space and its parameters for representing evolutionary phenomena (*Dawkins* [42.14], *Lloyd et al.* [42.15], see later discussion of genic selection and dynamical insufficiency).

With both genotype and gene frequency state spaces, treating the genetic system of an organism as being able to be isolated into single loci involves a number of assumptions about the system as a whole. For instance, if the relative fitnesses of the genotypes at a locus are dependent on other loci, then the frequencies of a single locus observed in isolation will not be sufficient to determine the actual genotype frequencies. Assumptions about the structure of the system as a whole can thus be incorporated into the state space in order to reduce its dimensionality. *Lewontin* [42.16] offers a detailed analysis of the quantitative effects of dimensionality of various assumptions about the biological systems being modeled. Interactions between genotypes, and between one locus and another cannot be represented in a single locus model (with the exception of frequency-dependent selection), for the simple reason that they involve more than one locus [42.16, pp. 273–81].

As far as the structure of the theory goes, although all single locus models should, in some sense, be grouped together, they are not all exactly the same model – each particular model has a different number of state variables, depending upon the number of alleles at that locus. Because a model type is simply an abstraction of a model, constructed by abstracting one or more of the models parameters or variables, a single model can be an instance of more than one model type. This is an extremely important aspect of the flexibility of this approach to theory structure.

Along similar lines, we may say that each model type be associated with a distinctive state space type. In the preceding example, the single locus model is to be taken as an instance of a general state space type for all single locus models, i. e., the different single locus model types are conceived as utilizing the same state space type. Alternatives, such as two-locus models, must be taken as instances of a different state space type.

*Parameters* are the values that appear in the succession and coexistence laws of a system that are the same for all possible states of the defined system. For instance, in the modification of the Hardy–Weinberg

equation that predicts the frequencies of the genotypes after selection, the selection coefficient,  $s$ , or multiplier, appears as a parameter in the formula  $p^2 AA + 2pqAa + (1-s)q^2 aa = 1 - sq^2$  [42.17, p. 102], [42.18, p. 81].

There are a variety of methods of establishing the value at which a parameter should be fixed or set in the construction of models for a given real system, for example, simulation techniques can be used to obtain estimates of biologically important parameters. In some contexts, maximum likelihood estimations may be possible. Parameters can also be set arbitrarily or ignored. This is equivalent to incorporating certain assumptions into the model for purposes of simplification [42.19, pp. 8,89].

One expects the values of parameters to have an impact on the system being represented; but variations in parameter values can make a larger or smaller amount of difference to the system. For instance, take a deterministic model that incorporates a parameter for mutation,  $\mu$ . The rates of change of this model can be virtually insensitive to realistic variations in the value of the mutation parameter,  $\mu$ , because they are several orders of magnitude smaller. (However, mutation rates do sometimes play important roles with significant consequences, for example, in *Kimura and Ohta* [42.20] (nearly neutral theory), and in *Kondrashov's hatchet* (in the evolution of sex, [42.21]).

Going back to Hardy–Weinberg models, the selection parameters play a crucial role in these models. A very small amount of selection in favor of an allele will have a cumulative effect strong enough to replace other alleles [42.16, p. 267].

Population size is another case in which the value assigned to the parameter has a large impact on the model results. The parameter for the effective population size,  $N$ , can play a crucial role in some models, because selection results can be quite different with a restricted gene pool size [42.22, pp. 48–50]. In many of the stochastic models involved in calculating rates of evolutionary change, the resulting distributions and their moments can depend completely on the ratio of the mean deterministic force to the variance arising from random processes [42.16, p. 268]. This variance is usually proportional to  $1/N$  and is related to the finiteness of population size. Thus, change in the value of the single parameter,  $N$ , can completely alter the structure represented by the theory.

The choice of parameters can also make a major difference to the model outcome. Theoreticians have choices about how to express certain aspects of the system or environment. The choice of parameters used to represent the various aspects can have a profound effect on the structure, even to the point of rendering the model useless for representing the real world system

in question. Group selection models provide a case in which choice of parameters not only alters the results of the models, but also can lead to the near disappearance of the phenomenon being modeled [42.23, 24].

Some authors, when discussing genetic changes in populations, speak of the system in terms of a type of state space involving phenotypes. This makes sense, because the phenotype determines the breeding system and the action of natural selection, the results of which are reflected in the genetic changes in the population; quantitative genetics is the set of models that concentrate on phenotypic state spaces. In his analysis of the present structure of population genetics theory, *Lewontin* traces a single calculation of a change in genetic state through both genotypic and phenotypic descriptions of the population [42.16].

But in addition, mating patterns, and probabilities of survival and reproduction, although influenced by genes, are a consequence of developmental events that are contingent on the environment of the developing organism, and involve more than any simple phenotype. In the most general case, environment includes influences of the phenotypes of previous generations by means of cytoplasmic inheritance through the egg. A complete general representation of genetic evolutionary processes then requires not two, as is usually done, but six spaces with sequential transitions within them and mappings from one to the other [42.15]. Haploid spaces represent only the single chromosome or set of one sex's genes, while (sexually reproducing) diploid state spaces represent both sets. The complete set of six spaces,  $S$ , is thus:

- $S_1$  A diploid phenotypic space
- $S_2$  A diploid genotypic space
- $S_3$  A diploid pair phenotypic space
- $S_4$  A diploid pair genotypic space
- $S_5$  A haploid phenotypic space and
- $S_6$  A haploid genic space.

(Assuming that organisms reproduce in discrete generations, with no overlap between generations.) While it is true that the system's transition from one generation to the next may be represented in any one of the six spaces, we need to know the entire loop – and all the parameter values in each of the model stages in that loop – in order to obtain a fully accurate representation of any chosen state space in the next generation, i. e., to get the state transformation equation between generations *within any one of the spaces* (e.g., if we want to move from ( $S_6$ ) to ( $S_6$  in the new generation)). For instance, for the transition in allelic space, we must move out of that space, into genotypic space to define the fitness parameters, and back into allelic space in order to

characterize the next generation [42.15, pp. 143–144]. This case illustrates the issue of the representational adequacy of models, to which we shall now turn.

### 42.1.3 Representational Adequacy of Models

The most common approach to comparing population genetic models has emphasized prediction of allele frequency changes: If two models both predict the same changes in allele frequencies, it is thought, then the models are *equivalent*. But this is an inadequate approach to understanding and confirming models. We advance the notion of *representational adequacy*, which we define as parametric and dynamical sufficiency. Why introduce representational adequacy? What is wrong with straightforwardly checking whether the model fits the allele frequency data? There are a variety of ways that models can be tested against data, and fitting the outcome or prediction of the model – in these cases, the predicted allelic or genotypic frequencies – is only one of them [42.25].

Other significant components of the empirical evaluation of any mathematical model include: testing the values of its parameters against the system independently (e.g., measuring or estimating the mutation parameter value in the model); evaluating the appropriateness of the state space and parameters used; and testing the model against a range of values in the variety of systems to which it is supposed to apply (variety of fit) (Sect. 42.2). In addition, a model is taken to be better confirmed when it has more of its parameter values – that is, a variety of them – estimated or confirmed independently [42.9, pp. 145–159]. Our notion of representational adequacy combines the traditional standards of predictive accuracy and goodness of fit with the broader requirements of confirming that the state space, parameters, and laws being used in the models are appropriate and sufficient to the task [42.26–28]. We take it as foundational to any notion of adequate representation that the standards of parametric sufficiency in model building be weighed in judging overall model adequacy. Parametric sufficiency is dependent upon choice of space and parameter set, in any particular case.

The concept of dynamical sufficiency is precisely defined in terms of a set of objects and their frequencies, and another set of objects and their frequencies. Dynamical and parametric sufficiency together provide a much more adequate measure of a model's empirical worth than the vague notion of empirical adequacy, or the overly simplistic idea that if a model's prediction of allelic or genotypic frequency is correct, then the model is empirically substantiated.

#### Parametric Sufficiency

Parameters are properties of objects, and may be properties of more than one object at a time. (Parameters are represented in the models as values that are not variables.) Two models may look as though they should be dynamically equivalent because of the similar appearance and *names* of their parameters, such as *fitness*, but real differences in their parameter measures may result in dynamics that are not equivalent. Two models should be considered *parametrically equivalent* if the parameters that apply in one model have a natural representation in the parameters that apply in another. One case in which similar-looking parameters yield very different dynamics concerns allelic and genotypic fitnesses, which has led to much confusion in current controversies.

#### Dynamical Sufficiency

The concept of dynamical sufficiency concerns what state space and variables are sufficient to describe the evolution of a system given the parameters being used in the specific system. What happens to the frequency of the variable over time? In a simple allelic model, this question becomes: Can we describe the changes in the frequency of allele A over time, with the information that we have, which includes the state space (variables) and the parameters (fitnesses, population size, etc.)?

*Problematic Claims.* One widely repeated set of claims has revolved around [42.29] assessment of the mathematical equivalence of a wide variety of population genetic models [42.30, p. 577], [42.31, p. 57, pp. 98–99], [42.32, pp. 168–169, p. 172], [42.33, p. 479, p. 508], [42.34, p. 312]

*Dugatkin and Reeve's Formulation of Allelic Equivalence.* Dugatkin and Reeve claim [42.29, p. 108]:

“A number of theoretical investigations [42.35–43] have shown that the mathematics of the gene-, individual-, kin-, and new group-selection approaches are equivalent [...] We will show [...] that this must be the case.”

They do this with a pair of inequalities [42.29, p. 109]. Dugatkin and Reeve claim that their inequality (2) “encompasses both broad-sense individual selection and any form of trait-group selection that one may care to envision.” Moreover, they conclude, “If broad-sense individual selection, genic selection, and trait-group selection all can be represented by a single condition based only on allele frequencies, then they cannot fundamentally differ from one another” [42.29, p. 109].

But there are serious problems here. The first is that their inequalities (1) and (2) hide completely the causes of why the numbers of alleles change, is misleading and illustrates the importance of both dynamic and parametric sufficiency.

For a true haploid dynamic, we would usually write for one locus, but this also necessarily involves genotypic parameters for the fitnesses, as well as the allelic frequencies. In other words, the apparently purely-allelic parameters depend crucially on genotypic fitnesses – but these values are usually *completely hidden*. The assumption of Mendelian transmission is also made in deriving (3) (see also [42.44]). For this two-allele diploid case, if meiotic drives were introduced, one more parameter,  $k$ , giving the probability that  $A$  is produced by  $Aa$  heterozygotes, would be necessary. Thus, we note that in describing the algebra, many discussions of allelic models and their algebra obscure the origins of that algebra and all the information it contains and represents. A common move is to infer that the genic state space, and its basic entity, the allele, have a metaphysically fundamental and autonomous character [42.30]. This is both biologically and mathematically problematic. Biologically, the changes represented are dependent on all changes in the entire generational cycle reviewed above, represented in the variety of spaces and parameters. Mathematically, because genic space is dynamically insufficient for representing many system changes, and because in diploids there are no allelic transition laws within allelic space with allelic parameters, there is nothing autonomous about it; thus, it cannot support the metaphysical inferences based on its supposed autonomy [42.15, 45]. But there is another account available which might be thought to avoid some of the above problems.

In this crucial case, from Dugatkin and Reeve, the allele frequencies  $G$  in the allelic state space are dynamically sufficient to study the evolution of genotype frequencies  $k$ . These equivalences depend, however, on the parameters,  $w_{11}$ ,  $w_{12}$ ,  $w_{22}$ , that could only be determined in the genotypic space.

Increasing attention has recently been paid to the phenomenon of epigenetics, which includes a variety of biological processes that act on genes and may be transmitted between generations, but not according to any of the rules of genetic inheritance. Formal models for the evolution of epigenetic objects or properties (Feldman and Cavalli-Sforza [42.45, 46]; see also Jablonka and Lamb [42.47]) utilize an additional state space  $S_7$ , the phenogentotype, in which changes may occur during organismal development.

Now consider a few particular aspects and forms of the *laws* used in population genetic models. Coexistence laws describe the possible states of the system

in terms of the state space. In the case of evolutionary theory, these laws would consist of conditions delineating a subset of the state space that contains only the biologically possible states. Laws of succession describe changes in the state of the system. In the case of evolutionary theory, dynamic laws concern changes in the genetic composition of populations. The laws of succession select the biologically possible trajectories in the state space, with states at particular times being represented by points in the state space. The law of succession is the equation of which the biologically possible trajectories are the solutions. The Hardy–Weinberg equation is the fundamental law of both coexistence and succession in population genetics theory. Even the dynamic laws of the theory are usually used to assess the properties of the equilibrium states and steady state distributions. The Hardy–Weinberg law is a very simple, deterministic succession law that is used in a very simple state space. As parameters are added to the equation, we get different laws, technically speaking. For example, compare the laws used to calculate the frequency  $p'$  of the  $A$  allele in the next generation. Plugging only the selection coefficient against a recessive into the basic Hardy–Weinberg law, we get the recursion for the dominant allele frequency as  $p' = p/(1 - sq^2)$ .

Addition of parameters for the mutation rates yields a completely different law,  $p'' = 1 - \mu p' + \nu q'$ , where  $\mu$  is the rate of mutation away from the dominant allele, and where  $\nu$  is the rate of mutation toward it. We could consider these laws to be of a single type – variations on the basic Hardy–Weinberg law – that are usually used in a certain state space type. The actual state space used in each instance depends on the genetic characteristics of the natural system, and not usually on the parameters. For instance, the succession of a system at Hardy–Weinberg equilibrium and one that is not at equilibrium but is under selection pressure, could both be modeled in the same state space, using different laws.

A theory can have either deterministic or statistical laws for its state transitions. Furthermore, the states themselves can be either statistical or nonstatistical.

#### Definition 42.9 Statistical Laws

*Statistical laws* are constructed by specifying a probability measure on the state space. For example, we could assign probabilities (frequencies) to each distinct possible value of gene frequency. Thus, the probability measure is constructed by taking a certain value for the gene frequency, obtaining the joint distribution (for example, through simulation) and making a new state space of probabilities on the old state space of gene frequencies.

In population genetics models, gene frequencies often appear in the set of state variables, thus the states themselves are statistical entities. In general, a law is deterministic if, when all of the parameters and variables are specified, the succeeding states are uniquely determined. In population genetics, this means that the initial population and parameters are all that is needed to get an exact prediction of the new population state.

In sum, the structure of evolutionary theory can be understood by examining the families of models it presents. In the case of population genetics theory, the set of model types – stochastic and deterministic, single locus or multilocus – can be understood as related families of models. The question then becomes defining the exact nature of the relationships among them, and how they relate to the rest of the evolutionary models, such as phenotypic or evolutionary developmental models.

#### 42.1.4 Expansions and Alternative Views of the Structure of Evolutionary Theory

In philosophy of science, the above analysis instantiates an approach to theory structure known as the *semantic view*, that focuses on models [42.3, 10, 11, 48–50].

##### Definition 42.10

The *semantic view* states that scientific theories are understood as being interpretable as families of models (viewed in terms of set theory, not necessarily algebraically). More recently it has gone under the name, the *model-based approach*. The *syntactic* or *received view* comes from the *logical positivist* tradition, where scientific theories are viewed as axiomatizable sets of sentences. The axioms are the universal laws of the theory, and all that can be derived from those axioms are the regularities of the theory. Evolutionary theory had been criticized for not being easily formulated in terms of the received view.

Some authors have misrepresented the semantic approach, while some also support what they tend to call a *model-based* approach, whose differences from the semantic view are unclear [42.51, 52]. For instance, Downes [42.51, p. 143], Godfrey Smith [42.52, p. 731], and Love [42.53, p. 7] all claim that the semantic view is committed to “mathematized theories,” which is not useful for some biological contexts. But both Beatty [42.5] and Lloyd [42.1] analyzed Darwin’s (non-mathematical) selection theory and models as their first presentations of the semantic view of evolutionary theory. So clearly the semantic view can be used to analyze *nonmathematized* theories and biological contexts. Especially in the hands of Suppes, the semantic view

can be used to analyze any structures into set theoretic terms, and thus into *mathematical* terms (mathematics concerns structures, and all structures can be seen as *mathematical objects*); but the whole purpose is to represent the system in the most accurate, most useful, or most beneficial, etc. way. This does *not* mean that the analyzed structures are themselves represented mathematically *before* the analysis, and also does not mean that they are represented in equations *after* the analysis. Some authors also neglect the various hierarchies of evolutionary models offered using the semantic view, as outlined in Sect. 42.1.1, with misleading results (e.g., Godfrey Smith [42.52, pp. 732–739], Lloyd [42.1, pp. 118–119]).

In contrast, biologist Samuel Scheiner has recently offered an expanded account of the structure of evolutionary theory that takes the semantic view as its touchstone, and goes on to include other areas of biology [42.54]. Alan Love has also provided a very interesting expansion of the analysis of evolutionary theory through the inclusion of developmental biology models and model types. The analysis of the structure of the theory offered above for population genetics can thus be advanced and expanded (using a variety of detailed methods of describing models, if needed), to incorporate developmental biology, by extending the linkages and overlaps of the model families understood to make up evolutionary theory. Love’s overall approach is extremely useful, as it focuses on which research problems in evolutionary biology subfields compose the theory as a whole [42.54, p. 428], [42.55, 56]. Just as on the earlier analysis of Darwinian models in Sect. 42.1.1, on Love’s view, the entire hierarchy of models is explored, from the very abstract or general, to the extremely concrete. He emphasizes that different researchers use mid-level models in different ways and toward different ends; the resulting fully filled-out and concrete models can even be incompatible with one another. Love offers lists of model constraints from cellular and developmental biology that add additional model structure that may be needed to complement evolutionary models in order to fulfill the requirements of an extended evolutionary synthesis [42.53, p. 8]. By combining different empirical generalizations, some developmental biologists create mechanisms for the *evolution of form* that can then be tested. (The component principles of these generalizations are not, themselves, best considered mechanistic models, according to Love [42.53, p. 8]). The relevant causal mechanisms operate on the level of individual ontogeny of organisms, not on population-level mechanisms such as natural selection or genetic drift. Thus, we get the concrete-level models just mentioned. Having a flexible and robust view of theory structure that

**Fig. 42.3** The semantic view structure of evolutionary theory, with overlapping substructures in an  $n$ -dimensional space. Each oval represents a subtheory in evolutionary theory, such as genotypic selection or species selection

can account for this wide range of models is imperative, for Love. He contrasts the complex and flexible view he derives from *Griesemer's* [42.58] semantic view account, as seen in Fig. 42.3, with that of biologists *Pigliucci and Müller* [42.57].

*Pigliucci and Müller* discuss the possibility of an expanded evolutionary synthesis, which is intended to incorporate evolutionary developmental biology (evo-devo) in significant and integrated ways. They see the need for such an expansion, based on new concepts and findings in evo-devo that cannot be forced into their view of the traditional evolutionary synthesis from the 1930s and 1940s [42.57].

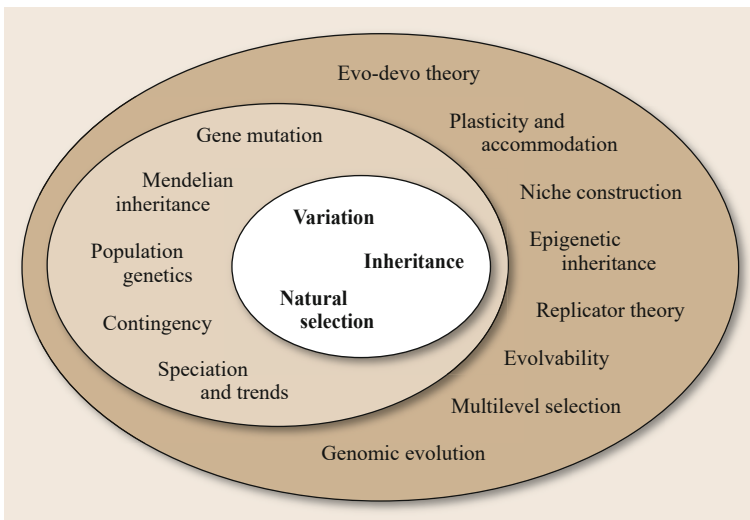

*Pigliucci and Müller* offer an onion-type diagram to show the structure of evolutionary theory: They place

*Darwinism* as a circle at the very center of the onion, which includes only natural selection, inheritance, and variation.

In the next outer ring, they place the *modern synthesis*, which includes things like *mendelian inheritance, speciation and trends*, population genetics, and gene mutation. In the last, outermost ring, which they call the *extended evolutionary synthesis*, *Pigliucci and Müller* place evo-devo theory, niche construction, multilevel selection, and genomic phenomena, etc., as shown in Fig. 42.4.

One apparent problem with this proposed structure, is: how does evo-devo theory interact with natural selection, when they are layers away in the onion? It seems that they have no integration, on this picture. Alan Love also complains that this model assumes a *core* of evolutionary population genetics, which is always in operation, even though many have no wish to make such an assumption, and may explicitly reject it [42.53, p. 6], [42.9, p. 8]. The general problem with the onion picture is thus the lack of integration and relations among its parts, which is available under analyses that approach the structure as hierarchical and intertwined families of models, which include the new evo-devo, detailed, models.

A valuable alternative approach to the structure of current evolutionary biology as well as its history is presented by *Telmo Piavani*, who offers a reconstruction inspired by philosopher *Imre Lakatos* [42.59]. *Piavani's* updated Lakatosian approach dispenses with some weaknesses in the original Lakatosian approaches, including any strong falsificationism, and analyzes contemporary evolutionary theory into a flexible structure that delineates the theory's *explanatory core* and its *protective belt*. The traditional *explanatory core* includes

**Fig. 42.4** The new, updated structure of expanded evolutionary theory, with its core and surrounding elements of theories (after [42.57])

such things as: evolution as a fact, the tree of life, common descent, and natural and sexual selection. The explanatory core of evolutionary theory serves as the basic theoretical and assumptive background when building evolutionary explanations, and can be combined with other explanatory and theoretical tools from the *protective belt*, which has expanded and contracted over time, depending on our state of biological knowledge. Currently, Piavani argues that the evolutionary core includes two hierarchies, one a genealogical hierarchy, namely of nested levels of transmission of genetic materials, organisms, demes, species, and monophyletic taxa. The other hierarchy is ecological, made up of, for example, organisms, populations like avatars, local ecosystems, and regional ecosystems, the key issue being the transfers of energy.

Using these two hierarchies in the explanatory core, Piavani then describes a “pluralistic protective belt,” that is, a set of models and assumptions, in addition

to the “explanatory core,” that may be appealed to by an evolutionary biologist when constructing an explanation [42.60, pp. 12–13]. This set of models and assumptions includes evo-devo, or evolutionary-developmental biology, which is now being appealed to in some applications of evolutionary theory. Piavani emphasizes that the theoretical changes that evolutionary theory has undergone since the modern synthesis in the 1930s and 1940s has been a progressive one, and now the theory is very healthy. The current dual core of the theory, and its various models and features of the protective belt demonstrate the growth of evolutionary knowledge since the modern synthesis (although they do have the disadvantage, according to someone like Love, of privileging some models as the *core* of evolutionary theory). Piavani also emphasizes that much of the theory is capable of *falsification*, but *has not been falsified*, which concerns the testability and confirmation of the theory, the topic of Sect. 42.2.

## 42.2 Confirmation in Evolutionary Biology

### 42.2.1 Confirming and Testing Models

In general, one evaluates a model by comparing the outcome of the model with empirical observations, and by independently testing the assumed conditions, including observations not available at the time of model construction [42.1, pp. 116–117]. In population genetics, the most obvious way to support a claim of the form *this natural system is described by this model*, is to demonstrate the simple matching of some part of the model with some part of the natural system being described. (Throughout this discussion, let us assume that each *match* of model to a natural system in the real world involves a specification of the model, by filling in variable and parameter values (on the model side), plus a determination from the real world of a *data model* into a similar format (on the real-world side). We will skip these specifications in our discussion, henceforth, and for simplicity, simply say that a *model matches or describes the natural world*.) In a population genetics model, the solution of an equation might yield a single genotype frequency value. The genotype frequency is a state variable in the model. Given a certain set of input variables (e.g., the initial genotype frequency value, in this case), the output values of variables can be calculated using the rules or laws of the model. The output set of variables (i. e., the solution of the model equation given the input values of the variables) is the *outcome* of the model. Determining the fit between model and natural system involves testing how well the genotype frequency trajectory cal-

culated from the model (the outcome of the model) matches that measured in the relevant natural (or experimental) populations. It can be evaluated by determining the fit of one curve (the model trajectory or coexistence conditions) to another (taken from the natural system); ordinary statistical techniques of evaluating curve-fitting are used.

Also, numerous assumptions are made in the construction of any model, and testing a model sometimes involves confirming some or all of these assumptions independently. These include assumptions about which factors influence the changes in the system, what the ranges for the parameters are, and what the mathematical form of the laws is. On the basis of these assumptions, the models take on certain features. Many of these assumptions thus have potential empirical content. That is, although they are assumptions made about certain mathematical entities and processes during the construction of the theoretical model, when empirical claims are then made about this model, the assumptions may have empirical significance.

For instance, the assumption might be made during the construction of a model that the population is panmictic, that is, all genotypes interbreed at random with each other.

#### **Definition 42.11 Panmictic, Panmixia**

All genotypes interbreed at random with each other.

The model outcome, in this case, is still a genotype frequency trajectory, for which ordinary curve-fitting tests

can be performed on the natural population to which the model is applied. But the model can have additional empirical significance, given the empirical claim that a natural system is a system of the kind described in the model. The assumption of panmixia, as a description of the population structure of the system under question, must be considered part of the system description that is being evaluated empirically. Evidence to the effect that certain genotypes in the population breed exclusively with each other (i. e., evidence that the population is not, in fact, panmictic) would undermine empirical claims about the model as a whole, other things being equal, and even if genotype frequencies (that is, the model outcome) provide good instances of fit. In other words, the assumption that genotypes are randomly redistributed in each generation is intrinsic to many population genetics model types. Hence, although the assumption that the population is panmictic often is taken for granted in the actual definition of the model type – that is, in the law formula – it is interpreted empirically and plays an important role in determining the empirical adequacy of the claim.

By the same token, evidence that the assumptions of the model hold for the natural system being considered will increase the credibility of the claim that the model accurately describes the natural system. Technically, we can describe this situation as follows. From the point of view of empirical claims made about it, the model has three parts: state variables, empirically interpreted background assumptions, and those aspects and assumptions of the model that are not directly empirically interpreted. Because the possible outcomes of the model (along with the inputs) are actually values of the state variables, we can understand the input and outcome of the model as a sort of minimal empirical description of the natural system.

#### **Definition 42.12 Three Parts of the Models**

State variables: such as genotypes. Empirically interpreted background assumptions: such as selection parameters, mutation parameters, relations between model parts. And those aspects and assumptions of the model that are not directly empirically interpreted.

If a model is claimed to describe accurately a natural system, at the very least, this means that the variables in which the natural system is described change according to the laws presented in the theoretical model. Under many circumstances, such models, in which only the state variables are empirically interpreted, are understood to be *mere* calculating devices, because the match with the (*data model* extracted from the) natural system is so limited.

Various aspects of the model – for instance, the form of its laws, or the values of its parameters – rely on assumptions made during model construction that can be interpreted empirically. The assumption of panmixia, discussed earlier, is an empirically interpreted background assumption of many population genetics models. Because it is empirically interpreted, the presence or absence of panmixia in the natural population in question makes a difference to the empirical adequacy of the model.

Finally, there may be aspects of the model that are not interpreted empirically at all. For instance, some parameters appearing in the laws might be theoretically determined and might have no counterpart in the natural system against which the model is compared.

Given that there can be aspects of the model structure that are not directly tested by examining the fit of the state variable curve, direct testing of these other aspects would give additional reason to accept (or reject) the model as a whole. In other words, it is taken that direct testing provides a stronger test than indirect testing, hence there is a higher degree of confirmation if the test is supported by empirical evidence. Direct empirical evidence for certain empirically interpreted aspects of the model that are not included in the state variables (and thus are confirmed only indirectly by goodness-of-fit tests), therefore provides additional support for the application of the model.

The above sort of testing of assumptions involves making sure that the empirical conditions for application of various parts of the model description actually do hold. In other words, in order to accept an explanation constructed by applying the model, the conditions for application must be verified. The specific values inserted as the parameters or fixed values of the model are another important aspect of empirical claims that can be tested. In some models, mutation rates, etc. appear in the equation – part of the task of confirming the application of the model involves making sure that the values inserted for the parameters are appropriate for the natural system being described. Finally, there is more abstract form of independent support available, in which some general aspect of the model, for instance, the interrelation between the two variables, or the significance of a particular parameter or variable, can be supported through evidence outside the application of the model itself. For example, a migration parameter can be measured independently of the application of the model by counting the numbers of organisms that move between designated populations.

Variety of evidence, of which there are at least three kinds, is an important factor in the evaluation of em-

irical claims. Three kinds of variety of evidence are discussed here:

1. Variety of instances of fit
2. Variety of independently supported model assumptions
3. Variety of types of support, which include fit and independent support of aspects of the model. In addition, we must consider the virtue of robustness of models.

First, let us consider variety of fit, that is, variety of instances in which the model outcome matches the value obtained from the natural system. Traditionally, variety of evidence has meant variety of fit. There are two issues that must be distinguished when considering the variety of fit. One involves the range of application of a model or model type, while the other involves the degree of empirical support provided for a single application. Both of these issues involve the notion of independence, which needs to be clarified before continuing.

One point of any claim to variety of evidence is to show that there is evidence for the hypothesis in question from different or independent sources. The notion of independence here is not the sort of independence that is found in the frequency interpretation of probability theory, where the independence depends only on accepting a particular reference class. Rather, in the context of scientific theories, independence is relative to whatever theories have already been accepted.

Significantly, in evolutionary theory, independence is usually relative to some assumption about natural kinds. Empirical claims are often made to the effect that a model is applicable over a certain range of natural systems. Inherent in these claims is the assumption that all of the natural systems in the range participate in some key feature or features that make it possible and/or desirable to describe them all with the same model type. Thus, there is some assumption of a natural kind (characterized by the key feature or features) whenever range of applications arises. The scientist, in making a claim that the model type is applicable to such and such systems, is making an empirical assumption about the existence of the key feature or features in the range of natural systems under question. Hence, for evolutionary models, testing for variety of fit depends on accepting an assumption about what constitutes different or independent instances of fit; this in turn, amounts to accepting a particular view of natural kinds. Part of what variety of evidence does, in a bootstrapping effect, is to confirm this original assumption about natural kinds. More technically, variety of evidence confirms the sufficiency of the parameters and state space.

Take the case in which a model type is claimed to be applicable over a more extended range than that actually covered by available evidence. This extrapolation of the range of a model can be performed by simply accepting or assuming the applicability of the model to the entire range in question. A more convincing way to extend applicability is to offer evidence of fit between the model and the data in the new part of the range. Provision of a variety of fit can thus provide additional reason for accepting the empirical claim regarding the range of applicability of the model.

For instance, a theory confirmed by 10 instances of fit involving populations of size 1000 (where population size is a relevant parameter) is in a different situation with regard to confirmation than a theory confirmed by one instance of each of ten different population sizes ranging from 1–1 000 000. If the empirical claims made about these two models asserted the same broad range of applicability, the latter model is confirmed by a greater variety of instances of fit. That is, the empirical claim about the latter model is better confirmed, through successful application (fits) over a larger section of the relevant range than the first model. Variety of fit can therefore provide additional reason for accepting an empirical claim about the range of applicability of a model. Variety of fit can also provide additional reason for accepting a particular empirical claim, that is, one of the form, *this natural system is accurately described by that model*. That is, variety of evidence can serve to increase confidence in the accuracy of any particular description of a natural system by a model.

Variety of fit is only one kind of variety of evidence. An increase in the number and kind of assumptions tested independently, that is, greater variety of assumptions tested, would also provide additional reason for accepting an empirical claim about a model. The final sort of variety of evidence involves the mixture of instances of fit and instances of independently tested aspects of the model. In this case, the variety of types of evidence offered for an empirical claim about a model is an aspect of confirmation. This kind of variety is not only related to robustness, which appears when numerous models all converge on the same result, but also is especially significant when the same model-type with a particular causal core is used to converge on the same result using a variety of assumptions, a condition that I call *model robustness*, and which warrants the conclusion that the core cause in the model-type has been confirmed by this configuration of evidence [42.61].

According to the view of confirmation sketched above, claims about evolutionary models may be confirmed in four different ways:

1. Through fit of the outcome of the model to a natural system
2. Through independent testing of assumptions of the model, including parameters and parameter ranges
3. Through a range of instances of fit over a variety of the natural systems to be accounted for by the model, through a variety of assumptions tested, and including both instances of fit and some independent support for aspects of the evolutionary model
4. Through *model robustness*, wherein the core of a model type is confirmed through robust outcomes and empirical support for the assumptions of the models.

## 42.3 Models in Behavioral Evolution and Ecology

### 42.3.1 The Phenotypic Gambit

The basic assumption underlying much behavioral biology and evolutionary theory is that the organisms under study are well adapted. This assumption amounts to the claim that many features of the organism are themselves adaptations, shaped by natural selection for their present uses. There are also many features of the organism that are byproducts of present adaptations, characteristics that Stephen Jay Gould and Elisabeth Vrba dubbed *exaptations*, or traits that may be useful, but were not adapted by natural selection for their present uses. We will continue to focus on the adaptations, for the present. We can ask, about any feature of an organism, *does this trait have a function?* And if the answer seems to be *yes*, then we can search for the specific, detailed function that it serves. Assuming that there is a genetic underpinning for a selected phenotypic trait, and that it does not matter what that genetic underpinning is called *the phenotypic gambit*. In researching traits in the population, the researcher delineates distinct *strategies* or behavioral characteristics, and then assigns fitnesses or reproductive success to those strategies. The phenotypic gambit [42.62, Ch. 3, p. 64]:

“Is to examine the evolutionary basis of a character as if the very simplest genetic system controlled it: as if there were a haploid locus at which each distinct strategy was represented by a distinct allele, as if the payoff rule gave the number of offspring for each allele, and as if enough mutation occurred to allow each strategy the chance to invade.”

Technically, the Gambit is almost always false, as few species studied by animal behaviorists are haploid, having only one set of chromosomes. But the soundness of behavioral ecology, whose “main aim is to undercover the selective forces that shape the character,” depends on ignoring population genetics, and hoping that their situations and traits do not violate their assumptions, especially the phenotypic gambit [42.62, Chap. 3, p. 64].

### 42.3.2 Evolutionary Stable Strategies, Animal Signalling

Using the phenotypic gambit, evolutionary models at the phenotypic level, usually game theoretic models, are created by animal behaviorists and behavioral ecologists to explore the evolutionary dynamics of animal behavior. W.D. Hamilton offered the rubric of his rule: if the degree of relatedness,  $r$ , times the benefit of a behavior, minus the cost of that behavior, would be greater than zero, then the behavior would evolve in the population. The benefits and costs are always counted in terms of numbers of offspring, not any other currency.

In the context of the phenotypic gambit, strategies in models borrowed from economics, in which stable equilibria are reached using simple strategies assigned to the phenotypes, are dubbed Evolutionary Stable Strategies. Such strategies are explored through optimal foraging theory, in models that represent searches for food and consumption and handling of that food in either simple or complex environments. Optimal strategies make the best use of the organisms’ net rate of energy intake and time, which are therefore optimized in the economic models adapted for animal behavior. Sometimes these optimality models are compared with experimental evidence regarding their assumptions, to good effect. For example, there is experimental evidence showing a connection between cognitive searching, a memory type of task, and the type of spatial searching done in optimal foraging theory, that are found to be evolutionary stable strategies in the models [42.63].

While *Lewontin* first suggested using game theoretical models in evolutionary biology [42.64], it was *Smith* who really established the use of such models in the field [42.55]. His analysis of adaptations using optimality models is now widely used. *Parker* and *Smith* [42.65] distinguish between general models and specific models, which are parts of a continuum. General models are used heuristically, to guide insights into the biological problem. Specific models are meant to be applied quantitatively to particular species, and

include measurable parameters. In creating an optimality model, an adaptation is assumed, and a range of strategies relating to the adaptive problem is defined, specifying the plausible alternatives. In the case of sex ratios, for example, the strategies would go from all males to half males and half females to all females. An assumption is made that Darwinian fitness is being maximized, usually the lifetime number of surviving offspring, or sometimes Hamilton's inclusive fitness, for each strategy. Assumptions are then made about the fitness consequences or payoffs of each strategy or behavior, which may require constructing mathematical models. For example, R.A. Fisher assumed, in his sex-ratio theory that all parents have equal resources to spend on sons and daughters, so more sons would be less daughters, etc.

The relationship between the fitness function and the strategy can sometimes be determined empirically, although this is often problematic. David Lack famously argued about optimal clutch size in birds, saying that bigger the clutch size, the more chicks that could be hatched. But the more chicks there are, the lower the chance that a given chick would survive, because the parent birds can only supply a limited amount of food to the fledglings. The cost to the parents can be manipulated experimentally by subtracting eggs from the nest as they are laid, to determine what the payoffs are. Ultimately, if the models do not fit, then we have misidentified the strategy set, the optimization criterion, or the payoffs, or possibly, the behavior identified is no longer adaptive. The assumptions of the model need to be revised and retested.

In an evolutionary stable strategy, individual strategies are optimized, which may not maximize fitness in a population sense. A strategy that might maximize population fitness may not be a competitive optimum or ESS (evolutionary stable strategy) because it is invadable by another strategy. Many optimality models have globally stable equilibrium solutions toward which selection is expected to converge. Thus, ESS models, as well as optimization models, may have multiple equilibria [42.65, 66].

### 42.3.3 Physiological/Evolution Models, Cognitive Ethology

Philosopher and cognitive scientist *Colin Allen* wrote in 2014 [42.67, pp. 82–83]:

“Cognitive scientists build many different kinds of models. There are various ways of classifying these models. They could, for instance, be classified according to the kinds of building blocks that they use: nodes and links for network models,

symbols and rules for computational models, probability distributions over hypotheses and conditional probabilities between hypotheses and evidence for Bayesian models, time-based differential equations for dynamical models [42.68], etc. They can also be classified according to the intended application of the model – some models seek only to capture overt behavior, while others are targeted at the mechanisms or processes underlying the behavior. Mathematical models (which, as the case of quantum mechanics shows, may also involve concepts from probability theory) use mathematical structures to provide theoretical insight and to generate empirical predictions that go beyond statistical interpolations or extrapolations of existing results.”

We see this in optimal foraging models. Optimal foraging theory involves optimality modeling of food search behavior in animals. Marmosets and tamarinds, two distinct species of monkeys, show different sets of behavior in their willingness to persist staying at a food source, in terms of maximizing returns, or patience. This makes sense in terms of the their ecology, because one eats insects, the other sap. The insects can easily be renewed, whereas when the sap is gone, it is gone. Thus, the cost to moving to a new resource versus staying at an exhausted resource is clear in each case. This is a model that involves cognitive, ecological, and evolutionary elements, thus is an example of evolutionary cognitive ethology.

Yet Fred Dyer notes that many optimal foraging models do not have any representation of the agents' own representation of their own environment, but they already know where things are in their environment. He does comparative work between species of bees to understand interactions between rewards. Bumblebees, which are diploid in their genetic systems, are individual foragers, while honeybees, which are haplodiploid, and share more of their genes with their hive-mates, are collective foragers, and are more inclined to hang around established sources to distribute the food [42.63].

Similarly, *Hills* finds physiological bases for optimal foraging and evolution, through connecting the rewards of foraging to the dopaminergic–glutamate axis in the brain [42.69]. Tracing the evolution of rewards for tasks through the brain rewards systems has enabled cognitive evolutionary ethologists to tie a variety of behaviors together. The ethologists talk about searching our memory, and offer models of that search as sharing mechanisms with a search in a spatial environment [42.70]. There is experimental evidence supporting the notion that there is a connection between cognitive searches and spatial searches [42.71].

### 42.3.4 Optimality Models Including Agent Models

Continuing the theme of the increased precision of the modeling of behavior, flocking and swarming behavior in birds and fish have been explained by the following

of very simple rules, and not bigger plans, by Craig Reynolds' boids simulations [42.72, 73]. Explain both swarming and predator-prey behavior by simple rules as well. The movement in modeling is toward more psychological modeling looking at agent behavior, rather than just strategies.

## 43. Models and Mechanisms in Cognitive Science

Massimo Marraffa, Alfredo Paternoster

In this chapter, we present and discuss models in the context of cognitive sciences, that is, the sciences of the mind. We will focus on computational models, which are the most popular models used in the disciplines of the mind.

The chapter has three sections. In the first section, we explain what is a computational model, give a pair of examples of it, illustrate some crucial concepts related to this kind of models (simulation, computational explanation, functional explanation, and mechanicism) and introduce a class of partially alternative models: dynamical models. In the second section, we discuss a pair of difficulties faced by computational explanation and modeling in cognitive sciences: the problem raised by the constraint of modularity, and the problem of the allegedly required integration between dynamical and computational models. Finally, in the third section, we provide a short recap.

### 43.1 What is a Model in Cognitive Science?

Cognitive science is the project of interdisciplinary study of natural and artificial intelligence that begins its maturation in the late 1950s and reaches a stable intellectual and institutional set-up in the early 1980s [43.1]. One point is worth emphasizing. Cognitive science (as a general framework) is the study of the mind as an information processing system, that is, a system behaving on the basis of detected and properly elaborated (in a variety of ways) information; yet research in cognitive science is typically about a *specific* type of information processor – for example, cognitive neuroscience investigates the *biological* processor, whereas artificial intelligence explores the *artificial* one. Therefore, cognitive science is better to be conceived of not as a discipline, but rather as a *doctrine* that has oriented inquiries in a number of disciplines (see [43.2, p. 521] and [43.3, p. 18]), some descriptive and empirical (e.g., cognitive psychology, linguistics and, more recently, neuroscience), some speculative and founda-

tional (e.g., philosophy), and some both speculative and applied (e.g., artificial intelligence) [43.4].

Although cognitive scientists are in agreement in considering the mind as an information processing system, their different disciplinary backgrounds lead them to make use of a large variety of approaches, methods, research styles and, for what we are concerned here, *models*. It suffices to mention symbolic systems, artificial neural networks, dynamical systems, robot-style artifacts, and so on.

#### 43.1.1 Computational Models

Yet, if we categorize models according to a sufficiently general (and arguably more useful) criterion, models in cognitive science are essentially of two kinds: mathematical and computational. (It seems reasonable to say that computational models are a subclass of mathematical models. However, it is a so relevant subclass that

it does make sense to assess them separately [43.5, p. 20]). In this chapter, we will mainly be concerned with computational models. We focus on these models for three reasons. First, we take computational models to be the best representative of the research in the discipline. This is confirmed by the fact that over 80% of articles in theoretical cognitive science focus on computational modeling [43.6]. Indeed, it could be argued (with some caution that will be justified later, see mainly Sect. 43.2) that the development of computational models is a *definitional* factor of the discipline [43.7]. Second, the class of computational models is large enough to cover many, arguably most, of the cases. Third, many among the most discussed foundational problems in cognitive science arise exactly from the role ascribed to computation. In other words, the future of the discipline depends crucially on the possibility of extending the use of computational models to a variety of further cognitive capacities and processes, and defending the computational approach from criticisms addressed by the supporters of the so-called *radical embodied cognition* [43.8] (see Sect. 43.2.1, *The Massive Modularity Hypothesis*).

The notion of computation – or algorithm – formalized by Turing [43.9], Church [43.10] and others, consists in an effective procedure to solve a given problem, that is, a finite sequence of elementary and totally explicit (= well defined and not ambiguous) instructions. In order to give a simple and concrete idea of what computations are, it is usual to mention cooking recipes for dummies: instead of saying, for example, *brown the onions*, the recipe specifies every possible elementary constitutive step of this action (*take a pan, put inside a pair of spoons of oil, put the pan on slow fire, add the onions, . . . , etc.*). Clearly, however, the paradigm cases of computation are computer programs. The leading idea in computational modeling is indeed that there is an interesting sense in which mental processes (such as perception, language understanding, reasoning, etc.) can be described as computer programs. In other words, some relevant aspects of mental processes are captured by certain features of computations.

As the reference to computer programs suggests, the notion of computation is closely related to the notion of information processing system; and this is indeed the main reason for the success of computational modeling and explanation in cognitive science: the notion of computation provides the *natural* way to develop the core idea of cognitive science, namely, that agents or their minds are regarded as information processing systems. Shortly put, taking seriously (quite literally) the idea that mental processes are computations is tantamount to saying that minds are information processing systems.

Weisberg [43.5, p. 7] defines *computational models* as sets of procedures that can potentially stand in relation to a computational description of the behavior of a system. The procedures constitutive of the model “take a starting state as an input and specify how this state changes, ultimately yielding an output” [43.5, p. 30]. Two points are to be highlighted in this definition. First, models are sets of *procedures*. It is mandatory, therefore, that the model is constituted of algorithms. However, to say that computational models are simply sets of procedures is arguably too strong. Models usually include some theoretical hypotheses that are not necessarily specified as parts of the algorithms. Weisberg seems to acknowledge this point when he says that “the procedure itself is the core component of the model, the structure in virtue of which parts of a target can be explained” [43.5, p. 30]. Therefore, procedures are *components* of the model, rather than being the model itself. Second, the model is in relation to a *computational description*. This means that a computational model is appropriate just in case the modeled system has a computational nature. What is usually intended by this claim is that the execution of one or more computations is causally responsible of the behavior of the system (see Sect. 43.1.1, *Computational Models and Computational Explanations*).

### Simulation

An execution of the *model-computation* (i. e., of the procedures constituting the model) is a *simulation*, an epistemologically crucial notion. Indeed, the results of simulation allow scientists to check whether a certain hypothesis embedded in the model concerning a cognitive ability or process is confirmed or falsified.

Vivid instances of the simulative method are robotic artifacts. For example, Grasso et al. [43.11] have studied the behavior of lobsters and developed a computational model to check the prediction that lobsters are able to locate sources of food through a very simple, rough mechanism to track turbulent odor plumes to their source (chemotaxis): the more a chemoreceptor is stimulated, the more is directly triggered the speed of the contralateral locomotive organ. Scientists constructed a biomimetic robot (RoboLobster) that works this way by implementing two algorithms:

1. Move forward when the gradient is below a minimal threshold; turn toward the side of the sensor detecting higher chemical concentration.
2. The same as algorithm 1 with one additional rule: back up when both sensors detect the lack of chemical substance.

Then RoboLobster was immersed in a stream of water to which a turbulent plume was added to check

whether it was able, in a variety of conditions, to reach the appropriate location. It turned out, however, that the robot failed in most trials. In trials running algorithm 1, it consistently failed to hit the source regardless of whether it began its trial 60 or 100 cm downstream from the source or ran in the normal or reverse sensor configuration; on average the robot approached the source much more when it started 60 cm from the source compared to the other conditions. In trials running algorithm 2, the robot never hit the source with reversed sensors; better results were obtained at the 60 cm, but not at the 100 cm starting distance, with sensors in the forward connectivity configuration. This allowed scientists to conclude that the hypothesized mechanism was not appropriate, too rough.

This case effectively shows that simulation is a very important empirical method in cognitive science. It is indeed part and parcel of cognitive science the idea that a good empirical practice for studying a phenomenon is trying to *reproduce* it. If the behavior, or certain behavioral abilities, of an organism are reproduced by an artifact or by a computer program, we have a reason to believe that the computational model is an explanation of the behavior of that system. Of course, this claim should be taken with much prudence. The legitimacy of regarding simulation as a kind of explanation is a crucial epistemological issue, and the simulative methodology calls undoubtedly for some methods of validation or evaluation [43.12, 13]. Nevertheless, it is hard to deny that the simulative approach has already demonstrated to be useful.

### Computational Models and Computational Explanations

Before providing another, more complex example of computational model, let us still spend some words on the distinction between computational models and computational explanations (or computational theories). This is important in order to assess properly the role of computational models.

According to *Piccinini* [43.14, 15], we have a computational *explanation* when the best way of accounting for the behavior of a certain system is to say that it performs a certain computation, that is, it is in virtue of the fact that the system computes a certain function that the system behaves the way behaves (as *Piccinini* puts it, the behavior of the system is *causally* explained by the computations it performs). For instance, it can hardly be denied that the behavior of a pocket calculator is explained by the fact that it computes certain (mathematical) functions; or that the behavior of a robot mounting a wheel on a car's body causally depends on computing the appropriate trajectory from the location of the stack of wheels to the hub (note that in

this case, as well as in many others, the behavior itself is a computational process, rather than being the result of a computation). Of course, it is not always so apparent that the behavior of a system is determined by a computation. In the most interesting cases, human and animal cognition among them, it has to be argued that describing the behavior of a system as the result of a computational process has an explanatory pay-off (more on this below).

In computational *modeling*, instead, a computation *C* is used to describe the behavior of another system *S* under certain conditions. *C* allows to generate subsequent descriptions of *S*, but the explanation of *S*'s behavior is based on *S*'s properties, not on features of *C*. As *Piccinini* points out [43.14, p. 96]:

“the situation is fully analogous to other cases of modeling: just as a system may be modeled by a diagram or equation without being a diagram or equation in any interesting sense, a system may be modeled by a computing system without being a computing system in any interesting sense.”

In light of these definitions, neither computational explanation implies computational modeling nor computational modeling of (the behavior of) a certain system implies a computational explanation of it, even if, generally speaking, given a computational explanation it is possible to derive a computational model from it. This characterization of computational models, however, is scarcely interesting for our goals. In fact, when we say, as cognitive scientists, that the mind is a collection of information processing systems, we are committed to the most theoretically interesting sense of this claim, that is, that the appeal to computation *explains* intelligent behavior. We suggest, therefore, modifying the definition of computational modeling, in such a way that computational models in cognitive science are intended to be descriptions of genuine computational systems, in the above-specified sense. Accordingly, one reasonable definition could be the following: a system  $S^*$  is a computational model of a computational system *S* when there is at least partial isomorphism between the behavior of  $S^*$  and the behavior of *S* (or vice-versa), so that (the behavior of) one of the two systems can be said to represent (the behavior of) the other. The idea is that a computational system (= the model) is used to reproduce some relevant aspects of the behavior of another (alleged computational) system. In other words, computational modeling *presupposes* computational explanation insofar as, when one builds a computational model, he is assuming from the start that the modeled system or phenomenon admits a computational explanation (at a certain level of description).

Of course, this leaves aside the aforementioned difficult problem of establishing whether a certain system admits a computational explanation – whether the system is genuinely computational, to put it shortly. One should not be misled by this latter formulation: the issue is epistemological, not metaphysics. As said earlier, the point is whether there is an explanatory pay-off; there is no question of discovering an objective fact of the matter establishing that the behavior of an organism is determined by computations. Yet, this does not mean that everything (every phenomenon, even every *thing* on earth!) could be described as a computation, as John Searle famously claims, making in this way the notion of computation completely vacuous. We do not want to say that, for instance, a rock, or a gas, are computational systems just because their dynamics could be modeled by computations. In order to escape this consequence, different constraints have been proposed on what counts as a computational system. Just to mention two of them, there is the *semantic* constraint, according to which something is a computational system only if it manipulates *representations*; and there is the *mechanistic* constraint, according to which something is a computational system only if it is a functional mechanism of a special kind, that is, (roughly), it has a complex, multilayered organization apt to cause its behavior (cf. [43.15]; the notion of mechanism is presented in Sect. 43.1.4). Both the constraints play an important role in the discussion on computational explanation (see Sects. 43.1.4 and 43.2), yet from now on we shall take for granted that only *some* phenomena, among which at least some cognitive capacities and processes, admit a computational explanation, without addressing the problem of what are the appropriate constraints that a system must satisfy in order to be regarded as computational in a nonvacuous sense – i. e., without making all phenomena computational (for convincing replies to Searle, see, for example, [43.14–16], [43.17, Chap. 3]). In the second section, we shall discuss some difficulties faced by the claim that minds are computational systems.

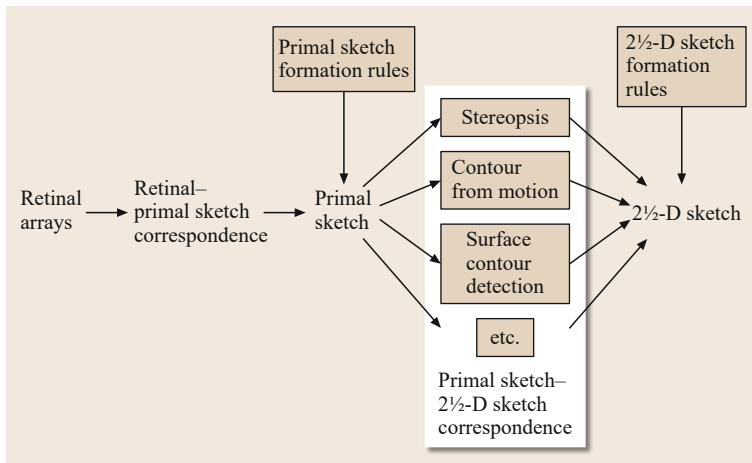

### 43.1.2 An Example of Computational Model

Computational models in cognitive science include at least classical symbolic models, that is, sequential algorithms working on data structures specified in some linguistic code, (artificial) neural networks, and artifacts-based models (robots). In order to give a concrete idea of computational modeling, here we present a classical symbolic model: Marr’s computational vision [43.18, 19]. Actually, what we are going to present is better to be called a computational *theory*, rather than a computational model; however, especially in light of

what we said in the previous section, the distinction is not much relevant. Indeed, Marr’s theory includes, as we shall see, a computational model. Our choice of Marr’s theory as an exemplar is motivated by three reasons. First, it has a formal, elegant definition and is extremely clear. Second, it is a paradigm case of (classical) cognitive science and third it provides an excellent starting point for the discussion in the following sections.

The target cognitive capacity of Marr’s theory is animal vision, more specifically a kind of vision typical of human beings and other superior animals. Vision is defined as a very complex computational system whose goal is to transform the pattern of light impinging retinas (the *input*) into a symbolic description of the observed scene (the *output*) – the collection of objects and properties present in the visual field of the observer.

Of course, this is an extremely complex task. For this reason, the task has to be decomposed in subtasks (each decomposable, in turn, in simpler tasks), so that we could say that each subtask is realized by a computational subsystem or mechanism (for the notion of mechanism, see Sect. 43.1.4). In particular, Marr identified three main subtasks: edge processing, surface processing, and object processing. Edge processing consists in the detection of strong variations of luminance. Luminance is the intensity of light in a retinal point. Therefore, a retinal image can be described as a function that associates to every point  $(x, y)$  of the retina its value of luminance. Surface processing consists in the determination, for each outgoing direction from the observation point, of the distance and orientation of the surface reflecting light in that particular direction. Object processing consists in the recognition of the (geometrical) shape of the objects present in the viewed scene. To put it simply, the first two processing stages or levels have the function of localizing an object, seen from a particular, egocentric, point of view (the observer’s perspective); the last stage has the goal of recognizing the object as an object possessing a certain shape. The shape is defined in an object-centered system of coordinates, that is, independently of the point of view. Each processing level produces an output, that is, a data structure containing the information relevant to the goal or function proper to that level. The output of the first stage is called *primal sketch*; the output of the second stage is called *2½-D sketch*; the output of the third stage (and of the whole system as well) contains one or more *three-dimensional (3-D) models*. As said earlier, each subtask admits further decomposition, not necessarily in serial tasks. Surface processing, for example, admits several *parallel* processing stages, each based on a different kind of information: shading, texture, movement etc. (Fig. 43.1).

**Fig. 43.1** The paths of information up to the  $2\frac{1}{2}$ -D sketch in Marr's architecture of the human visual system (after [43.20])

The first stage of processing occurs in the retina and the superior colliculus of human beings and other mammals. Its first product is the *raw primal sketch*, a description of the intensity changes in an image that is constructed using a primitive language of edge segments, bars, blobs, and terminations. From this, the *full primal sketch* is computed, namely a representation of the two-dimensional geometry of the field of view. The primal sketches of the visual fields of the two eyes are combined by the process of binocular fusion. The next stage in this process is the computation of the  $2\frac{1}{2}$ -D sketch, which represents the geometry of the surfaces visible to the observer – including their contours, depth, and orientation. Finally, the  $2\frac{1}{2}$ -D sketch is input to processes that construct the *3-D object-centered shape representation* that is vision's goal (Fig. 43.1).

What best qualifies Marr's model is another decomposition, vertical rather than horizontal. It is the idea that each task or subtask admits three different levels of description, all necessary in order to give an explanatorily adequate account of a given task or subtask: from the top, the computational level, the algorithmic level, and the implementation level. As we shall see, the articulation in a vertical collection of layers (the *stack*) is also a crucial characteristic of mechanistic explanations, which have indeed much in common with computational explanation (although they are not one and the same thing, see Sect. 43.1.4).

The computational level describes in the most general terms the *function* or cognitive task (or capacity) of the system to be modeled (and of its subsystems as well). This means providing a description of *what* the system does and what are the input and the output of the system. We already gave this specification for the entire system (the whole visual system) and for its immediate subsystems. Note that the individuation of the function is by no means easy, even at the highest level:

it cannot be taken for granted that the goal of vision – what the visual system does – is to individuate the (geometrical) shape of objects. Indeed many critics have pointed out that the function of the visual system, its basic goal, is allowing the agent to move effectively in the environment. Another important point concerns the vocabulary of the computational level. We could say that it is a macro-psychological, intentional vocabulary, in the sense that describes the mental capacities as relations between the agent and certain environmental properties (such as the surfaces present in the environment, or the shape of the object), and does not make use of any mathematical or (neuro)biological notions. At this level, the focus is on a certain capacity of an agent to do something in its environment.

The algorithmic level is what makes Marr's model specifically computational (despite his deserving the term *computational* to the upper level: Other, arguably better, labels for Marr's computational level have been proposed, such as *task level*, *project level*, *intentional systems level*.) Indeed, it is at this level that the programs that compute or realize functions postulated at the upper level are specified. For instance, the algorithm that processes edges (as we saw earlier, this is the first processing stage) is the Laplacian operator of the Gaussian function ( $\nabla^2 G$ ). Without entering in technical details, the idea is, intuitively, that a filter (the Gaussian one) is applied to the luminance function which describes the retinal image, and then the zero-points of the second derivative of the obtained image are calculated, since they correspond to the highest differences in luminance, namely to edges. For this reason, the algorithm is called *zero-crossing*. The role of the Gaussian filter is to *clean* the image, making more apparent the strongest bright/dark discontinuities.

Importantly, at the algorithmic level *representations* are also specified, that is, the input and the output of the

subsystem must be coded in a certain way in order to be manipulated by the algorithm. Other representations are also involved, since algorithms need further information to work successfully. Actually they embody certain assumptions on how the world is, which work as constraints restricting the space of the available solutions to the problem addressed by the algorithm. For instance, the visual system assumes that light comes always from above (although this could turn out to be false in a few cases).

Finally, the implementation (or hardware) level is constituted by the specification of the neural structures charged to execute the procedures specified at the algorithmic level. At the time Marr proposed his model (between 1976 and 1980), neuroscientific knowledge was not so developed, and the appeal to cerebral data in a model of a cognitive capacity was quite rare. Yet Marr proposed that the  $\nabla^2 G$  function is realized by off- and on-centred *X-cells* in the retina and lateral geniculate body, whereas some *simple cells* in striate cortex detect and represent zero-crossing segments [43.21, 22].

Thus, Marr was a pioneer of the current systematic attempt to integrate computational models with the specification of their neural implementation. Note that even though, strictly speaking, neural implementation is not part of the computational model, yet it is part of a mechanism that, taken as a whole, is computational (cf. Sect. 43.1.4). In other words, it is correct to say that the brain is a computational system, even if spelling out the computations performed by the brain is not something that can be done in a neurophysiological vocabulary.

Today, not only integrating computational models with brain data has become customary, but, often, brain data (neuropsychological and especially neuroimaging evidence) are even the starting point of the development of a computational model. We have here in mind what Zawidzki and Bechtel [43.23] call *interactive* view of explanation in cognitive neuroscience. On one hand, the functional knowledge obtained through psychological research allows us to identify the neural mechanisms, on the other hand the knowledge of structure is a heuristic guide to the development of more sophisticated psychological models [43.24]. In this context, *computational neuroscience* can be viewed as a *bridge* discipline between psychology and neuroscience which, on the one hand, puts bottom-up constraints on computational modeling, while on the other hand extends some principles of computational modeling to neuroscientific research, thus promoting the integration of neuroscientific theoretical constructs into computational psychology [43.25].

In the specific case of vision, a great impulse to the development of a neurophysiologically grounded com-

putational theory was the empirical discovery of two visual paths in the brain [43.26, 27], the *dorsal* one, which projects from the primary visual cortex (V1) to the parietal posterior cortex, and the *ventral* one, going from V1 to the infero-temporal cortex. This neurophysiological distinction grounds a corresponding functional distinction: the dorsal stream is associated with the visual control of action, having a *pragmatic* function, whereas the ventral stream realizes the identification of objects (*epistemic function*).

Based on this finding, Jacob and Jeannerod [43.28] put forward a dual computational model, one for each visual subsystem: the computational model of our capacity to identify objects, which is roughly based on a Marr's style architecture, and the computational model of our capacity to act effectively in the world, and specifically grasp objects, which is based on a sort of anticipatory scheme. The idea is that the dorsal stream codes (*represents*) only the pragmatically relevant features of the object, what J.J. Gibson called its *affordances* (i. e., the object's presenting itself as something that can be grasped, or can be filled, etc.), and processes this information so to produce, as output, a procedure that triggers the appropriate movement. The position of the object, which is crucial information in order to accomplish the task, is coded in a system of egocentric coordinates, namely relative to the axe of the body.

This should be enough to give an idea of what a computational model is. Now, in order to set the stage for the discussion of Sect. 43.1.4, concerning mechanistic explanation, it is worth to point out that, as Marr's example admirably shows, two important notions are closely related to computational models: the concept of *function* (as well as the related concept of functional explanation) and the concept of *module*. We address the former here in the following section and the latter will be introduced in the section that follows next.

### 43.1.3 Function and Functional Explanation

We saw that a certain cognitive ability is individuated in terms of its *function* (= the goal, what is for), and functions can be characterized as computations. Vision has (or is) the function of recognizing the shape of objects present in the visual field and in order to do that the visual system performs a certain I/O transformation: given as input retinal images in a certain description, it produces as output a symbolic description of the shapes present in the environment. In this sense, we could say that the notion of function involved in cognitive science is at the same time biological (more specifically, psychological) and mathematical (more specifically, computational). We have already explained what a com-

putation is; let us focus now on the biological notion of function and its importance for cognitive science.

In light of the analysis of the notion of cause predominant in the second half of the twentieth century, causally explaining a natural phenomenon amounts to subsuming it under laws (the so-called *nomological-deductive model*). In this *epistemic* perspective, causality is nothing over and above nomological regularity. However, philosophers of science see increasingly the nomological approach as inappropriate for special sciences like biology and psychology.

In most cases, the biologists' explanatory practices rest not on the concept of law, but rather on the notion of function. Mayr [43.29] has argued, however, that there are at least two ways of making biology – functional biology and evolutionary biology – which are very different from each other but co-exist and use different concepts and methods. In evolutionary biology, functions are conceived of in *etiological* terms, that is, they are characterized in terms of their history of natural selection (the *why* or *how come* question). Functional attributions are intended to account for the existence or maintenance of a trait in a given population, and functions are the effects of those traits that, by increasing fitness, have been favored by natural selection [43.30, 31]. In contrast, in anatomy and physiology the word *function* refers usually to the activities that an organism can perform, for instance, flying, digesting, finding viruses in one's own tissues, etc. Therefore, functional biology explains *how* organisms are able to do all that by means of what Cummins [43.32] termed *functional analysis*, where a certain capacity  $C$  is decomposed in a collection of (simpler) subcapacities  $S_1, S_2, \dots, S_n$ , in such a way that  $C$  emerges as a *programmed manifestation* of the exercise of  $S_1, \dots, S_n$ . In this context, the function of a trait is seen as the contribution that it makes to a given capacity of the system incorporating it. Such a contribution is termed *causal role function*. A causal role function is nonhistorical, that is, it ignores evolutionary history. The heart's function is pumping blood not by virtue of its history of natural selection, but because it is a part of a larger system, the circulatory system, in which it plays a crucial causal role. It is to be noticed, however, that in this case the causal-role function of a trait coincides with its etiological function – the heart pumps blood, and that is what it was selected to do. In other cases, the two kinds of functions diverge: it is very likely that birds' feathers evolved as a mechanism for regulating body temperature but their causal-role function is what they make for their owner in the present and in the future, namely to make flight possible [43.33, p. 223].

The distinction between causal role and etiological functions is also relevant for the philosophy of cognitive

science, since it may impart a different trajectory, internalist or externalist, to a *functionalist* theory of mind. Functionalism is indeed a very influential philosophical theory (or family of theories) concerning the nature of mental phenomena. At least in one of its versions, it is closely linked to computational explanation.

Functionalism is first and foremost a metaphysical theory, which characterizes psychological states according to the causal roles they play in a system (i. e., an agent's inner life), independently of how such roles are physically realized; or equivalently, the identity of a certain type of psychological state is established by the causal relations it entertains with stimulus input and behavioral outputs, as well as with other psychological (i. e., functional) and nonpsychological internal states of the system [43.34]. Putnam's [43.35, papers 16–21] formalization of functionalism via the theory of effective computability gave rise to an early version of computational functionalism, known as *machine functionalism*.

Machine functionalism was challenged on several fronts. For one thing, "it still conceived psychological explanation in the logical positivists' terms of subsuming observed data under wider and wider universal laws" [43.36, pp. 53–54]. However, Fodor [43.37], Dennett [43.38], and Cummins [43.39] noticed that psychology, like biology, does not traffic with nomological explanations, which are predictive tools based on laws; rather, psychological explanations are functional analyses in Cummins' sense [43.40, 41]. This explanatory practice has also been defined by decomposition, by identifying *homunculi*, by reverse engineering, by taking the design stance, by describing the articulation of parts, and by discovering mechanisms. As Craver [43.42, p. 107] suggests, these definitions can all be seen as contributions to a theory of *mechanistic explanation* (see Sect. 43.1.4 *Mechanisms and Mechanistic Explanation*).

In the *homuncular* version of functional analysis [43.38, 43, 44], behavioral data are manifestations of the complex cognitive capacities of an agent (vision, memory, face recognition, etc.); and those capacities are to be explained by assuming that an agent is a system of interconnected, hierarchically organized components. Every component (or module) is a *homunculus*, that is, an intelligent mechanism that is individuated by means of the function it performs; and swarms of homunculi cooperate with each other in such a way as to produce the overall activity of the system. The homunculi are in turn seen as teams of simpler homunculi, whose functions and interactions are similarly used to explain the capacities of the subsystems that they compose; and so on, *recursively*, until the sub-sub-... components turn out to be simple

neuroanatomical structures [43.45, p. 320]. Marr's computational theory of vision is an exemplar of functional analysis in cognitive science.

Another flaw in machine functionalism lies in its conception of the *functional realization* (the relation between an organism and the abstract program that it is supposed to instantiate) as a simple one-to-one correlation between the organism's repertoire of physical stimuli, inner states and behavioral responses, on the one hand, and the inputs, states and outputs specified by a machine table on the other. This criterion of realization, though, is too *cheap*: since virtually anything bears a one-to-one correlation of some sort to virtually anything else, *realization* in the sense of one-to-one correspondence is far too easily come by [43.46, Chap. 4]. To put this defect right, Lycan [43.43, 44] and Millikan [43.31] have imposed a *teleological* constraint on realization: a physical state of an organism will count as realizing a certain functional description only if the organism has genuine organic integrity and the state properly plays its functional role *for* the organism. The state must do what it does because this is its biological purpose. In this perspective, psychological functions are biological functions in the etiological sense, that is, effects that are promoted by natural selection.

The etiological notion of function implies environmental constraints. Here it can be useful to draw a distinction between *narrow* and *wide* function [43.47]. *Narrow* functional analysis only looks at the system as such. The function boils down to the causal role that a property plays in the *internal* economy of some system, which consequently is insulated from the *extra-cranial* environment where it is situated [43.48]. Famously, Fodor [43.49] has argued that narrow functional analysis is the only admissible form of functional analysis. According to the Fodorean *methodological solipsism*, psychological explanations should be restricted to quantifying over the formal, *intrinsic* properties of mental states, unlike the *naturalistic* psychology (exemplified by James' naturalism, learning theory, and Gibson's ecological optics), in which generalizations are defined by the relations between mental representations and their environmental, *extrinsic* causes – a research strategy, Fodor warns, that will hardly turn out to be fruitful.

In contrast, *wide* functional analysis refers to the extra-cranial environments in which an organism is situated, and it involves teleological functional considerations about the relationship between the organism and its environment. Pace Fodor, Harman thinks that “only a wide psychological functionalism can motivate appropriate distinctions between aspects of a system, irrelevant side effects and misfunctions” [43.50, p. 20]. This teleological notion of functional analysis leads us

to look beyond the mental apparatus as such to the way it deals with its environment.

Despite the fact that the first generation of research in cognitive science has largely adopted (at least implicitly) narrow functional analysis during last three decades, cognitive scientists have shown growing impatience against the idea that the scientific study of an individual's psychological states is required to abstract from all the environmental, extrinsic variables, to take into consideration only the *intra-cranial*, intrinsic properties of those states. Various factors contributed to this change of climate, including the rising success of Putnam's and Burge's semantic externalism, Searle's and Dreyfus' classical criticism of symbolic artificial intelligence, the consolidation of Gibson's influence in cognitive psychology. In this framework, research programs very different from each other – for example, the sensorimotor (or enactivist) approach to perceptual experience, situated robotics, and dynamic approach to cognition – have endorsed an *externalist* conception of explanation according to which biological cognition cannot be understood without taking into consideration its embodied and situated nature (see Sect. 43.2.2 *Active Externalism*).

#### 43.1.4 Computational Models and Mechanistic Explanations

##### Mechanisms and Mechanistic Explanation

Another serious shortcoming of machine functionalism is the extreme biological implausibility of its *two-level* view of human psychobiology. As Lycan [43.44, Chap. 4]; [43.45, p. 320] has incisively argued, neither living things nor even computers can be split into a purely structural level of neurobiological/physiochemical (in the case of computers: electronic) description and an abstract level of cognitive-algorithmic description. Rather, organisms and computers are hierarchically organized at many levels, where each level is *abstract* with respect to those beneath it but *structural* or concrete as it realizes those levels above it. The functional/structural or software/hardware distinction is entirely relative to one's chosen level of organization. In brief, Lycan concludes, “nature is functions all the way down” [43.44, p. 48].

This emphasis on the hierarchical organization of functional levels has been worked out by Craver [43.42], which represents a synthesis between Cummins' theory of causal-role functions and the thriving literature on mechanisms and mechanistic explanation.

The mechanistic explanation of a phenomenon consists in the specification of the mechanisms that produced it. But what is a mechanism, exactly? Accord-

ing to Machamer et al. mechanisms are “entities and activities organized such that they are productive of regular changes from start or set-up to finish or termination conditions” [43.51, p. 3]. These systems have a spatiotemporal organization that explains the way they realize their activities. One example, taken from Craver [43.52, 53], is the mechanism of the action potential. Here the entities are the axonal membrane, the  $\text{Na}^+$  and  $\text{K}^+$  ions, and two types of voltage-dependent ionic channels that allow  $\text{Na}^+$  or  $\text{K}^+$  ions, respectively, to spread through the membrane. Membrane, ions, and ionic channels regularly act and interact to produce the action potential. These activities essentially depend on the *spatial* organization of the mechanism’s components (e.g., ionic channels span the membrane, thus producing ion fluxes across it); but still more crucial is *temporal* organization: the shape of the action potential is explained by the relative orders and durations of the activation and inactivation of ionic channels (Fig. 43.2).

Moreover, mechanisms are intrinsically organized in multilayers, that is, they are involved in a hierarchical organization in which lower level entities and activities are the components of higher level entities and activities. Therefore, a mechanism is a hierarchically organized (to produce a certain goal or behavior) system, and a mechanistic explanation is usually, if not always, multilayered. Following Craver [43.42, 54], we can say that an *ideally complete* mechanistic explanation describes a mechanism by integrating three perspectives. The *isolated* perspective (level 0) describes the mechanism at its proper, characteristic

level. It is an ordinary causal explanation describing the input–output relations of the mechanism. The *contextual* perspective (level +1) locates the mechanism in the context of another mechanism, being the former a part of the latter; this means that the activities of the former contribute to the working of the latter. Finally, the *constitutive* perspective (level –1) breaks down the mechanism in its constitutive parts in such a way that we can understand how these parts enable the input–output relations of the mechanism defined at the level 0. Mechanistic explanation is thus aimed at integrating levels of mechanisms. However, ideally complete mechanistic integration is hard to attain, and ideally complete mechanistic explanations are correspondingly rare [43.52, p. 360]:

“Models that describe mechanisms can lie anywhere on a continuum between a mechanism sketch and an ideally complete description of the mechanism. [...] A mechanism sketch [...] characterizes some parts, activities, and features of the mechanism’s organization, but it has gaps. [...] At the other end of the continuum are ideally complete descriptions of a mechanism. Such models include all of the entities, properties, activities, and organizational features that are relevant to every aspect of the phenomenon to be explained. Few if any mechanistic models provide ideally complete description of a mechanism.”

To provide an example of this quest for the integration of levels of mechanisms, Craver [43.42] examines the development of the explanations of long-term potentiation (LTP) and spatial memory. He distinguishes at least four levels (Fig. 43.3a). At the top of the hierarchy (the behavioral-organismic level) are memory and learning, which are investigated by behavioral tests. Below that level is the hippocampus and the computational processes it is supposed to perform to generate spatial maps. At a still lower level are the hippocampal synapses inducing LTP. Also finally, at the lowest level, are the activities of the molecules of the hippocampal synapses underlying LTP (e.g., the *N*-methyl D-aspartate receptor activating and inactivating). These are mechanistic levels: the *N*-methyl D-aspartate receptor is a component of the LTP mechanism; LTP is a component of the mechanism generating spatial maps, and the formation of spatial maps is a part of the spatial navigation mechanism. Integrating these four mechanistic levels requires both a *looking up* integration, which will show that an item (LTP) is a part of an upper level mechanism (a computational-hippocampal mechanism); and a *looking down* integration, which will describe the lower level mechanisms underlying the

**Fig. 43.2** The action potential consisting of (I) a rapid rise in  $V_m$  to a maximum value of roughly +35 mV, followed by (II) a rapid decline in  $V_m$  to values below  $V_{rest}$ , and then (III) an extended after-potential during which the neuron is less excitable (known as the refractory period) (after [43.42])

**Fig. 43.3a,b** Levels of spatial memory (a). Integrating levels of mechanisms (b) (after [43.42])

higher level phenomenon (the molecular mechanisms of LTP) [43.42, 55, 56] (Fig. 43.3b).

Note that providing a mechanistic explanation of a certain phenomenon (capacity, system) is giving a certain type of *causal* explanation, since searching for mechanisms is searching the effective cause of a certain behavior. This is a much important point, since, on this perspective, mechanistic explanation confronts nomological explanation. Although it could be argued that there is some relationship between laws and causes (consider that it is not rare to hear that causal relations are instantiations of laws), from the point of view of the explanatory style mechanistic explanations do not involve laws. (For a recent discussion of the issue see [43.57].) We will come back later on the significance of this opposition.

### The Relation Between Mechanisms and Computational Models

Recently the notion of computational model has been embedded in the larger explanatory framework of mechanistic explanation. But what is, exactly, the relation between mechanisms and computational models? The relation is twofold. On one hand, mechanisms are physical systems that implement, or realize, computa-

tions. On the other hand, a computational model can be one among the multiple levels of organization that constitute a mechanistic explanation [43.14, 17]. For example, the above-mentioned computational process that hippocampus is supposed to perform to generate spatial maps. With regard to the first aspect, to the extent that mechanisms provide the nexus between abstract computations and concrete physical systems, they ground the notion of computation. The second aspect focuses instead on the issue of explanatory styles, subsuming computational explanation under the larger class of mechanistic, and thus causal, explanations.

To sum up, computations are realized by mechanisms, that is, if we give a computational explanation of a certain phenomenon or ability, there must be a mechanism – a system that admits a mechanistic description – which realizes or performs the computation. Also since computational systems may be articulated in several levels, as we have seen in the case of Marr’s model, it seems appropriate to say that a computational model is a complex part of a mechanistic explanation (and, correspondingly, a computational system is a certain kind of mechanism, usually a part of a complex mechanism).

Even if there are computational models that are defined with no reference at all to mechanisms (as it was

customary in classical cognitive science, since a full-blooded account of mechanistic explanation has been provided only about 15 years ago), we hold that computational models are always mechanistic too, since computational explanation is essentially mechanistic. It is mechanistic because the fundamental features of mechanistic explanations – entities realizing functions, components etc. – are saved in computational models (for a slightly different point of view, see [43.17]). This is one of the reasons to believe that computational models, *qua* mechanistic, can hardly be integrated with dynamical models (see Sect. 43.1.5).

### 43.1.5 Dynamical Systems

Neural networks and classical models are all computational models. Arguably, the same cannot be said for dynamical systems, at least if we consider them from the perspective of the explanatory style.

Dynamicism consists essentially in applying to behavior and cognition methods from the theory of nonlinear dynamical systems theory. A dynamical system is a physical system whose behavior is described by a set of differential equations. *Nonlinear* means that, given the initial conditions and the equations, the target behavior of the model cannot be analytically determined (except for some particular cases) and will be predicted only with a certain approximation. For instance, even once fixed the initial conditions, the system could evolve in two or more different states.

The dynamical approach focuses on the time evolution of a system, and seems particularly well equipped to deal with cases in which a system or a component of a system *A* constantly influences and is constantly influenced by another system or component *B* (which could in turn be sensible to another component *C*, and so on). Take, for instance, a tennis player who is going to reply the service: here the locations of the ball and of the other player change continuously and, at the same time, the player moves and acts, influencing in turn the other player, and so on so forth [43.58, p. 348]. In sum, “[e]verything is simultaneously affecting everything else” [43.59, p. 23]. These events, which are strictly *coupled*, appear to be difficult to model with the tools of classical computational models.

Let us examine an often-cited example of dynamical analysis [43.60, Chap. 2]. In one experiment, the subjects were asked to oscillate their index fingers back and forth with the same frequency in each finger. The oscillation could be in-phase (homologous muscle groups contracting simultaneously) and antiphase (homologous muscle groups contracting in an alternating fashion). At high frequencies of oscillation, however, the antiphase movement is unstable and at a critical frequency subjects spontaneously switch from the antiphase motion of the fingers to an in-phase symmetrical pattern.

A dynamical analysis of this pattern of results begins with plotting the phase relationship between the two fingers. This variable (= the relative phase) is constant for a wide range of oscillation frequencies but is subject to a strong shift at a critical value, namely, the moment of the antiphase/phase shift. Plotting the unfolding of the relative phase variable is plotting the values of a *collective variable*, that is, one whose value is set by a relation between the values of other variables (the ones describing individual finger motions). The values of these collective variables are fixed by the frequency of motion, which thus acts as a so-called *control parameter*. The dynamical analysis consists therefore in a set of equations displaying the space of possible temporal evolutions of relative phase as governed by the control parameter. This description fixes, in detail, the so-called *state space* of the system. In this framework, the collapse of the antiphase pattern of coordination into the phased one can be construed as the transition from a *landscape* where there are stable attractors for both patterns of coordination to one in which there is a stable attractor only for the in-phase motion. The dynamical analysis turned out to be very useful also in understanding the activity of simple robots [43.61] and the development of infant locomotion [43.62].

Although there are scholars who regard dynamical systems as a class of computational systems, essentially because differential equations are computable (and are a way to compute as well), we take dynamical models as an *alternative* to computational models, since the former are usually brought to bear in nonmechanistic explanations. We will discuss more extensively this issue in the next section.

## 43.2 Open Problems in Computational Modeling

In this section, we will take into consideration two different kinds of problem faced by modeling in cognitive science. The first problem concerns the scope of computational explanation and has specifically to do with its capacity of accounting of the so-called *central processes*. The second problem concerns the feasibility of integrating different styles of explanation.

### 43.2.1 Computationalism and Central Cognition

#### The Problem of the Central Cognition

Jerry Fodor's Computational and Representational Theory of Mind (CRTM) is one of the most important and, at the same time, controversial systematizations of computational functionalism. Among its virtues is a powerful response to Skinner's objection against the mentalistic explanation in psychology, the *homunculus fallacy*. This is a vital constraint on *any* serious mentalistic psychology: a plausible theory of cognition must avoid the infinite regress triggered by the attempt to explain a cognitive capacity by tacitly positing an internal agent with that very capacity. To discharge all the homunculi CRTM combines two ideas:

- *Formality condition*: The rules that govern the state transitions in a computational system are sensitive only to the *form* of representations, namely to their syntactic properties, whereas they are insensitive to the semantic ones.
- *Recursive decomposition*: Complex capacities are structured ensembles of much simpler capacities. Thus CRTM endorses the already-mentioned recursive decomposition of complex cognitive capacities into co-operating ensembles of simpler capacities.

Jointly, these two ideas ensure that a computational theory of cognition begs no questions. The theory *explains* intelligent agency rather than *presupposing* intelligent agency. For the formality condition guarantees that the elementary operations of a computational theory do not presuppose intelligence (do not involve *interpretations*); and the recursive decomposition guarantees that all cognitive functions are ultimately explicable by these elementary operations [43.63].

Is it really feasible to combine the formality condition with the recursive decomposition? In other terms, can the parts or modules into which the functionalists decompose the mind work as engines that satisfy formality condition? To answer this question, we need to distill from the heterogeneous collection of definitions of *module* and *modularity* those relevant to

our issue. For example, when many psychologists and philosophers speak of modules, they intend to refer to functionally individuated psychological systems. But then, *Fodor* justly notes, “everybody who thinks that mental states have any sort of structure that’s specifiable in functional terms qualifies as a modularity theorist in this diluted sense” [43.64, pp. 56–57]. It is therefore advisable to ascribe to the term a less diluted sense on pain of vacuity.

The first stronger sense of *module* is an epistemic one. A module is a *body of cognized information* – in Chomsky’s linguistics, the tacit beliefs of a speaker/hearer who masters the grammar of her own language, namely the principles of universal grammar, plus a choice of parameter values, plus a lexicon. Moreover, this psychological structure is *domain specific*, that is, it is dedicated to solving a restricted class of problems in a restricted content domain. By contrast, a *domain-general* or *general-purpose* psychological structure is one that can be used to do problem solving across many different content domains.

A knowledge base, however, cannot give rise to behavior through its propositional content alone. Mechanisms are necessary “to bring the organization of behavior into conformity with the propositional structures that are cognized” [43.65, p. 9]. If this mechanism is designed to compute only a restricted class of inputs (i. e., representations of the properties and objects found in a particular domain), we get a “vertical faculty,” namely a domain-specific computational mechanism. For example, the systems that compute the phonological analysis of speech are domain specific in that they operate only upon acoustic signals that are taken to be utterances: “[T]he very same signal that is heard as the onset of a consonant when the context specifies that the stimulus is speech is heard as a *whistle* or *glide* when it is isolated from the speech stream” [43.65, p. 49].

In some domains, a domain-specific computational mechanism and an *epistemic* module can form a single mechanism. For example, it may be supposed that a syntactic parser is a domain-specific computational mechanism that takes as input sensory (e.g., acoustic) representations of utterances and, in virtue of a database dedicated to linguistic information, delivers syntactic and semantic representations of physical sentence forms. It is important to note, however, that in other domains *general-* rather than specific-domain algorithms could employ domain-specific bodies of information. (See Sect. 43.2.1 *The Massive Modularity Hypothesis*.) A *Fodorean* module is precisely such a mechanism – a domain-specific innately specified processing system with an innately specified epistemic module as its pro-

proprietary database. Moreover, it has its own proprietary transducers; delivers *shallow* (nonconceptual) outputs; it is mandatory in its operation, swift in its processing, associated with particular neural structures, liable to specific and characteristic patterns of breakdown, and developed according to a paced and distinctively arranged sequence of growth.

The most important aspect of such a system, though, is that its information exchanges with other systems are architecturally constrained. First, the *central* cognitive processes (such as belief fixation and practical deliberation) can access only the output representations of the *macromodules* (= modules composed by *micromodules*). Consequently, the intermediate representations generated by the micromodules are *inaccessible* to central cognition. Second, Fodorean modules are isolated from the rest of cognitive system in that they are *informationally encapsulated*. This means that a module works by employing only its proprietary database, without any appeal to the more general knowledge available to the rest of cognition. Marr (and more recently Pylyshyn [43.66, 67]) thought that early vision mechanisms were informationally encapsulated; Fodor extends this idea to any peripheral input and output system – including audition, face-recognition, language-processing, and various motor-control systems.

Now, Fodor [43.64, 65, 68] rejects the idea that the entire human cognition is modular. For what he intends as *central cognition* are processes such as belief fixation and practical deliberation, as they are described in personal-level propositional attitude psychology. Also intentional psychology is distinctively flexible and nonmodular, as is shown by an analogy between the processes that lead to the formation of beliefs and the type of nondemonstrative inference that is characteristic of the confirmation of hypotheses in science. (Fodor's analogy is rejected by Carruthers [43.69] and Pinker [43.70]). Like scientific confirmation, central cognition is characterized by two properties: it is *isotropic*, in the sense that “in principle, any of one's cognitive commitments (including, of course, the available experiential data) is relevant to the (dis)confirmation of any new belief” [43.68, p. 115] and it is *Quinean*, in the sense that central systems compute over properties like simplicity, centrality, conservatism, which are fixed by the global structure of belief system. But if the central systems are Quinean/isotropic, then they are not encapsulated – processes of belief formation need to have free access to the whole belief system.

Fodor's claim that the architecture of the mind is mostly *non-modular* has very bleak implications for CRTM and computational psychology. The formality condition says that the rules that govern the state transi-

tions in a cognitive system are sensitive only to the *form* of representations, namely to their syntactic properties, whereas they are insensitive to the semantic ones. Here an analogy with a logical calculus holds: the form of the proposition  $P$  and  $Q$  is entirely a matter of the identity and arrangement of its parts; and this is everything one must know to infer that the proposition is true if and only if  $P$  and  $Q$  are both true – namely it is not necessary to know anything about either the meaning of  $P$  or  $Q$ , or the extra-linguistic world. Therefore, syntactic properties are *local* properties of representations, that is, “they are constituted entirely by what parts a representations has and how these parts are arranged. You don't, as it were, have to look ‘outside’ a sentence to see what its syntactic structure is, any more than you have to look outside a word to see how it is spelled” [43.64, p. 20]. In other terms, from the formality condition, which requires computations to be sensitive only to the form of representations, follows the *locality principle*, according to which computations work only upon the local properties of representations.

In the modular processes, it is encapsulation that assures the respect of the locality principle: for the computations of an encapsulated module are supposed to access only the information in the proprietary database, ignoring all other information held in the mind. However, central processes do not satisfy the locality condition, being isotropic and Quinean; consequently, they are not computationally tractable processes. In other terms, they face what is sometimes known as *the frame problem*.

### The Massive Modularity Hypothesis

In order to deal with Fodor's problem of the computational intractability of central cognition some cognitive scientists have pursued the *massive modularity hypothesis* (MMH), which is the core of evolutionary psychology, a research program in cognitive science that aims to combine computationalism, nativism, and adaptivism. Instead of a picture of domain-specific encapsulated modules feeding into a domain-general propositional attitude system, MMH portrays the mind as a swarm of overlapping *Darwinian* modules of varying degrees of specialization and domain specificity. Such systems are innate computational modules that take epistemic modules as their databases, and are the product of natural selection. The latter is their characteristic mark: they are adaptations, that is, cognitive mechanisms shaped by the forces of evolution to solve major problems posed in ancestral environments (foraging, avoiding predation, finding shelter, co-ordinating with others, choosing mates, etc.).

According to MMH, then, Fodor's problem of the huge informational load on the central cognition is the

result of misdescribing human cognitive capacities. The problem does indeed show that an intelligent general-purpose agent could not be thinking by computing. However, we are not such agents; our mind is a complex structure of Darwinian modules. This view avoids Fodor's problem of central cognition by rejecting the picture of a central functional arena where the contents of an agent's propositional attitudes are stored, processed, and poised for the control of behavior.

However, legitimate doubts have been raised about the empirical evidence offered in favor of MMH. *Samuels* [43.71], for example, pointed out three kinds of difficulties of the empirical arguments for MMH:

1. The supposed evidence for the existence of Darwinian modules can often be explained in terms of other less specific mechanisms. For example, it has been objected that the content effects in Wason's selection task are not cogent evidence for the existence of a module – the “social-cheater” mechanism – that would be specific to the domain of social reasoning, since they can be more plausibly explained in terms of general mechanisms of verbal understanding [43.72].
2. Even when there are data that suggest the existence of a specialized cognitive structure in a given domain, it is arduous to establish whether it is a computational module or an epistemic one. For epistemic modules can be easily integrated in a theory of central processing in which different corpora of knowledge are computed by a few nonmodular mechanisms. This point is very well illustrated by the debate on folk biology. As *Samuels* [43.71, p. 46] has rightly noticed, the problem here is that the main evidence for folk biology does not allow us to adjudicate between the domain-specific hypothesis [43.73] and the general-domain one [43.74]. All that it allows us to claim is that folk biology needs a dedicated and (perhaps) innate cognitive structure; but this, of course, is not enough to demonstrate the existence of a Darwinian module for folk biology.
3. Even when some robust evidence for computational modules is available, it is very hard to determine whether their domain of application is really central cognition. For example, the evidence for a computational module specialized in processing geometrical information [43.75] does not support MMH since it can be plausibly viewed as part of vision or visuomotor control [43.66]. The same holds for what is considered a strong candidate for central modularity, viz. Leslie's Theory of Mind Mechanism (ToMM). That ToMM is evidence for central modularity is highly controversial, mainly in the light of *Leslie's* most recent work, where ToMM

is viewed as a relatively low-level mechanism of selective attention [43.76], whose functioning rests on nonmodular executive systems like the selection processor.

### Narrowing the Scope of Central Processing

The difficulties afflicting the empirical arguments for MMH invite us to be very cautious about taking it as a *complete* account of human cognitive architecture. The most we can argue is that there are a number of domain-specific and/or encapsulated central systems, but there are also nonmodular (domain-general and unencapsulated) central systems as well.

In light of this, *Bermúdez* [43.77] argued that the interesting point about (this weaker form of) MMH is the suggestion that the role of propositional attitudes in human cognition has been overstated. MMH leads us to rethink the traditional nexus between intelligent behavior and propositional attitudes, realizing that much social understanding and social coordination are subserved by mechanisms that do not capitalize on the machinery of intentional psychology. The latter does not rule all social interactions; it is used far less frequently than is commonly assumed in philosophy of mind. In this perspective, MMH goes in the right direction since it narrows the scope of central processing, thus outlining [43.77, p. 242]:

“the possibility of more or less direct links between perception and action that are sophisticated enough to be characterized as forms of intentional behavior, and yet that do not engage the propositional attitude system.”

Emphasis on belief/desire as the source of action is strictly related to the endorsement of what can be called *the sandwich model of the mind* [43.78], whereby perception and action are systematically mediated by the central cognition layer. Central cognition is the sandwich filling: according to the sandwich model, perception yields beliefs, and these, in turn, trigger actions. The separation between the three layers, in particular between perception and cognition, is taken to be very neat, especially if the model is coupled (as often is) with the Fodorean view of modularity, according to which only perceptual systems are modular.

Therefore, if one rejects the sandwich model, beliefs and desires may no longer be considered as the unique causes of action. There are other mechanisms, not located at the level of folk psychology, which can explain action. These mechanisms, however, are not only the Darwinian modules. For instance, a mechanism of emotional sensitivity such as *social referencing* is a form of *low-level* mindreading that subserves social understanding and social coordination without in-

volving the attribution of propositional attitudes. Here Bermúdez is on the same wavelength as mental simulation theorists and social neuroscientists in drawing our attention to forms of *low-level* mindreading that have been largely neglected by philosophers. However, he goes a step beyond them and explores cases of social interactions that point in a different direction, that is, situations that involve mechanisms that can no longer be described as mindreading mechanisms. He offers two examples.

In game theory, there are social interactions that are modeled without assuming that the agents involved are engaged in explaining or predicting each other's behavior. In social situations that have the structure of the iterated prisoner's dilemma, the so-called *tit-for-tat* heuristic simply says: "start out cooperating and then mirror your partner's move for each successive move" [43.79]. Applying this heuristic simply requires understanding the moves available to each player (cooperation or defection), and remembering what happened in the last round. So here we have a case of social interaction that is conducted on the basis of a heuristic strategy that looks backward to the results of previous interactions rather than to their psychological etiology. We do not need to infer other players' reasons; we only have to coordinate our behavior with theirs.

There is another important class of social interactions that involve our predicting and/or explaining the actions of other participants, but in which the relevant predictions and explanations seem to proceed without us having to attribute propositional attitudes. These social interactions rest on what social psychologists call *scripts* (*frames* in artificial intelligence), that is, complex information structures that allow predictions to be made on the basis of the specification of the purpose of some social practice (e.g., eating a meal at a restaurant), the various individual roles, and the appropriate sequence of moves

According to Bermúdez, then, much social interaction is enabled by a suite of relatively simple mechanisms that exploit purely behavioral regularities. It is important to notice that these mechanisms subserve *central* social cognition (in Fodor's sense). Nevertheless, they implement relatively simple processes of template matching and pattern recognition, that is, processes that are paradigmatic cases of perceptual processing. For example, when a player *A* applies the tit-for-tat rule, *A* must determine what the other player *B* did in the preceding round. This can be implemented in virtue of a template matching in which *A* verifies that *B*'s behavioral pattern matches *A*'s prototype of cooperation and defection. Moreover detecting the social roles implicated in a script-based interaction is a case of template matching: one verifies whether the perceived

behavior matches one of the templates associated with the script (or the prototype represented in the *frame*).

Bermúdez notes that the idea that much of what we intuitively identify as central processing is actually implemented by mechanisms of template matching and pattern recognition has been repeatedly put forward by the advocates of the connectionist computationalism, especially by Paul M. Churchland. But unlike the latter, Bermúdez does not carry the reappraisal of the role of propositional attitudes in social cognition to the point of their elimination. For he argues that social cognition does not involve high-level mindreading when the social world is *transparent* or *ready-to-hand*. However, when we find ourselves in social situations that are *opaque*, that is, situations in which all the standard mechanisms of social understanding and interpersonal negotiation break down, it seems that we cannot help but appeal to the type of metarepresentational thinking characteristic of propositional attitude psychology.

### The Global Workspace Approach to Central Processing

To the extent that Bermúdez leaves room for forms of social interactions involving that type of metarepresentational thinking characteristic of propositional attitude psychology, he only made Fodor's problem of central cognition less pressing. The architecture for what is left of our central processing still consists in a freely accessible cognitive realm, or central arena, in which attitudes of all types can become active and enter in processes of reasoning and thinking. According to Carruthers [43.80], however, the evidence from cognitive science allows us to hold that there is not such an arena.

Carruthers's claim rests on the validity of a global workspace account of the conscious accessibility of our perceptual experiences. There is now extensive evidence supporting such models [43.81–87]. Moreover, subsequent analyses of functional connectivity patterns in the human brain have demonstrated just the sort of neural architecture necessary to realize the main elements of a global broadcasting account [43.88, 89]. Specifically, these studies show the existence of two main neurocomputational spaces within the brain, each characterized by a distinct pattern of connectivity.

The first space is a processing network, composed of a set of parallel, distributed, and functionally specialized processors or modular subsystems subsumed by topologically distinct cortical domains with highly specific local or medium-range connections that encapsulate information relevant to its function.

The subsystems compete each other to access the global neuronal workspace, which is implemented by long-range cortico-cortical connections, mostly originating from the pyramidal cells of layers 2 and 3 that are

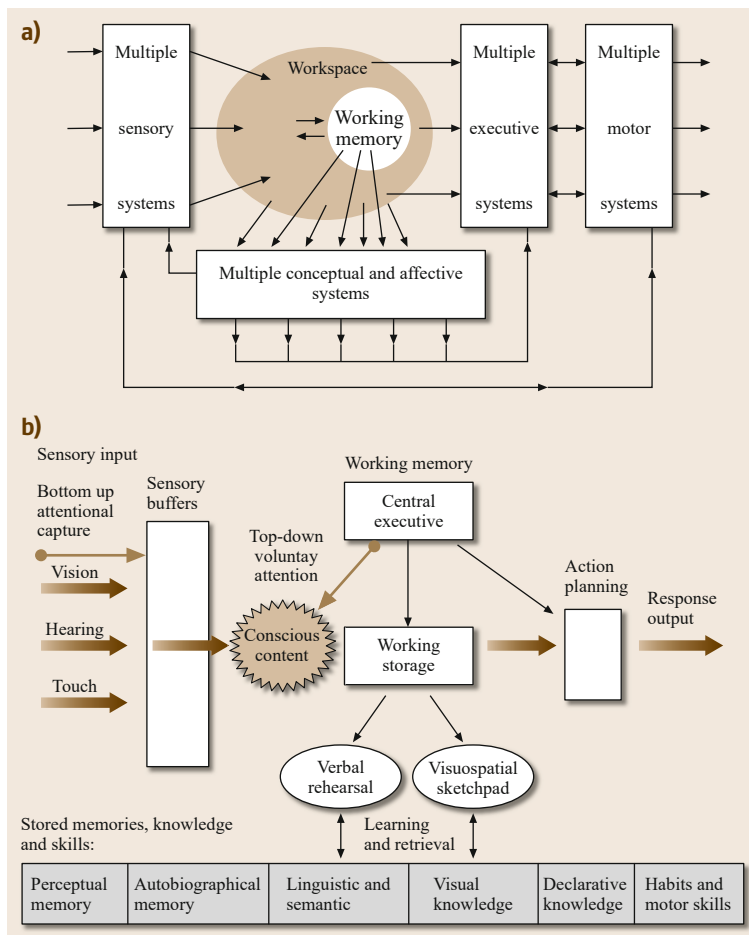

particularly dense in prefrontal, parieto-temporal and cingulate associative cortices, together with their thalamo-cortical loops. When one of these subsystems accesses the global neuronal workspace, its outputs (i. e., sensory information including perceptions of the world, the deliverances of somatosensory systems, imagery and inner speech) are broadcast to an array of specialized executive, conceptual, and affective consumer systems – for example, systems that consume the perceptual input to form judgments or make decisions (Fig. 43.4a).

Global broadcasting makes possible the development and subsequent benefits of a working memory system which exploits the mechanisms of global broadcast to subserve a wide variety of central cognitive purposes [43.90–92] (Fig. 43.4b). So there is, indeed, a central arena in the mind; but this is working memory. And what can be found within working memory are not propositional attitudes, but rather imagery, inner speech, and so forth; working memory’s operations are always sensory based.

Thus, a global broadcast architecture arranges in parallel specialized conceptual systems around the global broadcast of attended perceptual information, and makes entry into a general-purpose working memory system competitive. Such design features seem to enable us to circumvent many aspects of Fodor’s scepticism about being central cognition amenable to computational modeling [43.89, 93, 95, 96].

### 43.2.2 The Dynamicist Challenge: Is Integration Possible?

As mentioned in Sects. 43.1.4 and 43.1.5, dynamicism can better be regarded as a research paradigm alternative to mechanicism, therefore to computationalism too. In this connection, a standard reference is *van Gelder and Port* [43.59], which was the first major presentation of the dynamical approach to cognition. According to the authors, “to see that there is a dynamical approach is to see a new way of conceptually reorganizing cognitive

**Fig. 43.4** (a) Global broadcast and working memory (after [43.93]). (b) A functional framework for attention and conscious events (after [43.94])

science as it is currently practiced” [43.59, p. 4]. Such a reorganization takes a stand against not only classical computationalism but also the connectionist one – and this despite the fact that connectionists were the first to apply the dynamical systems theory to the study of cognition. However, van Gelder and Port argue, the limit of connectionism lies in the use of the dynamical systems tools within a paradigm that is still the computationalist and representationalist one, even though in a brain-like variant. The dynamicist wants to go beyond.

First, the dynamicist dissolves the boundary between the cognitive system and the system’s environment. Coupling between the equations describing a cognizing system and those describing the environment gives rise to complex *total system* behaviors. In this perspective [43.97, p. 373],

“the cognitive system is not just the encapsulated brain; rather, since the nervous system, body, and environment are all constantly changing and simultaneously influencing each other, the true cognitive system is a single unified system embracing all three.”

Second, the dynamicist expansion into the environment implies an explanatory model very different from the mechanistic one underlying the vertical expansion. In the 1950s, the appeal to the mechanistic explanatory strategy by early cognitivists was the logical conclusion of the battle waged against behaviorism and mathematical psychology, which conceived psychological explanation as discovery of laws or mathematical regularities in behavior [43.1, p. 96]. The dynamical approach, however, relaunches the covering law conception of explanation. The dynamical analysis identifies the critical variables characterizing the state of a system and attempts to construct laws (a set of differential equations) to account for the system’s trajectory through state space. The system can no longer be decomposed into subsystems (modules) that involve computations on representations. Consequently, the dynamical explanation is seen as incompatible with the explanatory style of the computationalist mechanistic (Fig. 43.5).

Dynamicism, then, puts forward the *radical embodied cognition thesis*: to understand the complex interplay of brain, body, and environment we do not need either the concepts of internal representation and computation or the mechanistic decomposition of a cognitive system into a multiplicity of inner neuronal or functional subsystems; all we need are the analytic tools and methods of dynamical systems theory [43.98, p. 148]. In this form, however, the dynamicist project is not a *third contender* (the other two contenders are Fodor’s CRTM – or, more generally, symbolic models –

and neural networks) in the controversy on the foundations of cognitive science but, rather, the denial of the possibility of such a science – to the extent, of course, that we are right in claiming that (some form of) computational functionalism is at the core of the very idea of a cognitive science.

However, a reformist perspective challenged the dynamicist obituary for cognitive science. It uses the objections to the individualism of classical cognitive science as guidelines to reconstruct the conceptual bases of cognitive science.

### Active Externalism

Such a reformism has been pursued by Andy Clark in the externalist framework introduced in Sect. 43.1.3. Clark thinks that the computational and representational framework can be reconstructed making due allowances for the embodied and world-embedded character of natural cognition but without collapsing into the radical embodied cognition thesis. Accordingly, he pursues the transformation of that framework into just one component in a three-tiered explanatory strategy [43.98, p. 126]:

- (i) A dynamicist account of the gross behavior of the agent–environment system
- (ii) A mechanistic analysis, describing how the components of the agent–environment system interact to produce the collective properties described in (i)
- (iii) A representational and computational account of the components identified in (ii).

Clark calls this tripartite explanatory strategy *minimal representationalism*, and puts it into a wider theoretical framework: *active externalism* [43.100, 101]. Unlike *semantic externalism*, where the mental *contents* of an agent are showed to partly depend on aspects of the environment which are clearly external to the agent, Clark’s externalism sees the environment as playing an active role in constituting and driving the agent’s cognitive processes. In the wake of Gibson’s

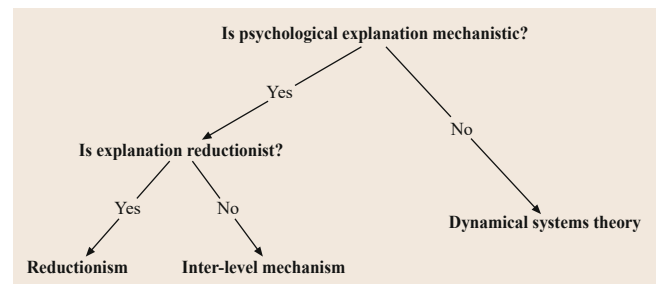

Fig. 43.5 The debate on explanatory style in cognitive science represented as a decision tree (after [43.99])

ecological optics, this environment is viewed as a collection of affordances that are the source of a particular variety of inner states, namely the *action-oriented* representations which, unlike the symbols in the language of thought, are *personal* (in that they are related to the agent's needs and the skills that she has), *local* (in that they relate to the circumstances currently surrounding the agent) and *computationally cheap* (compared with Marr's rich inner models of the visual scene).

It is important to notice, however, that action-oriented representations are only a representational *genus*. Clark rightly notices that the concept of inner representation was introduced in cognitive science to account for cases in which a cognitive system must coordinate its behaviors with environmental features that are not always reliably present to the system. In such cases, the cognitive system is able to decouple from the external environment and act in an offline fashion by creating some kind of inner item that stands in for the absent phenomena. These inner stand-ins are what cognitive scientists have termed *inner representations* [43.102]. Such cases of environmentally decoupled cognition are really a tough nut to crack for the antirepresentationalists, who are concerned exclusively with cases of *adaptive hookup*, that is, cases in which the inner states of a system (e.g., a sunflower, or a light-seeking robot) are supposed to coordinate its behaviors with specific environmental contingencies [43.98, p. 147]. Such cases of adaptive hookup, however, cannot ground a *general* antirepresentationalist argument: they are not sufficiently "representation hungry" [43.103].

In light of these considerations, Clark replaces the classical notion of mental representation with a *continuum of representational genera*. At one end of the spectrum there are the inner states that border the simple causal correlation and environmental control. At the other end of the spectrum, we find the type of inner stand-in that allows us to deal with the representation-hungry problems. Then between these two poles are the action-oriented representations.

According to Clark, therefore, depending on the coupling or decoupling between agent and environment, one must appeal to the dynamical nonrepresentational explanation or the representational one respectively. It can be objected, however, that this implies a division of labor between the two styles of explanation, and not their complementarity; as a result, they cannot be the tiers (i) and (iii) of a single explanatory strategy, as Clark would want.

Moreover, it is not clear how Clark's model of explanation can motivate the integration between the tiers (i) and (ii): if the interactions between the components of the global system can be described in mechanis-

tic terms, is there still need to conceive the system in dynamicist terms? In the next section, we will see how *William Bechtel* and his collaborators [43.104–110] tried to deal with the issue.

### Integrating Dynamical Modelling and Mechanistic Analysis

*Bechtel* [43.105] has rejected antimechanistic construals of the dynamical approach to cognition in that they can be traced to a misunderstanding of the nature of mechanistic explanations. The source of this misunderstanding is *van Gelder's* [43.97] analysis of the Watt governor (Fig. 43.6). The latter is contrasted with a hypothetical computational governor that is characterized by the following classical features: it uses computations on representations, is sequential and cyclic, and has a *homuncular* (= mechanistic) character. According to van Gelder, the Watt Governor fails to exhibit these features because of the continuous and simultaneous relations of causal influence among the various factors involved. It is the continuous reciprocal causation that requires dynamical analysis.

However, mechanistic explanations are not required to have the sequential and cyclic character that van Gelder ascribes to the computational governor. *Bechtel* and *Richardson* [43.109, Chap. 7] note that in the early stage of the process of developing mechanistic models scientists often assume that the processes that they are considering are performed serially. However, when it is not possible for scientists to develop a linear model that is adequate to the phenomenon, they start to introduce feedback loops and other nonlinearities in attempting to develop adequate models. The outcome is what the authors define as *functionally integrated systems*, namely, systems that are not sequential and cyclic in van Gelder's sense.

Again, as in the case of representation, a continuum emerges. At one end of the spectrum, we have *fully decomposable* (or *highly modular*) systems, which are composed of subsystems that are completely independent except for the mutual exchange of outputs (this is the case of Fodor's encapsulated modules). If the interactions amongst the subsystems are weak but not negligible, the system is *nearly decomposable* [43.111]. As the complexities of interaction amongst parts increases, the explanatory burden shifts from the parts (or more precisely, the interactions *within* subsystems) to their organization (i.e., the interactions *between* subsystems). Thus, we reach the other end of the spectrum, where we find *holistic* systems whose components are functionally equivalent and hence interchangeable. In between the nearly decomposable systems and the holistic ones, there are the integrated systems. In these systems, unlike the holistic systems, it is possible to iso-

**Fig. 43.6** (a) Watt's centrifugal governor for a steam engine. (b) A schematic representation showing that the angle of the spindle arms carries information about the speed of the flywheel for the valve, which uses the angle to determine the opening, thereby regulating the speed of the flywheel (after [43.107])

late different parts that make distinctive contributions but also give rise to a complex set of interactions that are nonlinear, and hence much stronger than those of a nearly decomposable system.

Now, the Watt governor is an integrated system. Although it does not use the sequential and cyclic elements of the computational governor, it nonetheless can be explained in mechanistic terms. In explaining how it works, we identify separate modules, each of which contributes something different to its operation; the components are tightly coupled with each other, but no more so than in the case of fermentation. Analogously with psychobiological cognition – Bechtel [43.106] and Clark [43.98] suggest that much of it is likely to take up the intermediate space between nearly decomposability and holism.

Some proponents of a radically holistic view that rejects the very possibility to decompose the mind–brain are neuropsychologists who use dynamical systems tools to revive the Gestaltist principle that higher level activities depend upon the dynamical organization of the entire cortex [43.104, §3]. For example, Van Orden et al. [43.112] criticized the double-dissociation and neuroimaging studies that explain cognitive activities in terms of *single causes*, and promoted the approaches that rest on the notion of continuous reciprocal causation.

A piece of evidence that is supposed to confirm this holistic view is the presence in the brain of a vast number of feedforward, feedback, and collateral connections. However, as Bechtel [43.113, 114] has convincingly argued, the hypothesis of the neurobiological reality of holism is scarcely plausible. Important contrary evidence comes from the studies by David van Essen and

his collaborators, who have almost completely mapped the areas of the Macaque monkey's visual system over the last two decades [43.115–119]. The researchers have identified 32 different areas in the macaque visual cortex and more than 300 connections between these areas; and the tool-kit of dynamical analysis can be very useful to model this vast number of feedforward, feedback, and collateral connections. However, although these regions are highly interconnected, we can still determine what each area contributes to visual information processing; i. e., it is not a holistic system, but an integrated one. Indeed, Bechtel takes this work to be an exemplar of mechanistic analysis of how the brain performs a cognitive function. And in an integrated system mechanistic analysis “provides the foundation for dynamical analysis” [43.106, p. 483] since the latter has explanatory force only insofar as it describes “the operations of the underlying mechanism” [43.110, p. 443], only to the extent that it reveals “aspects of the causal structure of a mechanism” [43.120, p. 602].

Bechtel and Abrahamsen [43.108] refer to accounts integrating mechanistic decomposition of systems into parts and operations with the quantitative tools provided by dynamical systems theory as *dynamic mechanistic explanations*.

And yet Bechtel's dynamic mechanistic explanations do not appear to be really successful in harmonizing mechanistic–computational explanations with the dynamical ones. To see why, let us go back to the notion of integrated system.

Integrated systems have parts (subsystems) that are individuated according to a mechanistic principle; at the same time, however, since the inter-relations among parts are nonlinear (e.g., they cannot be reduced to sim-

ple input/output connections), their global organization requires a dynamical description, i. e., the whole system turns out to be a dynamical system. Note that in this picture the burden of explanation is carried by the mechanistic component, since the mechanistic decomposition of the system in parts is a non-negotiable condition. In other words, dynamical explanations make sense only against a mechanistic background – their role consists only in, so to speak, *filling the (explanatory) gaps*.

This idea is highly plausible since, in the case of cognition, computational models seem to possess a higher explanatory force [43.120], and computational models are mechanistic. But here again, as in Clark's case, how the integration actually works remains to a large extent obscure. First, computational explanations require (at least preferably) *modular* subsystems, whereas, according to Bechtel's model, the richness of interactions makes it difficult to regard subsystems as modules (and, if all parts were modules, of course we could dispense with dynamical explanations completely). Second, it is by no means obvious how to link the output of modules to the relevant dynamical variables of the whole system. The notion of integration is required to put together, in some way, computational descriptions and dynamical descriptions; by contrast, in the current view, the two kinds of explanations are merely alternative.

### 43.3 Conclusions

In this chapter, we gave a comprehensive account of *computational models* and showed their relevance in cognitive science. We discussed computational models from a variety of perspectives. First of all, from an explanatory perspective, making explicit the relation among computational models, computational explanation, and mechanistic explanation; second, from a metaphysical perspective, illustrating the relation between computational explanation and functionalism in the philosophy of mind. Also, we introduced dynamical models, focusing more on their differences, rather than similarities, from computational models. Then, in the second section of the chapter, we took into consideration and extensively discussed a pair of important difficulties faced by computational models (considered as parts of computational explanations): the problem of central cognition and the challenge of dynamical models, considered as a thoroughly alternative explanatory style. Dealing with these difficulties is indispensable if we really want to understand the mind: the future of cognitive science depends crucially on our capacity to accept this challenge. We argued that there is

In short, the appeal to dynamical models is typically invoked for integrated (sub)systems in Bechtel's sense, which are very *weakly* modular, since each of their parts is influenced by the activity in some other parts of the system. This degree of modularity, though, is hardly sufficient for those cognitive scientists who argue that a mechanistic–computational explanation requires constraints on the concept of part far more demanding than what is required for the notion of integrated system. What they need is a form of modularity that is not vulnerable to the problem of central cognition (Sect. 43.2.1). Carruthers [43.96], for instance, distinguishes a *narrow-scope* form of encapsulation from a *wide scope* variety. Influenced by the *simple heuristics* research program of Gigerenzer and Todd [43.121], he argues that the computational tractability does not require Fodor's *narrow-scope* form of encapsulation whereby – as we have seen – the encapsulated system cannot draw on information held outside of it in the course of its processing [43.96, p. 58]. Rather, the computational tractability only requires that a system is encapsulated in the sense that it can draw on the information that is present in other systems during the course of its processing but, on any given occasion, can draw only on a *subset* of the *exogenous* information – a property that Carruthers calls *frugality* or *wide-scope encapsulation*.

a promising account of central cognition, based on a development of Baars' global broadcast model; as to the problem of dynamicism, we presented a sort of *ecumenical* proposal, based on the idea of integrating mechanistic explanations with dynamical models in different degree, according to the kind of cognitive task, we have to account for. Yet, difficulties remain in realizing this integration.

In short, we can say that, despite some strong criticisms that have been addressed to the concept of computation and the related notion of representation, computational models are still at the core of the disciplines of the mind. Computational models and, more generally, mechanistic explanations are still the dominant methods in cognitive science. Indeed, on one hand, the complexity of animal and specifically human behavior requires an appropriately complex model, such as computational models, on the other hand, more traditional nomological explanations appear not to be explanatorily much apt to hit the target: psychological explanation is closer to the biological one rather than the physical one. Moreover, the alterna-

tives to computational models appear to be not very solid.

This claim should not be intended as a way of hiding certain difficulties of computationalism, as we saw in the previous section. To put it generally, it is far from being definitely established that computational explanation can be extended to all mental processes and capacities. For this reason, we believe that the appropriate attitude in the epistemology of mind is explanatory *pluralism*, at least at the moment. This has to be intended in a twofold sense. On one hand, mental phenomena require a variety of explanatory levels, whose inter-relations are of two kinds: decomposition and contextualization (in other words, we think that mechanistic explanation vindicates pluralism). On the

other hand, the arguably quasi-holistic character of some cognitive tasks suggests that the mechanistic style of explanation has to be integrated in these cases with a dynamical explanatory style.

*Cartwright* [43.122] suggested that the most appropriate metaphor of explanation in cognitive science is the *patchwork*: a disparate arsenal of modeling *weapons*. Not only each mental capacity calls for its distinctive collection of explanatory layers, but it is also necessary to relax the constraints on the overall explanatory architecture. We are essentially in agreement with such a point of view, though, at the same time, we try to maintain confidence in computationalism as a general explanatory framework in the sciences of the mind.

## 44. Model-Based Reasoning in the Social Sciences

Federica Russo

Social scientists use different types of model to reason about social objects and to study social phenomena. In this chapter, I provide an overview of various forms of model-based reasoning in social research, especially quantitative and qualitative. In the course of the chapter, I highlight differences with other variants of model-based reasoning, notably the one inherited from logical positivism, and I discuss the use of experiments and simulation in social contexts. The chapter also investigates intersections between model-based reasoning and other notions, such as explanation and causality, truth and validity.

The notion of model occupies an important part of the debate in the philosophy of science. One reason why this notion deserves so much attention is that models lie at the interface between the epistemic agent (in this context, the scientist) and the system under investigation (be it physical, biological, or social). Thus, models allow us to study, understand, and interpret the surrounding reality. The literature is incredibly vast, spanning very many scientific disciplines as well as philosophical traditions. As a consequence, providing an exhaustive summary of the contributions, or finding the main conceptual research lines, is far from being an easy task. A further difficulty is that the term *model* is currently used by scientists coming from different backgrounds, as well as by logicians and philosophers having different perspectives on the topic. This created distortions that might be dubbed *episodes of conceptual imperialism*: a discipline and its basic concepts are used as benchmarks to evaluate or discuss another discipline and its basic concepts. This has often happened

in the social sciences, for instance in the debate about their status, that is, whether they rightly belong to the realm of the sciences, alongside the natural sciences, and physics in particular. Thus, the social sciences have been often judged according to the standards of *other* disciplines, typically physics. What is at stake here is a question about their methods – and, consequently, about their *objectivity* – typically so different than those of the natural sciences. For this reason, it is worth opening the chapter with an overview of the methods and models used in the social sciences, before discussing in detail the concept of model.

The chapter is organized as follows. In Sect. 44.1, I examine the objects of study of the social sciences and different types of models: quantitative vs qualitative, experimental vs quasi-experimental. To be sure, this is not the only possible categorization of social science models, and I shall refer, when appropriate, to other types of models, such as theoretical models or simulations. In Sect. 44.2, I distinguish two concep-

tions of models: as representations and as objects. For each of these, I examine two variants. For models as representations (Sect. 44.2.1), I consider the notion of set-theoretic structures and of a family of probability distributions. For models as objects (Sect. 44.2.2), I analyze those positions that interpret models as fictional entities and as epistemic objects.

The idea that a model is a representation of a given system is, in some way, the received view which any other position subsequently developed has to confront with. In particular, the first conception, namely representation in the set-theoretic sense, is the most discussed one in philosophy of science. The second conception (family of probability distributions) corresponds instead to what a statistician would think of as a model. As we shall see, there is a specificity in the use and meaning of the concept of model in the social sciences that is not entirely captured by the received view and that is instead captured by the idea that models are families of probability distributions *and* epistemic objects.

In Sect. 44.3, I discuss a selection of philosophical positions concerning the relationship between models and reality. I focus on three positions: models as mediators, isolations, and maps. These positions should not be seen in opposition with each other, and, in fact, they complement each other, as they highlight different aspects of modeling practices and of model-based reasoning in the sciences.

Finally, in Sect. 44.4, I examine the concept of model in relation to types of model that had not been discussed earlier in Sect. 44.1 – viz. simulations – and to some central issues in model-based reasoning: causality and explanation, validity and truth. The philosophical questions tackled in this section arise in social research and in any other scientific domain alike, but here I will privilege discussion on issues concerning modeling in the social sciences.

Before starting, it is worth lingering on the position of this essay in the *geography* of the philosophy

of science. To begin with, the choice of starting from a thorough description of the scientific practice is not accidental. In fact, I adhere to the view according to which philosophical discussions must be rooted in a practice, or a problem, or an issue that emerges in contemporary science or in the history of science [44.1, 2]. This, however, does not rule out a priori philosophical investigations as an important part of the process (for a nuanced view on the relations between science and metaphysics, see, for example, [44.3]). I will then examine those philosophical positions that help us clarify controversial aspects or important conceptual issues, as they arise in the scientific practice. The comparison with the received view (model in the set-theoretic sense) is important for two reasons. On one hand, the methodological literature in social research developed its own version of the representation view (i. e., as a family of probability distributions); on the other hand, such comparison will help us foster a dialogue between different subdisciplines in philosophy of science.

It is also necessary to locate this essay in another area, namely within the (philosophy of the) social sciences themselves, and especially within the tradition of hermeneutics, of historicism, and of critical theory that developed since the mid-nineteenth century. There is no doubt about the value of the methodological contribution of authors such as Wilhelm Dilthey, Theodor Adorno, Jürgen + Habermas, or Max Weber. No doubt the scientific practices presented in Sect. 44.1 have, in different ways, a conceptual debt to these traditions. However, these will not be examined here.

Finally, I felt it important to give voice to scientific practices that are relatively less discussed in the literature, such as qualitative models (Sect. 44.1.3). However, the reader will notice that the arguments discussed in later sections (notably, Sects. 44.2 and 44.3) focus more on quantitative than qualitative modeling, which makes the discussion somewhat incomplete. Yet, the hope is to draw the attention to a form of model-based reasoning in need of further philosophical inquiry.

## 44.1 Modeling Practices in the Social Sciences

### 44.1.1 Social-Scientific Objects

The social sciences study individuals and societies from different perspectives; to do so, they use methods and approaches that are highly heterogeneous. Demography, for instance, studies populations according to the parameters of fertility and mortality, morbidity, and migration. It does so with the help of statistics and of quantitative analysis of data, which allow us to get

a snapshot of a population, to see how it changes over time, and to predict how it will be at some future time. Economics focuses on the behavior of individuals and of groups (a family, a company, a market, or a state) with respect to the management of resources. Sociology is interested in the social behavior of individuals and groups, identifying specific contexts and environments as the sociology of work, of science, or of health. Anthropology studies human beings within a given society

in their various dimensions, such as cultural, emotional, or spiritual. Epidemiology deserves a special note, as it is at the border that separates the social sciences from the biomedical sciences. Epidemiology studies the distribution and variation of mortality and morbidity of the population, according to biological and socioeconomic characteristics of individuals. Needless to say, the scientific objects of these disciplines do not always have sharp and precise contours. Understanding and conceptualizing the objects of study of the social sciences is in itself an interesting and important topic – see for instance [44.4].

The label *social science* has been persistently used since the mid-nineteenth century, which is when the social sciences *come into existence* as autonomous fields of scientific investigation. Yet, the social sciences are, in fact, highly heterogeneous both in their objects and in their methods. On one hand, some social scientists, for instance sociologist Émile Durkheim, worked hard to establish the autonomy of their discipline with respect to other areas of investigation (notably, psychology). On the other hand, economics has an object of study that clearly falls within the realm of the social, and yet it is often considered apart from other social sciences. Examples abound. This is the case, for instance, in disciplinary panels for the allocation of national or European funds. To give another example, this series of volumes on model-based reasoning or the Italian online journal *APhEx* devoted specific essays to *models in economics* ([44.5] and Chap. 19) and to *models in the social sciences* (Chap. 52, [44.6], and this chapter). Consequently, it is difficult to find *one* concept of model that fits the social sciences *as a whole*; nevertheless, it is possible to isolate some common conceptual points.

In the following, I will present models and approaches in the social sciences according to a classification that is quite widespread and that distinguishes two lines of research that are seemingly very different: *quantitative models*, based on statistical analyses of data (Sect. 44.1.2), and *qualitative models*, typically based on the direct study of small groups of individuals (Sect. 44.1.3). As we will see, however, this does not mark a difference between models that are intrinsically better, more robust, or more valid. The quality of models, or rather their *validity*, is to be assessed on different grounds and concerns them all – see later Sect. 44.4.3. In the social sciences, quantitative models are very often *observational* models, in the sense that, once data is collected, it is analyzed using the tools of probability theory and statistics, but the process of data generation is not repeated, as can happen in experimental modeling practices instead. Experimental models may generate data repeatedly, control certain experimental conditions in labs with more precision,

and use sophisticated instrumental apparatus for measurement. To be sure, experimental models are used in the social sciences too, and I illustrate some aspects of this modeling practice in Sect. 44.1.4. The reader interested in learning about scientific practices inside and outside the laboratory will find [44.7] an inspiring read. Another possible classification distinguishes between empirical and theoretical models. Empirical models use empirical data, collected in different ways, while theoretical models are developed theoretically, that is, in the abstraction of any empirical investigation and are sometimes formalized. Theoretical models are often used in economics and try to reconstruct, a priori, various processes involved in economic behavior. One example is Schelling’s model of segregation or Friedman’s hypothesis on permanent income. I will not discuss these models in detail – for an extensive discussion, see [44.5] and Chap. 19.

### 44.1.2 Quantitative Modeling

Quantitative analysis has a long tradition, tracing back to pioneering methodologists such as Adolphe Quetelet, demographer and astronomer, and Émile Durkheim, sociologist, both active in the second half of the nineteenth century. During the first half of the twentieth century, and until the 1970s, the social sciences saw continuous improvements and refinements of techniques for data analysis, developing increasingly sophisticated statistical models and tests. Several reknown scholars have been protagonist of these developments, for instance, Sewall Wright was active in the field of population genetics in the first half of the last century, or Otis Dudley Duncan and Raymond Boudon both sociologists have been active since the 1960s and 1970s of the last century. In the last 30 years or so, economists, statisticians, and computer scientists such as James Heckman, Kevin Hoover, Judea Pearl, Clark Glymour, or Donald Rubin (and their collaborators) prompted further progress in the use of probability, statistics, and automated reasoning for the study of the social.

Probability theory and statistics provide us with useful means to analyze random phenomena like flipping a coin, waiting time in a queue, or other more complex social phenomena such as migration or changes in the morbidity of a population.

Data analyzed in a statistical model typically come from censuses, surveys, or other similar methods. But what is data? Data consist of observations or measurements of characteristics of populations or individuals under study. This seemingly simple characterization, hides a conceptual complexity which I will only gloss over. The generation, use, and re-use of data are all activities that deserve a deep epistemological, method-

ological, and metaphysical reflection (for a thorough discussion, see, for instance, [44.8, 9]). It is worth emphasizing that data are not *just* data, but are already heavily *theory-laden*, to borrow the famous expression of N.R. Hanson. Some data are generated in a rather simple and noncontroversial way. For instance, nowadays population registers in Western countries allow us to determine the age of an individual very easily and precisely. Other data, however, are much harder to generate. For example, there is not a unique way of measuring *socioeconomic status* or the level of education of individuals. Similarly, other data are indirectly generated by measuring *other* characteristics. For instance, school motivation can be measured by recording class attendance.

Once generated, data are then organized and grouped according to variables. Here is a possible taxonomy of variables (see also [44.10, Chap.3]):

1. Gender and scale: continuous/discrete; quantitative/qualitative
2. Role: observed, latent, instrumental, proxy
3. Level: individual, aggregate
4. Scope: socioeconomic, demographic, biological, etc.

Using a type of variable rather than another depends on reasons that can be methodological, empirical, or other. Variable *age*, for instance, is clearly a continuous variable, but for convenience scientists analyze populations by *age structures* (taxon 1). Age, in turn, can provide information regarding socioeconomic characteristics of individuals – for example, a 10-year-old person is likely to be in school age and a 30-year-old to be in work age; age may also provide information on biological aspects – for example, we record hearing loss typically after 60 years of age, and yet with the increased use of headsets, the phenomenon begins appearing much earlier, thus providing information on *behavioral* aspects (taxon 4). Thus, *age* can be an observed (and directly measured) variable, or a proxy, that is, a variable that *stands for something else* and that is not directly measured (taxon 2). Finally, most characteristics are measured for each individual in the sample or population, for example (individual) income; however, some phenomena are better modeled using aggregate variables, for example, the average income for a given population (taxon 3).

Once data are organized, we have to organize the variables. This is the task of *quantitative* models. Typically, a quantitative model consists of (a system of) equations and of a graphical representation of these equations. The social sciences have, in the course of time, developed more sophisticated quantitative models, tailored to specific scientific problems. For instance,

multilevel models are designed specifically to study the relationships between *individual* and *aggregate* variables. As mentioned above, an individual variable measures a certain characteristic for each individual in the sample, for example, *individual* income. An aggregate variable *sums up* individual measurements into aggregate measurements, such as mean income at the regional or national scale. Or, structural models are specifically used to model the *structure* of the relationships between variables, which in turn serves to explain the socioeconomic mechanism(s) underlying a given phenomenon.

Quantitative analysis can be used to provide a description of a social phenomenon. In this case, the model studies how a variable *changes* depending on how other variables change. For example, we can trace how the variable that records births in Alsace varies depending on the variable that records the presence of storks in the same region, thus establishing a correlation (or co-variation) between the two variables. At this point, the model only attests to a statistical dependence between the variables. This dependence is symmetrical: the birth rate in Alsace changes depending on the change in the number of storks in the region. But we can reverse the equation: the number of storks in Alsace changes depending on the change in the birth rate.

As is well known, correlation alone does not allow us to determine whether there is a causal relationship between two variables, and in which direction it flows, nor it allows us to explain a phenomenon. This is because of the *third variable problem*. Given a correlation between two variables, it is possible to find a third variable such that, when included in the model, makes the correlation disappear. Let me illustrate with a toy example. Yellow fingers are correlated with lung cancer. Include now the variable *cigarette smoking* in the model. It is easy to show that the correlation disappears because cigarette smoking is the cause of *both* yellow fingers and lung cancer. The philosophical literature discussed the issue under the headings of *screening off* and of the *common cause principle*, while the methodological literature more often talks about *confounding variables* and *statistical control*.

How to infer causation from correlation is a vexata quaestio in philosophy of causality. Positions proposed in the literature vary, but there seems to be agreement at least on the fact that a causal model has more constraints than an associational model. In other words, causal models have some *augmented* technical features compared to an associational model, notably with respect to assumptions, the types of test, and the use of background knowledge (for a discussion, see, for example, [44.11]). I will briefly mention just two types of tests. Exogeneity tests are used to check if cause

and effect are properly separated, that is, if the (probabilistic) structure of the model is correct from a causal point of view. Exogeneity is typically explained by saying that exogenous variables are caused *outside* the model, while the endogenous ones are caused *within* the model (by the exogenous variables) – for a discussion, see [44.12]. Invariance tests, instead, are used to check that the causal structure is sufficiently stable across different partitions of the population of reference, or under interventions or manipulations [44.13].

Introductions to quantitative modeling and to the concepts mentioned above, also accessible to non-experts in probability and statistics, are available in [44.10, 14].

### 44.1.3 Qualitative Modeling

Qualitative models are mainly used in ethnography and anthropology, in some branches of sociology, and also in educational science. A first difference with the quantitative models is of *scale*: the larger the sample size of a quantitative model, the better its quality. The same, however, does not necessarily hold for qualitative models. A second difference concerns the *techniques* for data analysis. While a quantitative model typically uses the tools of probability theory and statistics, in a qualitative model, researchers select small groups of individuals and study them in detail, for example, by integrating into their community and observing them *from the inside*. In this case, data not only *quantitatively* measure certain characteristics, but also *qualitatively* describe social practices, behaviors, language use, etc.

It is worth noting that this does not necessarily mean traveling to remote or distant places to study particular ethnic groups. Ethnographic research also concerns the societies close to us, whether geographically or culturally. Ethnographers and sociologists are interested, for instance, in how young people socialize in the digital era in Western countries, or how doctors interact as a team in an operating room, or in the way in which citizens can be part of decision-making processes relating to the environment or the like – on ethnography conduct *at home*, see [44.15]. What triggers anthropological interest is the object of anthropology itself – on this, see, for example, *Montuschi* [44.4], who discusses the distinction between ethnography and anthropology, or *Eriksen and Nielsen* [44.16], who introduce the concept of *home blindness*, viz. the difficulty of seeing and studying our own culture, because we belong to it.

It is a widespread misconception that qualitative methods are less rigorous than quantitative ones, but this view is wrong. Scientific rigour is not an intrinsic feature of a method. Rigour is instead a property of the *process* of project design, model building and test-

ing, and of the interpretation of results, and it depends on how scientists *in practice* carry out such a process. *Cardano* [44.17] offers an interesting presentation of qualitative methods and explains, step by step, what are the aspects to be taken into account in the preparation of an ethnographic study: what individuals to study, when and how long for, what are the assumptions, how to perform tests on the hypotheses, how to use theoretical assumptions in the interpretation of results, etc. All these are elements that belong to the long and complex process of modeling, even when formal methods or quantitative models are not at stake.

Cardano's approach is interesting because, if we have previously pointed to some of the differences between the quantitative and qualitative models, we can now identify a similarity. The way Cardano describes ethnographic research is perfectly in line with the precepts of modern scientific method and of a hypothetico-deductive methodology: the formulation of hypotheses, data collection and data analysis, hypothesis testing, and validation of the model. Therefore, the difference in the techniques for data analysis (quantitative or qualitative) does not draw a line between scientific and nonscientific, objective and nonobjective. For a discussion on the issue of objectivity, see also [44.18].

### 44.1.4 Experimental and Quasi-Experimental Modeling

Models presented earlier belong to the category of *observational models*, which are often opposed to *experimental models*. I will use, in this context, the term *experimental model* to refer to those modeling strategies that make use of experiments. Often, experimental models are conceptually associated with the natural sciences (physics, biology, etc.) and observational models with the social sciences and humanities. This is not entirely correct. Psychology, for instance, increasingly uses experimental methods to study the mechanisms that regulate certain phenomena, such as attention or memory. Economics too uses experiments, as it seeks to develop and validate economic theories based more on empirical data and less on theoretical hypotheses such as the *homo oeconomicus*, who always maximizes expected utility and has perfect knowledge. The relations between theory, experiment, and reality raise many questions, some are epistemological, others are methodological and, of course, some others are ethical and moral. The literature is vast. The following contributions touch on various issues related to the use of experiments in social sciences and economics: [44.19–24]. These issues are all the more pressing in areas where experimentation has severe limitations for ethical or practical reasons, as in the social sciences.

To illustrate the use of experiments to model social phenomena, consider the case of the *invisible gorilla*, a famous experiment in psychology [44.25]. The researcher asks a person to observe two teams playing and to count the number of times that the players pass the ball. At the end of the game, the researcher asks the person whether he or she has also seen a gorilla walking through the playing field. In about half of the cases, the gorilla goes unnoticed. This is because attention works in a very selective way. Researchers talk, in cases like this, of *inattentional blindness*. The experiment has been repeated several times, with significant variations, in order to confirm the stability of the results and of the assumptions. This allowed researchers to capture different aspects and dimensions of the phenomenon of attention. The results of studies go far beyond the understanding of the phenomenon itself. For example, results of the *invisible gorilla* have been used for campaigns to raise awareness about the problem of *invisible cyclists* among city drivers. Experiments like the *invisible gorilla* may have other functions within the modeling process. For instance, they can be used to test a theory, or to formulate more precise assumptions, or to examine different aspects and dimensions of the same phenomenon. These issues are, in different ways, aspects of external validity (see also [44.26, 27], and Sect. 44.4.3).

Of course, experimentation in the social sciences, as well as in the biomedical sciences, is subject to significant restrictions. We cannot force people to smoke to study the effects of nicotine, as we cannot force people to work 20 hours per day to understand the effects of stress. An ethnographer can, however, go to the City of London and study the behavior of young and ambitious people who try to make a career in a prestigious financial company. Experimentation in the social sciences (as well as any other method) has limits. For this reason,

observational models, both quantitative and qualitative, are an invaluable resource for studying those phenomena on which we cannot directly intervene.

Modeling social phenomena – whether concerned with economic, medical, or psychological dimensions – also make use of quasi-experiments or natural experiments. There are empirical studies designed to assess the impact of an intervention (e.g., a socio-economic or public health policy, or a natural event) in a given population. The basic idea is the same as in randomized trials (RCTs), but with an important difference. In quasi- or natural experiments, the allocation of individuals to the treatment is quasi-random. Potential outcome models also use techniques called *propensity scores* to match individuals for the cases and the controls. Let us reason about an example. Suppose we want to study the effects of attending private or public school on income. Researchers will select individuals that are as similar as possible for most characteristics (age, social class, family situation, etc.) and differ only in the type of school attended. The two groups will then be compared in order to find differences in income that are due to the type of school attended.

Sometimes, however, this quasi-random allocation is made by nature, or by the course of events. A famous example is the outbreak of cholera in London in 1854, stopped by epidemiologist John Snow. Snow was able to stop the epidemic because he figured out that the exposure to the bacterium, resulting in contraction of the disease, was associated with the use of public water pumps. These were, in fact, served by two aqueducts, which filtered water in a different way, the one holding the bacterium and the other releasing it into the water. Two groups were naturally created, the exposed and the nonexposed, and they could be studied and compared *as if* a real experiment had been performed.

## 44.2 Concepts of Model

In the previous section, I offered an overview of the models used in social sciences. Yet, two crucial questions were left in the background: What is a model? And what is it for? I will answer these questions starting from the most classic position offered in philosophy of science: models are representations. Thus, I will be able to locate the debate on models in the social sciences within the broader framework of the debate in general philosophy of science. Moreover, I will be able to isolate some peculiarities of model-based reasoning in social research.

### 44.2.1 Models as Representations

According to an established tradition, a model is a representation of a phenomenon or of a certain portion of reality. Models can be represented in at least two ways. Let us examine them in order.

#### Set-Theoretic Structures

A model is a representation of a phenomenon, or of a certain portion of reality, in the sense that it captures the main features of the phenomenon, and expresses

them in a formal manner. Set-theoretic or mathematical models fall under this category. Here, a model consists of a set of statements having a set-theoretic structure. Statements are verifiable, either directly, because they contain terms that refer to observable entities, or indirectly, because they contain terms referring to theoretical entities, for which we have correspondence rules that bring us to observational statements. The motion of a pendulum, the motion of particles like electrons or protons, or the Higgs mechanism, are examples of this sense of model. This characterization, however, does not so much answer the direct question: *What is a model?*, but rather the question about the nature of scientific theories, in particular physical theory.

This sense of *model* is clearly a legacy of logical positivism, which based the methodology of science on the idea of meaningfulness and verifiability. Let me elaborate on this point. Neopositivists were interested, among other things, in the nature of knowledge, particularly scientific knowledge. This can be read as a legacy of the first Wittgenstein. In the *Tractatus*, Wittgenstein claims that “To understand a proposition means to know what is the case if it is true” (Proposition 4.024). To understand a proposition, we have to establish a relationship between language (expressed in well-formed formulas) and the world. This position found fertile ground among the neopositivists, who applied it to scientific knowledge. On this approach, scientific knowledge can be expressed in well-formed formulas and verified against empirical experience. This was the origin of the formulation of the verification criterion for scientific statements and of the criterion of demarcation between science and nonscience as developed by Karl Popper. Both criteria greatly influenced the philosophy of science in the years to come.

Thus science, according to the neopositivists, *produces* theories; but what is a theory? The short version of the answer may be formulated as follows: theories are sets of statements that must meet very specific requirements. What requirements? Those developed by the neopositivists (and inspired, by and large, by Wittgenstein). The verification criterion occupies a special place: a theory is scientific if it is verified to a sufficiently high degree. Later on, Popper proposed replacing this criterion with a criterion of falsification. A theory is scientific if it is falsifiable, that is to say, if, from the theory, we can deduce observational statements that we can empirically falsify. Both of these criteria are based on a specific understanding of *theory*. Theories are not just sets of statements. For a set of sentences to be considered a theory, it must have a certain structure, in particular a set-theoretic structure. Without going into the technicalities, this means that from a certain set of axioms (for which no proof

is required) and following certain rules of inference (in particular, deduction), we can prove other statements as theorems. Basically, the set-theoretic structure is what gives *certainty* to the theory and, consequently, to scientific knowledge.

Let us get back to the structure of the theory. We defined a model as a set-theoretic structure. More generally, a model is an abstract structure, such as a mathematical structure, or a set of statements formalized in first-order logic or other logic. This makes the starting axioms of the model true, in the sense that we will now see.

To see if what happens corresponds to what the theory would predict, we need corresponding rules. For instance, if the theory states that Fuji apples are red, we need to establish a correspondence between the theoretical terms *Fuji apple* and *red*, and for all objects covered by such terms. We will then be in a position to tell if it is true that Fuji apples are red and not, for example, green or yellow. The difficulty lies not so much in verifying properties of observable entities, but of the unobservable ones. These difficulties are also at the basis of the realism–antirealism debate. Think of physical theories developed in the first half of the last century and the difficulty of establishing, for example, the correctness of statements about electrons or about other theoretical entities not directly observable. Consider, also, all the theoretical and experimental apparatus to confirm the existence of the Higgs boson, recently *found* by researchers at CERN.

In philosophy of science, the position that models are representations or structures (in the sense explained above) has also been developed by *Suppes* [44.28], *van Fraassen* [44.29], *French* and *Ladyman* [44.30], or *Boniolo* [44.31]. For a recent discussion of representation through mathematical structures, see also *Pincock* [44.32] or *Molinini* [44.33].

The idea that a model represents a phenomenon, or a portion of reality, intuitively captures some aspects of modeling processes described in Sect. 44.1.2. However, the sense in which models in the social sciences represent a certain reality is not given by the set-theoretic structures. So let us examine a possible alternative.

### Families of Probability Distributions

In the social sciences, there is a sense in which models – especially quantitative models – *represent*. If you ask a statistician what a model is, the answer will most likely be that a model consists in a family of probability distributions. These probability distributions, in turn, represent some aspects of the reality under examination, in a way that I will now explain.

Let us consider an example. Suppose we run a survey to see how Italians are doing. To do this, we can

measure their well being with a number of indicators in additions to the gross domestic product (GDP). This means that we will try to measure well being not only from an economic perspective, but also physical or psychological. A study like this was discussed back in February 2012 in front of the Italian Parliament, where the president of Italian National Institute of Statistics (ISTAT) presented different ways to measure well being. *Neodemos*, an online journal of demography, published a popular science article about the ISTAT study, offering also the point of view of the social sciences on the issue [44.34].

Let us try to reconstruct the key moments of the modeling process of a study like the one just mentioned. First, we collect the data and organize the observations (i. e., the answers of the respondents) into variables. To answer the original question, we have to understand the structure of the relationship between these variables. Such models are called *probabilistic* because the probability distributions are related to the variables in the database (see also Sect. 44.1.2). A probability distribution is a function that assigns a probability value to each of the possible values of a variable. To say that a model is a family of such distributions means *putting together* the probability distributions for each of the variables in the database and then studying their behavior.

The use of probability theory and statistics to study phenomena (social or natural) presupposes a *stochastic representation* of reality, rather than a deterministic one. This is mirrored in the inclusion of *error terms* that can stand for measurement errors, latent variables, or even for the fact that the phenomena are genuinely indeterministic [44.35]. In other words, it can be argued without contradiction that a *phenomenon* is deterministic, and that our *representation* of the phenomenon is stochastic. A corollary of this position is that the representation of a phenomenon is *partial* – the presence of terms of errors or latent variables means that we cannot take into account all possible aspects of the phenomenon.

It is worth explaining this sense of model, also with respect to the distinction made in the previous section between *theory* and *model*. In set-theoretic models, there is a close relationship between the two. In some ways, the model is the formal part of a theory, notably of a physical theory and, typically, for each physical theory we admit more models, or interpretations – think, for instance of the various models, or interpretations, of quantum mechanics.

However, in the social sciences, which interest us here, we are in a different situation. With the exception of economics and some branches of sociology, the social sciences do not have theories. Or, at least, they do not have strong ones (for a discussion, see, for exam-

ple, *Wunsch* [44.36]). It is also worth noting that the majority of theories developed in classical economics fall into the category of *theoretical models* (mentioned at the end of Sect. 44.1.1) but that will not be discussed here. Instead, the empirical models presented in Sect. 44.1 are used precisely to develop theories of the social (broadly understood) through the analysis of empirical data. Think of studies on migratory movements that are carried out systematically in different countries and at different times. One goal is to try to formulate a *general* theory of migration, that can be applied to different populations, times, and cultures. Part of the difficulty in developing such general theories in social contexts is due to the object of study: human behavior changes, and it does so very quickly in time and space, across cultures, and also as a result of the implementation of socioeconomic policies. Of course, this distinction is not, in scientific practice, so sharp. Empirical models are sometimes used to test and refine theoretical models. Yet, it is still controversial whether theoretical models (like rational choice theory) should be amended on the basis of empirical studies in behavioral economics or psychology.

To conclude, the idea that a model is a representation of a given reality belongs to the classic philosophical debate about the nature and function of models as well as to the methodological literature in the social sciences. However, as the previous discussion hopefully showed, this idea is cashed out, in the social sciences, in a way that has some important differences with respect to the neopositivist position.

#### 44.2.2 Models as Objects

In the literature, another position has also been proposed to answer the question about the nature of the models. Models, according to this position, are *objects*. More precisely, according to one variant of this position, they are fictional entities, while according to another variant they are epistemic objects. We will see how this second account, in particular, offers interesting insights for the social sciences.

##### Fictional Entities

The sciences produce different types of model. Some are *physical* objects, such as a relief map of an archeological site, or a globe. Many others, however, are *abstract* objects, such as Bohr's atomic model, or the model of the inverted pendulum.

Both characterizations of *model* presented earlier (in the set-theoretic sense and as a family of probability distributions) hinge upon the idea that models are representations of reality. In turn, these representations are

structures (set theoretic or probabilistic). According to philosopher Frigg [44.37], however, this conception of models leaves unanswered the question about their *nature*. What kind of *object* is a model? Frigg proposes to conceive of models as *imagined physical systems*. Models are *hypothetical* entities that have no actual space-time existence but they are not mere set-theoretic structures either. In Frigg's words, "they would be physical things, if they were real" [44.37, p. 253].

There are, according to Frigg, two reasons to embrace his thesis. The first is that it better mirrors the use that scientists make of *model* – here, *model in physics*. Frigg comments on popular physics textbook, written by Young and Freedman [44.38]. The two scientists explain that the physics model describing the motion of a baseball abstracts from a number of aspects present in the real system, such as the air friction or the mass of the ball. This makes complex systems manageable. In such a description, says Frigg, we find no reference to the mathematical structure of the system, but rather to a simplified hypothetical situation. Mäki's account that will be examined later in Sect. 44.3.2 also emphasizes aspects related to abstraction and isolation.

The second reason is more fundamental and has to do with the relationship between the *structure* and the *real system*. The problem, for Frigg, is that there is no relationship of *morphism* (isomorphism, homomorphism, ...) between the structure and the real system. These types of relationships hold between two *structures*, but not between a structure and a worldly system. This should prompt us to re-think the relationships between mathematical representations of a system, models, and worldly systems. Frigg does not abandon completely the notion of representation. Mathematical representations *are* part of the modeling process. But his argument is that the model is *not* a representation. Models are simplified and idealized systems, distinct entities that share many of the characteristics of fictional entities in fiction, just like Sherlock Holmes or any other character or object in a novel.

This position emphasizes the role that abstraction plays in the process of modeling (for a discussion, see also [44.39]). Making assumptions about the a-dimensional nature of atoms, or about the absence of friction in the motion of the pendulum means eliminating some empirical elements and reasoning about a distilled version of reality, which typically is too much complex to be modeled as such. Some of these aspects are also discussed by other authors, and their positions will be discussed in Sect. 44.3. Frigg's position, however, stays silent on an important aspect: the role that these objects (the models) play in several activities carried out by the epistemic agent (typically, the scientist).

This is instead explicitly discussed by Tarja Knuuttila, as we shall now see.

### Epistemic Objects

Tarja Knuuttila, together with other scholars, proposed considering models as *epistemic objects* [44.40–42].

Models are *objects* because they are concrete, tangible products that we can manipulate in different ways. We can not only manipulate a physical model as a globe, but we can also manipulate a theoretical model, for example, by changing or setting the value of a variable. For Knuuttila, it is important to highlight what aspects of modeling allow us to produce knowledge. Consequently, in her account, it is not vital to distinguish different types of manipulations on the models. It is instead important to isolate those elements common to the various practices of modeling.

Models are *epistemic* objects because they mediate between the epistemic agent and the system examined, and because they provide an understanding of the phenomenon. This idea, as we shall see, is central also in another debate, that is about the relationships between models and reality. Knuuttila's account is, in fact, closely related to the one developed by Morgan and Morrison (Sect. 44.3.1).

This account of model is largely *instrumentalist*, but not so much in the classic sense of the term, that is, leading to antirealist positions about models. Rather, they are instrumentalist in analogy to the role of technology. Models are *tools* that we build, manipulate, and use to gain the knowledge of a given phenomenon. In this sense, they share many of the properties of technological artifacts. Of course, we lose a clear demarcation between the scientific objects and the tools to acquire knowledge about them. The ontology of model also becomes less neat, and the boundaries between the natural and the artificial are now blurred. But, perhaps, this is a price worth paying, if the expected gain is a better understanding of the scientific practice. The instrumental role of the models will be further discussed in Sect. 44.3.1.

At first sight, this position may seem rather unconventional, especially if one is used to engage with the mainstream literature, according to which models provide us with knowledge because they *represent* (in one way or another) a system. However, if we expand our horizon, it will not be difficult to see that this position fits very nicely in another stream of philosophy of science, one that is interested in more practical – and less abstract – aspects of the scientific practice. Paradigmatic contributions in this area have been those of *Hacking* [44.43], *Daston* [44.44], and *de Regt* et al. [44.45], to name just a few.

## 44.3 Models and Reality

The account of models as epistemic objects allows us to introduce the next theme of this chapter: the relationship between models and reality. In fact, besides the question of the nature of the model, it makes sense to inquire about its function within the process of acquiring knowledge of reality. The first two accounts examined below have been developed in the philosophy of the social sciences (specifically, philosophy of economics). The third account is more general in scope, and it offers some interesting ideas for our topic.

### 44.3.1 Mediators

The first approach I consider is the one developed by *Morgan* and *Morrison* [44.46]. The purpose of the discussion of Morgan and Morrison is to clarify the dynamics of the construction of models, their function, and their use. In particular, Morgan and Morrison try to articulate the idea that models have *autonomy* and that their function in scientific practice is to be *mediating instruments*.

To begin with, models are said to be *autonomous*. But with respect to what? Models, according to Morgan and Morrison, have partial autonomy compared to the *theories* on the one hand, and the *reality* on the other hand. But, note, partial autonomy also means partial *dependence*. This partial autonomy (and dependence) is already clear at the model-building stage. According to some schools of thought (especially in economics), models are derived entirely from theory (for a discussion, see, for example, [44.47]), and according to others models are instead entirely bootstrapped from data alone (as in data mining). But Morgan and Morrison argue that *both* theory and data are involved (as well as other elements that do not concern us here).

Morgan and Morrison also want to defend the autonomy of the *function* of the model. Consider, by analogy, the use of a hammer. A hammer is separated (autonomous) from both the wall and the nail, and its function is to *connect* the nail to the wall. In this sense the models mediate – and here kicks in the second idea, that of mediating instruments – between the two sides: reality on the one hand and theory on the other hand. The analogy of the hammer is, however, insufficient to understand the use and function of models. Models are useful, in fact, also because of their ability to represent something, which allows us to use them as epistemic tools (see Knuuttila discussed earlier in *Epistemic Objects*). Yet, while the hammer only allows us to connect the wall and the nail, a model also allows us to *learn* about the two sides that it connects. An interesting aspect of this view is that we do not learn from the model

just by looking at it, but by building it and manipulating it, and that is why they are *tools* (or, as Knuuttila would say, epistemic objects).

It is worth emphasizing that conceiving of models as (some sort of) instruments does not commit us to an instrumentalist position about models. Typically, instrumentalist accounts of models are accompanied by antirealism. Models do not give epistemic access to an objective reality, which is independent of the epistemic agent. But Morgan and Morrison in no way deny that there is a reality out there to be discovered and studied. They emphasize, instead, the instrumental function of the models as they mediate this *access* to reality. Models allow us to gain the knowledge of reality, and this also in virtue of their representative function. Similar positions have also been developed by *Hesse* [44.48] and *Cartwright* [44.49].

### 44.3.2 Isolations

In his work, *Mäki* [44.50, 51] is interested in the modeling process in economics, with particular reference to the broader problem of realism and antirealism. Mäki makes the point that the entities studied in economics are not really independent, in the same sense as a realist in physics can think of the electron as an independent entity. Some economic entities certainly are dependent on the epistemic agent. That is to say, some objects in economics, such as the preferences of economic agents, are not directly accessible through our senses, but are instead *mind dependent*. Yet, many of the objects described and studied in economics are part of our common sense of understanding of the social world, to which belong other economic entities such as prices, wages, and taxes. Some entities, such as wages, have also the physical counterparts (assuming we grant physical reality to our bank account balance!), while others remain theoretical constructs, such as, for example, preferences or values.

Mäki is interested in the modeling process of those economic phenomena that affect these *common sense* entities. Mäki points out that since the early history of economic theory – think of John Stuart Mill, Karl Marx, Carl Menger, or Alfred Marshall – we proceeded by *abstraction* and *isolation*. On one hand, economic theory starts from premises that are incomplete, and in a sense, even false. For instance, economic rationality, which does not take into account all factors involved in the choices taken by economic agents. This incompleteness is also accompanied by a form of idealization, or *isolation*, of those factors considered instead relevant. Isolating means that, in explaining a phenomenon,

some elements are deliberately removed in order to simplify it. This process of isolation makes a complex phenomenon more tractable from a theoretical and also a practical point of view.

The purpose of these idealized – and strictly speaking *false* – assumptions is to implement some *theoretical isolations* in a controlled manner. This allows, according to Mäki, to make complex phenomena understandable and manageable. A similar account of modeling can also be found in the work of Nowak [44.52].

### 44.3.3 Maps

Giere [44.53] develops an account of the relationships between models and reality. Giere supports two related positions. One is that the results of science are *perspectival*. This means that scientific results are the product of the perspective adopted in studying a phenomenon. A relevant analogy is with color vision, which is not an objective fact, but depends both on the inputs received and on the instrumental apparatus used (including our perceptual system). More explicitly, this means that, whatever science establishes – or, whatever the *scien-* *tists* establish – vitally depends on a several aspects, from the data used to the analytical methods used (instrumental and experimental apparatus, and various types of models). How is this related to the discussion about models?

First, for Giere, models are models *of data*, not of theories. Giere emphasizes the empirical aspect of models: once data are collected, they must be modeled. Surely we need theories to develop models, but *data* are the starting point. This aspect is important because, contrary to what is sometimes said, data do not speak for themselves, not even if you torture them. The adage “If you torture the data enough, Nature will confess” is attributed to British economist Ronald Coase, Nobel Prize for Economics in 1991, who claimed the importance of studying real, rather than hypothetical markets.

## 44.4 Models and Neighboring Concepts

Modeling is at the very heart of scientific reasoning and rightly occupies an important place in the philosophy of science. But we cannot discuss models and modeling abstracting from other important issues. In this section, I will examine some selected topics that are closely related to model-based reasoning.

### 44.4.1 Simulations

In Sect. 44.1, I offered an overview of the various models used in the social sciences. That overview, however,

To use the classification of Sect. 44.1, Giere focuses on empirical models (either quantitative and qualitative), not on theoretical models. Second, models are like *maps*. Maps, to be sure, are not true or false, but useful or useless for a specific purpose. An important consequence of this position concerns the concept of *truth*, which ceases to have a *metaphysical load*, and is instead used only in a *minimal* sense. I shall get back to the issue of truth in Sect. 44.4.3.

A notable aspect of this perspectival account is that it pays careful attention to the scientific practice, or rather the practices of the scientists, that form a community. In other words, Giere discusses the meaning and use of models in very specific terms, anchored to the scientific practice and the activities of those who practice science. Thus, the epistemic activities involved in science, in which modeling is certainly central, are then *distributed* – distributed across all the individuals that belong to the scientific community (on distributed cognition, see also [44.8]).

Although Giere’s account is not specifically tailored to the social sciences, it is helpful in order to address the vexata quaestio of *objectivity*. The development and the increasing use of quantitative methods in the social sciences can be read as an attempt to give objectivity to disciplines which, historically, have been blamed for being too subjective and not rigorous enough (on this, see, for example, *Montuschi* [44.18]). However, if we embrace a perspectival approach such as Giere’s, then the role of the epistemic agent (the scientist) in model-based reasoning should not be reduced as much as possible, but should instead be studied and understood as much as possible. Some of these issues are also touched upon in the positions discussed earlier (Knuuttila, Morgan and Morrison, Mäki) and more generally in the literature on scientific understanding, whose impetus was given by the article by *de Regt* and *Dieks* [44.54] and continued in the volume edited by *de Regt* et al. [44.45].

has a striking omission: simulations. Models have been classified according to their quantitative or qualitative character, and according to whether they are experimental or observational. Yet, some models do not fit in this categorization: these are the simulations. Simulations are increasingly used in the sciences, including the social sciences, and offer insights into philosophical investigations.

The goal of a simulation is to emulate a certain system, also called a *target* system. For instance, one can simulate the flight of an airplane; the airplane is repro-

duced on a smaller scale, placed in a wind tunnel and its behavior studied in simulated weather conditions, such as a storm. In these cases, we try to reproduce the target system on a smaller scale. This type of simulations raises quite a number of questions, not least because they are based on the assumption that a reduction of scale leaves unchanged the essential characteristics of the system.

There are other types of simulations, which perhaps raise even more philosophical questions. These are *computer simulations*. These simulations mimic or attempt to reproduce the operation of a real system in silico. We can simulate biological systems, such as the cell's apoptosis, or physical systems, such as collisions between particles. In the social sciences, simulations are used to study processes like urbanization of a city, of socialization between groups, etc. Simulations are often used to model complex systems, whose behavior is not easily predictable (think of models in meteorology). The aim is to be able to reproduce the state of a system as it evolves from certain initial conditions that are set in the computer program. Simulations have an interesting, hybrid status between experiment and theory.

In the social sciences, we are often confronted with a further difficulty: available background knowledge may be quite poor. In these contexts, in fact, simulations are used precisely to *acquire* new knowledge of a phenomenon. Part of the debate is about whether, and to what extent, computer simulations accrue the explanatory and predictive power of models. This is far from obvious, as the output of the computer program *depends* on the instructions entered by the programmer. This does not mean that the simulations are not useful. On the contrary, their extensive use both in physics and biology, as well as in the social sciences, suggests that there is a conceptual and methodological potential to be explored, and to which philosophy is paying increasing attention ([44.55–59], and for the social sciences more specifically see, for example, [44.60–62]).

In sum, simulations are an important topic for a chapter on model-based reasoning for two reasons. On one hand, simulations *are* part of the methodological baggage of the social sciences; on the other hand, because of their hybrid status between theory and experiment, they are a fertile area for philosophical investigation.

#### 44.4.2 Causation and Explanation

In Sect. 44.1.2, I quickly outlined the distinction between associational and causal models. It is worth developing the issue further, as it is not just about technical and methodological aspects, but also (and especially) of philosophical and conceptual importance.

At the very basis of this distinction lies the perennial question about causal inference: how/when/under what conditions we can infer causation from correlations and probabilities? In turn, this question brings us to the following one: What is causality? Does causality have a special meaning in social contexts?

Instead of addressing the question directly, I shall get to it via a distinction that has been made in the recent debate in the philosophy of causality: production versus difference making (or, in the terminology introduced by Hall [44.63], *production and dependence*). Here, I shall apply concepts, more narrowly, to the *evidence* that supports a given causal claim, rather than to *types of causality*. Thus, for instance, establishing that smoking is a risk factor for lung cancer (actually, for most types of cancer), means establishing, in the first place, a *difference-making* relation between two variables: smoking and (deaths due to) lung cancer. A difference-making relation would state that variations in the quantity of smoked cigarettes (e.g., less than 10, between 10 and 20, more than 20) are associated with the number of deaths due to lung cancer (in a given population and in a given timeframe). It is in this sense that smoking *makes a difference to* lung cancer.

Often, however, to determine whether these difference-making relations are causal, we also need evidence of production, namely of *how* smoking causes cancer. Evidence of production includes information coming from biomedicine, for instance about the mechanisms of carcinogenesis triggered by smoking. But it also includes information about social, psychological, or behavioral mechanisms. These help understand the production of cancer in a nonreductive way (on this point, see [44.64]). An overview of the question causality and evidence is offered in [44.14], who frame the problem of evidence not only within the debate on evidence-based medicine, but also within the broader question of the methods for causal inference.

The distinction between evidence of production and of difference making, and their complementarity, is relevant to model-based reasoning in the social sciences. In fact, while the quantitative models presented in Sect. 44.1.2 generate evidence of difference making, it is less clear how they also generate evidence of production. The issue is investigated in [44.11], who examine the case of econometric models in particular.

Another important aspect concerns the explanatory power of a quantitative model. In analytical sociology and in the structural modeling tradition, some scholars emphasized the role played by mechanisms in explaining social phenomena. *Ruzzene* [44.65] clearly explains how the social sciences developed and used the concept of mechanism, building a bridge between the social science and the philosophical literature. Another inter-

esting line of research worth mentioning concerns the interpretation of structural models. To be more precise, what is at stake is the interpretation of a probabilistic structure as a mechanism (for a phenomenon) – on this point, see *Mouchart et al.* [44.12, 66], who discuss different positions found in the literature.

### 44.4.3 Truth and Validity

In the course of the chapter, I mentioned several possible purposes and uses of models, some of which have just been discussed: models may be used to explain, to establish causal relations, or to simulate a phenomenon. In this section, I address the following question: What makes a model *good* or *useful* or *real*?

To begin with, it is worth emphasizing that models, strictly speaking, are neither true nor false. This idea underlies the account of Giere, discussed in Sect. 44.3.3, as he emphasizes the *usefulness* of the models. The view is also supported by Mäki, discussed in Sect. 44.3.2, as he highlights the process of idealization and simplification of certain hypotheses and assumptions in model-based reasoning. *Basso and Marchionni* [44.5] discuss the issue of the falsity of the assumptions of model-based reasoning in economics. All these arguments are based on the analysis of scientific practice. In the following, I would like to offer different line of argument instead.

Truth and falsity apply, strictly speaking, to statements. For instance, the statement *The program Word is used to write texts with the computer* is true. Most competent speakers will also consider true counterfactual statements such as the following, although their truth conditions are notoriously more difficult to establish: *Had I heard the alarm, I would not have missed the train.* The results of models too can be formulated as well-formed statements and consequently – one might argue – they can be true or false. As we have seen in Sect. 44.2.1, this was the strategy of the neopositivists at the beginning of the last century in order to clarify the notions of model and theory.

How do we *build* a scientific statement? Suppose that we study the effects of smoking cessation on mortality rates due to lung cancer. Suppose that the analysis of the data allows us to establish that the mortality in the target population (that quit smoking, or smoked less) actually decreases. We will be inclined to express the results of such a study as follows *Quitting smoking reduces the chance of developing cancer by 60%* (the numbers are clearly imagined). Note that this is what we routinely find in popular science articles, TV programs, etc. Is it true that eating broccoli and cauliflower prevents cancer? Is it true that banner ads influence our purchasing decisions? These questions can be answered

with simple, well-formed statements summarizing the results of scientific studies. However, I would like to suggest that the crucial question is *not* whether these statements are true or false, but rather whether the entire model behind it is *valid* or not. The suggestion is to *freeze* the question about truth until we clarify how we build such statements, and then get back to it. The intention is not to create a conceptual opposition between truth and validity. On the contrary, the proposal is to sketch a possible path of research. So the first step is to shift the discussion toward a different notion: validity.

In the social sciences, *Cook and Campbell* [44.67] laid down the foundation for a systematic discussion of the concept of validity. These scholars distinguished two types of validity within quantitative modeling: internal and external. *Cook and Campbell* [44.67] actually distinguish four types of validity: internal, external, statistical, and construct. For the sake of simplicity, I present only internal and external validity, which are the most discussed ones in the literature. Internal validity refers to the possibility that the relationship between two variables, within a given model, is causal or, conversely, to the possibility that, given the lack of correlation between two variables, we conclude that there is no causal relation between them. External validity concerns the possibility of generalizing a causal relationship, established within a specific model, to different populations or settings. External validity, or extrapolation, is the object of another debate, extremely relevant to the philosophy of science and to the scientific practice. Some philosophers, notably *Guala* [44.68] and *Steel* [44.69], tried to explain the conditions and procedures that allow us to generalize, or extrapolate, the results of a study to other populations. Paradigmatic cases concern the biomedical sciences, where it is far from obvious that we can draw conclusions about the aetiology of a disease or the active ingredient in a drug for human patients from animal models.

For instance, demographer Daniel Courgeau developed a multilevel model to explain the phenomenon of migration in Norway using data from censuses in 1960, 1970, and 1980. Simply put, Courgeau explained that the farmers, usually nonmigratory, underwent pressures to migrate, because the percentage of farmers within their region considerably increased. An explanation based on a multilevel model delivers results that are valid for Norway during those years. However, this is not necessarily applicable to other countries, including Norway itself, but in a different historical period (or under different socioeco-demographic conditions). The account of Cook and Campbell sparked a lively debate in the methodology of the social sciences. For instance, some think that internal validity is more important, some the opposite. Under debate is also the

issue of whether external validity is necessary, or even attainable, in the social sciences. The concept of validity is sometimes given different meanings, as it can refer to the data, the model, or the results. So far I have addressed a question about the meaning of the concept of validity. Let us see how we decide whether a model is valid or not.

In Sect. 44.1, I touched upon the issue of building and testing models. I mentioned that data can be collected, for example, with surveys or interviews. I also mentioned that we analyze data in different ways, for instance using statistical models, which in turn may be very different depending on the type of data to be analyzed and on the phenomenon to be studied. I also briefly sketched the main features of the hypothetico-deductive method that embraces different stages of modeling building and testing, from data collection to the interpretation of results. To determine whether a model is valid or not means to determine whether the entire modeling process is cogent. At each and every step of the process, we can ask if things have been done correctly, or if they could have been done differently, or better, or if there were errors that influenced later stages of the modeling procedure.

Now, the question is: Why should validity be opposed to truth? In fact, whether there is opposition or not depends on what conception of truth one adopts.

According to a well-established philosophical tradition that traces back to Aristotle, the truth of a statement is established via a correspondence between a linguistic expression and some state of affairs. According to a Tarskian analysis, *The snow is white* is a true statement if, and only if, the snow is white. That is, I open the window, I verify that snow is actually white, and declare the statement true. This interpretation of truth is plausible until we deal with simple things like white snow, the desk I work on, and any other situation within the remit of unsophisticated empirical tests. This is an over simplification, however. Think of the empirical test of the color of my desk, made by myself and by my colleague, who is color blind on some frequencies. The statement *This desk is grey* will be true for me, and most likely false for my colleague. The problem is known to philosophers of science, who, however, addressed the issue in relation to nonobservable entities (including, most famously, electrons). This simple example shows that the problem of empirical control, and consequently of the truth of a (scientific) statement, arises already at the level of the observables. For a discussion of a verificationist approach and realism Dorato [44.70].

Consider again the (fictitious) study on the effects of smoking cessation on mortality due to lung cancer. The question is whether we can determine the truth of

the statement *Quitting smoking reduces the chance of developing cancer by 60%* by some kind of correspondence. In this case, as in many others, it is not obvious to find a *fact*, *state of affairs*, or *truthmaker*. Every study has a population of reference; does it follow that there is a truthmaker for each of these? Or is there *one* truthmaker that transcends them? The majority of studies make use of variables constructed from different indicators. Does it follow that there is a unique way to isolate facts or states of affairs like *quitting smoking*? In sum, the difficulty in finding an easy and clear correspondence between our scientific statements and some facts, state of affairs, or truthmakers stems from the fact that social reality is notoriously elusive and, to some extent *constructed* (but some may argue the same holds for natural phenomena) – an idea that has been developed by Latour [44.71] or Hacking [44.72], to name only the most prominent theorizers.

One option is to reduce the metaphysical burden of the concept of truth, and to make it less rigid and more usable. We can do this by trying out the conceptual tools that come from the philosophy of information. There, *truth* is not cashed out in terms of correspondence but with respect to the information network in which a certain expression is embedded. Truth, according to this view, does not collapse into the concept of validity. The truth of a statement (e.g., a scientific statement) is established (also) on the basis of the validity of the model within which it has been formulated. Let us see how truth can be conceptualized from an informational perspective, and then go back to the relationship between truth and validity.

The concept of information has a relatively recent history. In the last decades, mathematicians, engineers, and information technologists developed theories of information that revolutionized, in many ways, our information and communication technologies. Philosophers also deserve credit, as they initiated a new branch in philosophy that makes central the notion of information and also offers new methods for philosophical inquiry. The main theorizer and proponent of the philosophy of information is Floridi [44.73].

Floridi offers the following general definition of information (GDI) coupled with the *veridicality thesis*. Simply put, according to the veridicality thesis, truth *is* part of (semantic) information: *p* is an instantiation of information, understood as semantic content, if, and only if:

- (GDI1) *p* consists of *data*.
- (GDI2) Data in *p* are *well formed*.
- (GDI3) Well-formed data are *meaningful*.
- (GDI4) Meaningful well-formed data are *truthful*.

According to this definition, the four basic elements of semantic information are:

- (i) Data
- (ii) The *structure* of data
- (iii) Their *meaningfulness*
- (iv) Their truthfulness.

For Floridi, structuring data is not confined to giving a set-theoretic structure to well-formed formulas, but includes any *rule* for governing a given system, code, or language being analyzed. Thus, a probabilistic structure of the type discussed in Sects. 44.1.2 and families of probability distributions counts as structuring the data. *Meaningful* refers to any way of complying with the semantics of a given system, but not confined to language. Thus, nonsense correlations, such as the correlation between the rise of bread prices in England and sea level in Venice, would be *meaningless* under this account. The next step is to connect meaning to truth. In this context, *true* does not have a correspondentist meaning. Floridi defends a *correctness* theory of truth that provides an account of how well formed and meaningful data become truthful. Simply put, a truthful expression is one that is *correct* within the modeled system. There is not a truthmaker making a statement true, in a correspondentist sense. There is a network of information that the agent (the competent speaker, the scientist, etc.) processes in order to establish the

truth of a statement, and this highly depends on the data considered and on the way they are (or are not) well formed.

Let us get back to scientific statements. How shall we determine if they are true? The network of information includes considerations made to decide about the validity of the model. We establish the truth of a statement within the framework of a modeled system, analyzing the various stages of model building and model testing. Therefore, in establishing the truth of a statement, we are not referring to a fact or state of affairs or truthmaker that makes it true. We refer to a whole network of information that includes the accuracy of the modeling phase, the adequacy of the empirical results with respect to background knowledge, the role of scientific evidence in its various forms (correlations, mechanisms, etc.). Then the *plot* or informational network that the epistemic agent builds – and that constitutes their knowledge – gives us the truth of a statement.

There is no doubt that these sections do not exhaust the problem. I lack space, here, to develop this approach in detail. The interested reader can consult *Floridi* [44.73] and also the introductory textbook available on the website of the Society for the Philosophy of Information, outlining the main arguments about truth, knowledge, and validity from an informational perspective.

## 44.5 Conclusion

The objective of this chapter was to provide an overview of model-based reasoning in the social sciences, to locate it within the debate on models that extends outside social research, and to highlight some of the aspects worthy of further philosophical investigation.

I opened the chapter with a description of several modeling practices in the social sciences and categorized them according to the techniques for data analysis they use (quantitative or qualitative) and according to their observational or experimental character. What emerges from this overview is a multifaceted concept. There is not one account of the concept of *model* that captures all the aspects involved in these different modeling practices. Also, the received view – according to which models represent portions of reality using set-theoretic structures – does not seem to fit the case of the social sciences. Yet, models in social research (especially quantitative models) do represent portions of reality, but by means of families of probability distributions. These are the heart of statistical models and

raise important questions about the stochastic character of phenomena (and of causality) and about the possibility of explaining phenomena mechanistically.

Models are also *objects* that we can manipulate to gain knowledge of phenomena. This view offers an account of the concept of “model” and also offers ideas to investigate relationships between models and reality. The three accounts I presented (models as mediators, maps, and isolations) do not answer *exactly* the same question. Rather, these approaches tackle *some* aspects of the relationship between models and reality highlighting different stages of the modeling process. These accounts should not be seen in opposition or competition to each other, but should instead be seen as being part of a complex mosaic portraying model-based reasoning in science.

From the discussion of the previous section, it should be clear that the interest in the concept of the model is not confined to finding the most appropriate definition. Model-based reasoning is the heart of the scientific process and this is closely linked to other no-

tions, all central in the philosophy of science. In this chapter, I could only provide a preview of debates and issues that are far more complex and fascinating. Some, such as the relationship between the model, causality and explanation, belong to the perennial questions in philosophy of science. Others, for instance, concerning the explanatory or predictive role of simulations (especially in silico), are more recent but no less controversial or relevant. Finally, I suggested that the question of truth, at the basis of science as well as philosophy, can be addressed in the light of another concept: the validity of a model.

Many issues have not been covered in this chapter, sometimes for the lack of space and sometimes because they are outside the area of competence of the author. For instance, philosophy of science has traditionally given a lot of importance to the predictive power of models and theories (especially in physics). In the social sciences, the problem of prediction has rather different contours, however. I will just mention two points, hoping to stimulate the reader's interest. A demographic projection is not meant to test the predictive power of a theory, that is, to predict a *new* observation. A demographic projection aims instead to anticipate the structure of the society in 20 or 30 years, in order to design adequate socioeconomic or public health policies. Another aspect deserves attention. Typically, in the social sciences, the best predictive models are the ones with less explanatory power. That is to say,

simpler statistical models, with fewer variables, deliver more reliable projections than more complex, structural models with many explanatory variables. We are then confronted with an interesting asymmetry between prediction and explanation which, to my knowledge, has not been sufficiently investigated.

To conclude, a philosophy of modeling – covering both a discussion of the concept of the model and the various epistemological and methodological aspects of model-based reasonings – must seek synergies with the scientific practice, on the one hand, and with other branches of the philosophy of science, on the other hand. In fact, given the hyperspecialization of both science and philosophy, we need to engage in a dialogue, in order to formulate relevant questions and useful answers. At the same time, and again because of this hyperspecialization, philosophy of science must try to build an integrated view of the scientific practice (current practices, or found in the history of science) where various concepts find their place, like in a mosaic.

**Acknowledgments.** I wish to thank the editors, Mauro Dorato and Matteo Morganti, for the opportunity to contribute to this volume. I owe much of what I know and understand about model-based reasoning “in practice” to social scientists Michel Mouchart and Guillaume Wunsch. Finally, I wish to thank my friend and colleague Phyllis Illari – for her insightful comments and most enjoyable conversations.

of Financial Markets**

Giovanna Magnani, Pavia, Italy

**52 Application of Models  
from Social Science to Social Policy**

Eleonora Montuschi, Venice, Italy

**53 Models and Moral Deliberation**

Cameron Shelley, Waterloo, Canada

The chapters contained in this part provide an overview of model-based reasoning in a variety of humanistic disciplines. Some of these disciplines relate to the material practices of humanity, including architecture, archaeology, design, and technological innovation. Others relate to humanity through its policy practices, such as pedagogy, crime, economics, the social sciences, and moral reasoning. Of course, the disciplines discussed here are diverse, and have specialized histories and concerns. At the same time, each one is devoted to what might be termed *inhabitation*, that is, ways that people have of living in and adapting the world around them.

For present purposes, inhabitation refers to how people interact with their material environment, especially for the purpose of adapting it to their wants and needs. It also refers to how people organize and regulate their activities, adapting their actions in view of their significance for others. The demands of inhabitation are a crucial part of human nature and history.

It is striking how significant model-based reasoning is to studies of inhabitation. In reading the chapters of this volume, readers will be impressed with the diversity of models employed and the variety of insights that can be gained through them. It becomes quite apparent that inhabitation itself is crucially dependent on different kinds of model-based reasoning. The same can be said for studies of inhabitation in divergent disciplines. So, it is fitting to have an overview of human sciences with model-based reasoning at its center.

**Chapter 45** provides an overview of modeling as it figures in the practice of architecture. This chapter well illustrates the, not always appreciated, fact that what counts as a model, and as model-based reasoning, depends upon the tools at hand. Traditionally, architects employed sketches of plans and elevations, as well as scale models. Recently, the tool kit has expanded to encompass an array of computer-based aids. Modern architecture, then, requires command of an expanding set of modeling tools and a facility for integrating them in the minds of the architects. The chapter shows how such integration occurs through a recurrent process of abductive, deductive, and inductive reasoning.

**Chapter 46** presents a taxonomy of model-based reasoning as used in archaeological interpretation. Models have long been employed to characterize and understand the archaeological record, either through abstraction from archaeological traces or comparison across cultures. A key issue of debate has been how well models can support substantial, scientific conclusions rather than merely whimsical speculations. The chapter illustrates challenges posed by models in archaeology

and how practitioners have employed models with satisfactory results.

**Chapter 47** illustrates how ideologies affect the use of models by the designers of material technology. Besides aiming to meet technological requirements, designers also use models to promote social ideals. Those ideals could include a religion, such as Catholicism, social arrangements such as universalism, lifestyles such as consumerism, or disciplinary traits such as reductionism. The chapter indicates how model-based reasoning can be an expression of the reasoner as well as a response to external requirements.

**Chapter 48** illustrates how models may constitute and facilitate technological innovation. Traditionally, innovation is viewed as the domain of producers of technology. However, consumers also participate in innovation through ways they find to adapt and find new value in products or services. The Innovation Marketplace shows how this process of invention relies on models and model-based reasoning, and has also been adopted as the standard method for data exchange by government and industries in Japan.

**Chapter 49** surveys the sciences of education from a variety of perspectives. In the history of the subject, models of pedagogy have been constructed on psychological, philosophical, institutional, and ideological premises. In all cases, accounts of pedagogy focus on the central problem of teaching and learning for which models are constantly being proposed, applied, and assessed. Continuing focus on this process shows how important models and modeling are to it.

**Chapter 50** shows how models may figure in the study of crime and law enforcement. Computational modeling has been employed chiefly to clarify theories of crime. As the ambient intelligence model suggests, computational models may also be employed to guide responses to crime by law enforcement through analysis based on the concept of crime displacement. Thus, model-based reasoning is crucial to both understanding crime and reacting to it.

**Chapter 51** reviews and discusses models of the behavior of financial markets, their response to risk and uncertainty, and the resulting tendency toward economic crises. As the crisis of 2007 illustrates, modern capitalism is prone to sudden periods of instability. Famously, this same crisis brought about a resurgence of attention to Keynesian ideas about finances and financial policy. This crisis and Keynesian models for its explanation are the point of departure for this chapter, which explores how uncertainty conditions the sometimes vertiginous behavior of financial markets.

Chapter 52 considers the role of causal models in social science research and their use in social policy construction. Although models are used throughout the social sciences, their ability to account rigorously for social phenomena and to motivate effective interventions is disputed. This chapter explores the nature of causal models and the qualities they have that support rigorous and applicable social science research.

Chapter 53 discusses various ways in which models figure in people's thinking as they solve everyday moral problems. Not surprisingly, models are central to this kind of moral deliberation. However, accounts of this phenomenon vary widely due to the different accounts of models adopted. This chapter surveys the main accounts of moral deliberation with their varying representations of models. The result is an improved understanding of the crucial work models do as people make moral decisions.

# Models in A

## 45. Models in Architectural Design

Pieter Pauwels

At one time, architects and construction specialists used to rely mainly on sketches and physical models as representations of their own cognitive design models. Today, they rely increasingly on computer models including parametric models, generative models, as-built models, building information models (BIM), and so forth. Of course, processes of abstraction and the actual architectural model-based reasoning itself remain in the mind of the practitioner who is in control of the design and construction process. However, this whole new array of alternative computer-based representation models has profoundly affected decision-making in architectural design and construction. In this chapter, a brief overview is first given of the state-of-the-art in design thinking research. Following this, an outline is given of how diverse data models, such as BIM and parametric models, are currently used in architectural design and construction. An indication is then given of how these models relate to the in-mind model-based reasoning on which architectural designers and construction experts rely in decision-making and creative thinking. This outline will not only review well-known theories of design thinking and architectural design practice, it will also integrate ongoing theoretical research about analogical reasoning and about abductive, deductive, and inductive reasoning.

The word *model* is ubiquitous in the current practice of architectural design and construction. Whereas architects and construction specialists used to rely mainly on sketches and physical models as representations of their own cognitive design models, now they rely more and more on computer models (or computer representations of their cognitive design models). Parametric models, generative models, as-built models, BIM, and so forth,

are used day in and day out by any architectural design and construction practitioner. Although processes of abstraction and the actual architectural model-based reasoning itself still occur in the mind of the practitioner, who is in control of the design and construction process, of course, this whole new array of alternative computer-based representation models has its impact on decision-making in architectural design and construction.

## 45.1 Architectural Design Thinking

Understanding how designers think has been the goal of many research initiatives during previous decades. Several relevant overviews are available that describe the evolution of these research initiatives and their outcomes [45.1–3], therefore we will not elaborate here in extensive detail. With the emerging interpretation in the 1970s of the design process as a process in which *wicked problems* [45.4, 5] or *ill-structured problems* [45.6] are to be *re-solved*, over and over again, design is now more and more considered as a practice or a discipline in its own right, rather than a science that can be addressed using a rigid methodological approach (see for example [45.7, p. 11]).

### 45.1.1 The Architectural Designer as a Practitioner

The basis of this interpretation relies heavily on the theories by *Cross* [45.8], *Lawson* [45.9], *Schön* [45.10], and *Simon* [45.11]. These theories typically acknowledge the complexity of the design process and the role of design thinking within this process. An architectural design situation is not necessarily considered as a design *problem* that is defined by a well-structured set of constraints, and in which a number of adjustable parameters is available. Instead, a design situation in these theories is typically understood as a snap-shot, in terms of time, in the overall design process, in which a limited number of constraints and parameters are taken into account and adjusted by a designer, in order to *satisfice* the design situation, as interpreted at that moment, into an alternative and new design situation. The term *satisficing* refers to the attitude of architectural designers to *sufficiently*, instead of *entirely*, satisfy constraints (see also [45.6] and [45.12, p. 224]). In terms of optimization approaches to design, it is typically indicated that designers look for suboptimal (but satisfactory) solutions rather than for *the* most optimal solutions.

In the theories following the above understanding, a key role is typically taken by the designer as a decision-maker. Designers are considered to be reflective practitioners [45.10]. *Schön* hereby refers to architectural designers, baseball pitchers, and musicians as example practitioners [45.10, pp. 54–55]. These practitioners continuously decide which constraints they wish or do not wish to adhere to, and which parameters they wish to use in what way. In contrast to the earlier belief of designers having a *problem-focused* strategy, they are now believed to have a more *solution-focused* or *goal-oriented* strategy instead [45.11, 12]. They proceed forward through the design process, continuously facing new design situations and addressing them as

they see fit in order to obtain the goal they have in mind at that specific moment in time. After addressing these design situations, the goal and the architectural knowledge (that were used to rely on) are typically adjusted based on the “back-talk of the design situation” or “situational feedback” [45.10]. Continuously taking action on design situations results in a co-evolution of problem space and solution space (see Fig. 45.1 and [45.13, 14]). In other words, architectural designers learn while doing, not only about the design situation at hand, but also about architecture and design in general.

Two key features of the prevalent current understanding of the design process can be distinguished in the above paragraphs:

1. An intensive interaction exists between designer and design context, thereby resulting in a stepwise proceeding through the design process.
2. Design thinking has an important reflective, *learning-while-doing* character [45.10], enabling designers to learn from experience.

We provide a simple schematic image of this interpretation of the (architectural) design process in Fig. 45.2. It indicates how a designer forms a mental model from an observation of the external world or design situation, and uses this mental model to devise an appropriate action for altering the design situation into a new one that can ideally be considered more optimal than the previous one.

### 45.1.2 Where Are the Models in all This?

The title of this chapter suggests that models are key to the above outlined features of the interaction between designers and design situations. Although the above paragraphs did not contain the word *model* too abundantly, it is present in all stages of the design process, in each step taken by designers in the direction of a fi-

**Fig. 45.1** Maher and Poons problem-design exploration model

nal (satisficing) design situation (not solution). In each interaction, namely, architectural designers rely on their background knowledge in making the appropriate decisions. This background memory is central to the above design process. After each decision, feedback or situational backtalk is returned to the designers by the design situations with which they interacted [45.10] (see also the oil painting example given by *Simon* [45.11, p. 163]). As this situational backtalk is interpreted by the designers, it also reshapes the background knowledge of these designers.

In learning-while-doing, designers build up knowledge in direct reference to concrete experiences. This knowledge might be related to “a designerly way of knowing” [45.8, 15], which was originally put forward by *Archer* in 1979 [45.16, p. 348]. On the basis of this kind of knowledge, designers make design decisions in newly encountered design contexts. Through their ongoing interaction with new design contexts, designers continuously modify or adjust their designerly way of knowing. Obviously, these adjustments have a significant effect on future design decisions.

It is important here to consider the stepwise evolution of the design process. As each step in the design process (or each consecutive design situation) can be considered a snapshot, the evolutions in design knowledge of the designer can also be considered in a stepwise manner. Each step in the evolution of someone’s design knowledge can hereby be considered a design model. This idea follows the theory by *Schön* about the architectural designer as a reflective practitioner, continuously interacting with the surrounding context and being affected by the backtalk of that surrounding context [45.10]. As explained here, Schön also indicates that design thinking depends on the repertoire or knowledge and experience of the designer. So, the context and background of designers play a key role in all steps of the decision-making processes of those designers. This idea also explains the notion of co-evolution in design problem and design solution [45.13, 14], assuming that the design *problem* can be considered the same as the

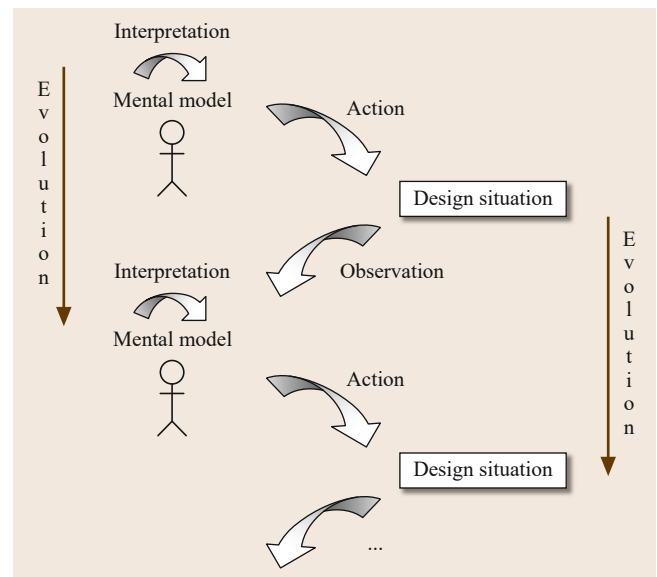

**Fig. 45.2** Schematic outline of the steps (observation – interpretation – action) that are taken by designers during the interaction with an external design situation

current design situation, and that the design *solution* can be considered the same as the internal interpretation or model of the design situation in the designer’s mind (Fig. 45.3).

The changing background knowledge of the designer has been discussed at length by *Lawson* [45.9, p. 159]. He uses the term *guiding principles*. These guiding principles can be understood as the personal background knowledge or the knowledge by experience of a designer. They consist of familiar design patterns that a designer relies upon throughout the design thinking process. A designer thus never starts a design from an empty page, never from scratch or a blank mind. Instead, a designer always relies on a lifetime of knowledge built up by experiences. It is documented in [45.9, p. 179] how these guiding principles, in combination with a mental model of the situation at hand, essentially guide practitioners (including designers) through their thinking process. They play an important role not only in framing the design situation, but also in generating solutions for a problem, devising experiments, and in learning from experiences.

According to *Lawson* [45.9, p. 159], these guiding principles include not just objective, factual information, but include much more information, involving, for instance, motivations, beliefs, values, and attitudes. Guiding principles may be very intense and clearly structured or, on the other hand, vague and unclear, but they always influence design decisions one way or another. These characteristics of guiding principles can be related to the tacit dimension suggested by

**Fig. 45.3** Schematic outline of the co-evolution of the mental model of a design situation and the external design situation

Polanyi [45.17, 18], who states that some knowledge cannot be formalized and is essentially experience-based, vague, and thus tacit. In some research initiatives, guiding principles are almost considered part of a *personal religion*, thereby implicitly redefining design as “a very complicated act of faith” [45.19, p. 3]. This refers to the sometimes profound intensity of the designer’s belief in personal guiding principles, making it *morally right* to follow them. It is similarly indicated by Ward [45.20] how imagination relies almost entirely on known concepts, and, although modifications are made, they are typically only constituted by different combinations of known elements. It is hard to entirely step outside one’s own categories and beliefs, also in imagining [45.20].

It is very unclear in what form guiding principles are stored in the mind of a designer. What is clear though, is that this background information serves as a kind of repertoire of reference models for the designer to continuously and actively reorganize and restructure new design situations in memory into new abstract mental models or understandings of those design situations. In this context, references can be made to the work on case-based reasoning (CBR) [45.21–23], in the sense that the concept of CBR captures the idea of matching new cases with previously encountered cases in order to appropriately act upon them (Fig. 45.4).

### 45.1.3 Abstraction, Sense-Making, and Framing into Mental Models

From the previous sections, we now see that there should be some mechanism or phenomenon that allows architectural designers to *link* incoming design situations to their available repertoire of reference models (their experiential background information) so that they can obtain an abstract in-mind interpretation of those design situations. Basically, this is a moment of *interpretation* or *abstraction*. It occurs when a designer is sketching and all of a sudden gains an insight in the form of recognizing a part of the sketch as something he has seen before in an alternative context. It occurs when an architectural designer is visiting architectural building sites in order to find inspiration for the issues he is struggling with in the design he is working on. It occurs when the architectural designer communicates his latest design to a client or to any related or unrelated third party and gets insight from the feedback he receives through simple conversation. While doing each of these things, the architectural designer appears to interpret or make abstraction of the incoming information, after which he relates it in his mind to what he has experienced before. Previously used names for this phenomenon are *retrieval* (in the context of

Fig. 45.4 Schematic outline of the case-based reasoning (CBR) process (after [45.21–23])

CBR – Fig. 45.4), *sense-making* and *problem framing/setting* [45.10, 24–27].

In [45.10, 26], for instance, design thinking is characterized as a specific kind of problem solving, in which the designer “must make sense of an uncertain situation that initially makes no sense”. Making sense of the situation then happens by switching back and forth between problem and solution, while continuously reframing both. Schön [45.10, pp. 39–40] refers to problem setting as:

“the process by which we define the decision to be made, the ends to be achieved, the means which may be chosen. In real-world practice, problems do not present themselves to the practitioner as givens. They must be constructed from the materials of problematic situations which are puzzling, troubling, and uncertain.”

In architecture, this often happens in the interaction between the client and the architect. This interaction usually starts with a client having an impression of what he wants to achieve, and an architect who does not have a clue of the client’s desires and needs. Often, these desires and needs are conflicting or do not seem to make sense. But, through the continuous feedback that the architect receives from the client, this design brief gets an increasingly clear structure in the designer’s mind. The architect thus sets the problem (how many floors

are requested in the building, who will be accessing and using the building, and so forth) through interaction with his surroundings. Initially, these surroundings are constituted by the feedback of the client, but later on, they will be formed by the sketch on his paper, visits to the building site, conversations with third parties, and so forth. One might say that the problem and solution are continuously reframed, resulting in a co-evolution of problem and solution. One might also say that the design situation is evolving step-by-step by the impact of an architect who decides based on his background knowledge and the context he is working in.

It is made clear by Schön [45.10] just how important the element of reframing the design situation is in his documentation of the differences between problem solving in a rational world and problem solving in the real world [45.10, p. 40]:

“When we set the problem, we select what we will treat as the *things* of the situation, we set the boundaries of our attention to it, and we impose upon it a coherence which allows us to say what is wrong and in what directions the situation needs to be changed. Problem setting is a process in which, interactively, we name the things to which we will attend and frame the context in which we will attend to them.”

In an architectural design situation, this occurs, for example, in the form of an architectural designer deciding at some point to look at the structural design in that particular design session, and leave out considerations in terms of energy or user comfort. In the following sessions, he might focus on material use, or user access, or something entirely else. But in each session, only one frame of the entire design situation is considered.

What is probably the most interesting moment in this reframing process, is the point where a solution is considered satisfactory enough and ready to be put into practice. This moment resembles the moment in which the well-known flash of insight occurs. This moment is described by [45.27] as the moment in which the two oscillating points, *problem* and *solution*, are still and close enough to be bridged by an *apposite concept* [45.27, pp. 439–440]:

“The crucial factor [...] is the bridging of these two partial models by the articulation of an apposite concept [...] which enables the models to be mapped onto each other. The *creative leap* is not so much a leap across the chasm between analysis and synthesis, as the throwing of a bridge across the chasm between problem and solution. Such an apposite *bridge* concept recognizably embodies satisfactory relationships between problem and so-

lution. It is the recognition of a satisfactory bridging concept that provides the *illumination* of the creative *flash of insight*.”

The term *apposite* makes an intended reference to the notion of appositional reasoning, which was originally coined by Bogen [45.28] and which is considered similar or the same as *abductive reasoning* by Cross [45.29].

Suppose that our architectural designer is still focusing on the structural load-bearing capacities of a building (cfr. framing of the situation). This architect might successfully relate the current design situation with a situation he encountered before and consequently decide to apply a similar structural design (for example, steel columns for load-bearing instead of concrete columns or brick walls), because the features of this structural design choice not only address issues in the overall building structure, they also appear to geniously address many other issues in terms of light penetration in the building, accessibility, fire safety, and so forth. This train of thought involves a bridge between an unsure problem and an unsure solution by an apposite concept.

#### 45.1.4 Accessing Background Knowledge Through Analogical Reasoning?

The above distinguished *apposite bridge* between current design situation and the designer’s background knowledge is often addressed and investigated as a kind of analogical reasoning or CBR (see for instance [45.30–33]). Analogical reasoning is hereby explained as the cognitive ability to think about relational patterns [45.34–37], which allows one to find a structural alignment or mapping between a base and a target pattern residing in (partially) different domains [45.34, 37–40]. During design practice, architectural designers thus continuously make alignments between the current design situation (the base pattern) and previously experienced design situations (the target pattern). Relying on such alignments, designers infer which action to take for specific design situations and hence move forward.

This understanding was formed earlier by the investigations of Douglas and Isherwood, and Cross. Douglas and Isherwood [45.41], for example, indicate that [45.41, p. viii]:

“there is a prior and pervasive kind of reasoning that scans a scene and sizes it up, packing into one instant’s survey a process of matching, classifying and comparing. [...] Metaphoric appreciation, as all the words we have used suggest, is a work of

approximate measurement, scaling and comparison between like and unlike elements in a pattern.”

Later on, *Cross* [45.29] refers to several other research initiatives that distinguish a very similar kind of reasoning as fundamental for design thinking, thereby mentioning the terms abductive reasoning, productive reasoning and appositional reasoning as called by their respective inventors *Peirce* [45.42], *March* [45.43] and *Bogen* [45.28].

This kind of reasoning is obviously relied upon in the interpretation step which is considered in the previous sections of this chapter. This kind of reasoning is very poorly understood in general. The only thing we appear to know, is that it happens. As we are confined to behavioral studies of human design activity, and we cannot simply access the human mind during design activity, there is no real trustworthy indication of *how* it happens. When turning to the interpretation of the “work of approximate measurement” or “metaphoric appreciation” [45.41, p. viii] as a kind of analogical reasoning, we can find out that analogical reasoning often occurs between a new design-related experience (building, sketch, three-dimensional (3-D) model, conversation, and so forth) and a previous design experience as it is stored in the human mind [45.30]. But also in the very act of sketching, analogical reasoning is crucial, because it allows reinterpreting or *seeing as*, as *Goldschmidt* puts it [45.32, 33]. In *seeing as*, the designer reinterprets the sketch and, as such, adds new and origi-

nal meaning to it, thereby generating new ideas [45.32, 33]. For many student designers, who have little experience in architectural examples, *seeing as* often occurs in a more superficial way. They tend to find similarities between their sketches and other, often unrelated concepts and things based on geometrical features and shape (*Look, this looks like a ship. Maybe we can... or We are near the sea, why don't we make the building in the shape of a wave?*). Experienced architectural designers often make more abstract, meaningful and/or direct analogies, because they have a much richer set of background experiences on which they can rely.

Because analogical reasoning is guided by encountered target patterns [45.34, 37–39], the designer appears to proceed *in an unstructured and perhaps aimless way*. Therefore, the earlier mentioned definition of imagining [45.9, 44] is also closely related to analogical reasoning. A similar conclusion is given by *Boden's* research on the creative mind [45.45]. She stresses the importance of the incubation phase in creative thinking. In this phase, the conscious mind focuses on other domains, problems, or projects, thus enabling the creative mind to make diverse alternative and previously unconsidered analogies with the situation at hand [45.45, pp. 33–35].

When turning back to our initial schema of the design process (Figs. 45.2 and 45.3), we can locate the position of analogical or appositional reasoning somewhere between the design situation that is observed and the mental model resulting in the designer's mind (Fig. 45.5).

**Fig. 45.5** The approximate location of analogical or appositional reasoning in our earlier schema of the design process (Figs. 45.2 and 45.3)

### 45.1.5 Abstraction from Representation Model to Mental Model

If the bridging between the current design situation and the background knowledge of the designer occurs through analogical reasoning, the *base pattern* [45.34, 37–39] is tremendously important. Namely, this implies that what designers experience from design situations are the sole *seeds* from which they are able to make interpretations and act creatively upon.

Of course, it is not realistic to assume that designers interact with design situations as a *whole*, something that might be concluded from the schemas in Figs. 45.2, 45.3 and 45.5. Instead, designers interact with a *medium* that provides a bounded interface (a frame) to the current design situation (Fig. 45.6). These media of interaction are of various kinds, including people, objects, sketches, 3-D models and so forth.

The most obvious experiences of design situations in architecture (elements of interaction in Fig. 45.6) are sketches [45.46]. As *Goldschmidt* indicates [45.32, 33],

sketches are not only visual expressions of what one wants to express, they are also elements for reinterpretation and thus for generating all kinds of new knowledge. *Cross* similarly refers to the importance of sketching as it enables a designer to explore several solutions and problems to a certain design situation at once, thereby considering several levels of detail at once [45.8, 47]. *Schön* [45.10], in turn, refers to the habit of many designers to continuously make representations of the design situation at hand in documents, plans, sketches, and so forth, thereby allowing a designer both to answer a previous design situation, and frame the design situation anew into an alternative perspective. To say it in *Schön's* words, the designer “shapes the situation in accordance with his initial appreciation of it, the situation *talks back*, and he responds to the situation’s back-talk” [45.10, p. 79].

We will not dive into all the characteristic features of sketching, but we will instead generalize among very diverse possibly available base patterns used to initiate analogical reasoning. Sketches, namely, are but one of the many possible representation media that can be used by designers to reflect on the design situation. Besides sketches, designers can use conversations with colleague architects, physical scale models, walking around on construction sites or inspiring related pieces of architecture, and so forth. Rather recently, this array of interaction media has notably enlarged through the development of all kinds of information technologies. New media are now available to the designer, among which there are parametric design models, two-dimensional (2-D) computer-aided design (CAD) models, 3-D BIM models, databases, websites on the Internet, teleconference applications, virtual game engine environments, and so forth. So, design representations can

**Fig. 45.6** Indication of the diverse elements with which a designer can interact: people, objects, other

take on many forms, including a sketch [45.32, 46, 48], a simple discussion [45.49], a CAD model, and so forth.

The main idea here is that by making alternative representations, designers aim at confirming the abstract model they have of a particular design situation, which is always to some extent unclear, wicked or unknown. By experiencing the resulting design representation, a new understanding or abstract in-mind model of the design situation thus emerges, which reframes the previous design situation and thus alters the design process.

## 45.2 BIM Models and Parametric Models

The apposite bridging, interpretation, or abductive reasoning step is a capacity that is not available in a computer. As we do not know the way in which our background information is stored in our neurological brain, we are obviously unable to replicate this. As a result, no information system exists that is able to store the target patterns that are required for analogical reasoning, let alone one that is able to match these target patterns with incoming sensory information and thus make analogies in a creative and autonomous manner, as we do as human beings. So, no information system is able to take over such a typically human capacity.

### 45.2.1 New Technological Media in Design Thinking

Nonetheless, architectural designers can still take advantage of information systems as an additional medium that allows them to make alternative representations with which they can interact in their sense-making or interpretation process. Any computer-based representation thus functions similar to how a sketch functions. Each such representation hereby represents only a limited semantic domain, only a partial reflection of the complete design situation. They are representations of the designer’s mental model, and by no means do they

come close to the original mental model which is always in the mind of the architectural designer and which is inherently ungraspable. Instead, the representations in these media are to be considered as representations that result from this mental model and that form, as such, initiators for further reflection on this mental model. In the following section, we will briefly look into the consequences in the context of BIM modeling and parametric modeling software, as reference examples.

### 45.2.2 BIM Models and Parametric Models

There have been many developments in information and communication technologies (ICT) for the domain of architecture, engineering and construction (AEC). Most ICT applications in this domain allow to build a certain representation or model of an architectural design (element). A considerable number of the developments in ICT for the AEC domain have focused on enlarging the amount of semantics that can be included within the resulting representations or models. In other words, instead of allowing designers to model a design using lines, points, boxes or surfaces, they now typically allow to model typed objects, such as walls, doors, structural columns, and so forth. Each instance of one of those object types can then automatically be represented using the properties that were predefined for these object types. These properties typically include basic features, such as height, width, and location, but they also include far more complex properties, such as relations with other objects (aggregation, decomposition, neighborhood, etc.), representational properties (texture, geometry, etc.), and so forth.

These developments have resulted in a number of modeling applications with capacities that make them stand out from the traditional CAD or computer-aided drafting applications. One can distinguish the following modeling application types.

#### Building Information Modeling (BIM) Applications

BIM applications allow to represent buildings using a hierarchical structure of typed objects, including building objects, materials, people, and so forth [45.50]. References can be made to the concept of feature-based modeling (FBM) [45.51]. The workflow in such applications results in a single 3-D BIM model, which is supposed to include all the information needed to build the building (Fig. 45.7).

#### Parametric and Generative Modeling Applications

Parametric and generative modeling applications allow to represent a design using a number of typically

geometric parameters. By moving sliders, parameter values are changed, and a design model can be regenerated from these modified parameter values. The design model is hereby formed by a network of parameter values and control functions that generate geometry using the associated parameter values (Fig. 45.8).

#### Database Applications

Many more basic applications in the architectural design and construction industry still rely on rather basic relational database systems. This includes, for instance, four-dimensional (4-D) (time scheduling) and five-dimensional (5-D) (cost scheduling) applications, facility management (FM) applications, energy performance calculation software, and so forth. Of course, such applications also use a semantic model of the architectural design, represented by tuple values in a relational database.

### 45.2.3 Features and Issues in the Usage of the New Modeling Applications

Obviously, for all of the three technology types mentioned above (BIM software, parametric software, database software), there are numerous interpretations and implementations. We will not dive into the details for each of these technology types in this chapter, as the focus is here on the role and function of these new interaction media within the design process. Within the scope of this chapter, it should suffice to keep in mind that each of the outlined software environments allows to build a simple or complex semantic model as a representation to interact with.

The semantic model that can be built using the outlined modeling environment typically follows the information structure that is defined by the programming code behind the corresponding modeling application.

**Fig. 45.7** Revit Architecture is one of the available BIM modeling applications that allow architectural designers to model a BIM model representation of their design

**Fig. 45.8** Rhinoceros, together with the Grasshopper plugin, is an often used environment for the parametric modeling of building geometry. This environment is typically relying on nodes and sliders to represent the semantics of the designed geometry

A Revit BIM model (Fig. 45.7) is something that cannot be captured by a parametric model in Rhinoceros and Grasshopper (Fig. 45.8), because both modeling environments deploy different programming codes and corresponding information structures. Basic 2-D CAD applications enable the user to model a design in 2-D geometric object models, using lines, points, surfaces, and so forth. Basic 3-D applications allow this in 3-D, using boxes, spheres, voids, and so forth. More advanced CAD systems typically focus on information management, and thus enable the user to model a design in more informative elements, such as walls, windows, columns, beams, and so forth.

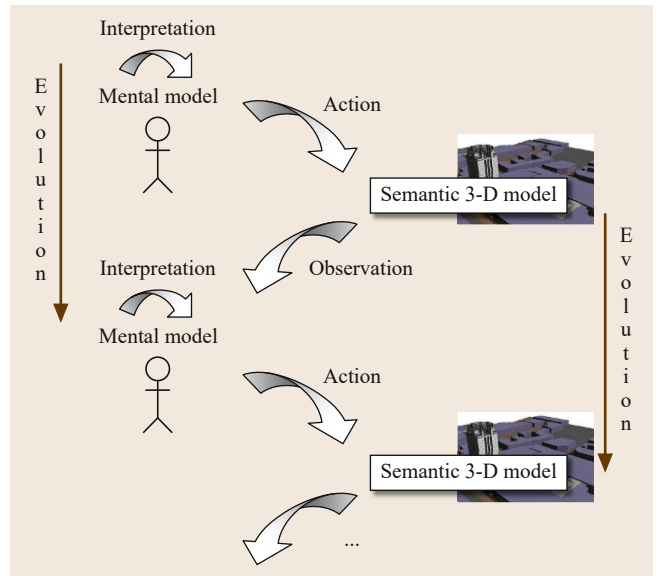

By allowing designers to model their design in a more meaningful manner (more semantic object types such as walls and doors instead of the more syntactic points and lines), designers are supposedly enabled to represent their design as a model that is much more closely related to the in-mind abstract model that they use in the design thinking process (Fig. 45.9). In concrete terms, rather than only being able to represent a design using pencil marks on a paper, semantic features in software applications allow the designers to model a semantic structure (the ontology) that reflects the in-mind structure of their designs and then use that semantic structure to represent the actual design (instantiation of the ontology). It is then easier to make decisions, as the gap between the semantic model of the design (Fig. 45.9, right) and the in-mind design model (Fig. 45.9, left) is smaller and the interpretation step that is to be made by the designer should be easier.

This functions relatively well. There are, of course, a number of issues that are commonly identified in using these modeling applications:

1. *Too much time is needed* to build the appropriate semantic structure for one's particular in-mind design model, resulting in a preference for quicker draft-

ing applications or drafting media (computer-aided drafting or sketch environments).

2. As the in-mind design model is continuously changing (cfr. co-evolution of problem and solution), one's *semantic structure is never up to date* with that in-mind design model. In other words, the semantic 3-D model (Fig. 45.9, right) is always a number of steps behind the in-mind design model (Fig. 45.9, left).
3. A need arises to share the semantic model of the design with other people, as is typically also done with sketches. However, transferring/communicating the meaning of the custom semantic structure to anyone else requires considerable effort from that other

**Fig. 45.9** The design process, as schematically represented earlier, indicating how semantic 3-D models are used by architectural designers

person as the presented semantic structure never matches with his own in-mind model. This is related to the well-known *interoperability* problem (see for reference [45.52–56]).

When considering the theories presented in the first section of this chapter, it is rather obvious and understandable that these three main difficulties emerge. If the abstract in-mind design model changes at every single snapshot of interaction with some kind of interaction medium (Fig. 45.9), of course, the representation on the medium with which is interacted is outdated at every single moment in time. Hence, it would also be a futile attempt to make a complete representation of an abstract in-mind design model in any of the available 3-D modeling applications. Note that it would likewise

be a futile attempt to make such a complete representation in one paper sketch.

Furthermore, in order to get information into another information structure (the interoperability challenge), no matter in what kind of information structure it was originally captured, one *always* requires interpretation if it is to be done properly. Thus, this requires human effort. The best option in this context of interoperability problems is to at least make flexible and intuitive tools available so that a designer can at least do the required interpretation effort in a relatively smooth and efficient manner and transform information from one semantic schema into another. Semantic web technologies might provide some of such flexible and intuitive tools, as is indicated in [45.56–59].

## 45.3 Implementing and Using ICT for Design and Construction

Considering the above writings in this chapter, modeling applications will remain to be used as alternative media for interaction by architectural designers and construction experts, no matter the amount of semantics they allow designers to represent. The semantic structures of these applications might to some extent match or resemble the in-mind model of the designer, but it will always fall short in comparison. That being considered, there is, first and foremost, a need for a flexible, intuitive, and above all, pragmatic usage of modeling applications in architectural design and construction. Many examples of such usage strategies exist in practice. Unfortunately, this pragmatic approach remains to include the effects caused by limited interoperability of information [45.53], namely an increased loss of time and an increased number of construction errors during the construction process due to the necessary remodeling of information from one environment to another.

### 45.3.1 Pragmatic Usage of Semantic Modeling Applications

A first example of this pragmatic approach is documented in [45.60] and elaborates on the pragmatic usage of BIM systems in the construction of the Port House in Antwerp. Initially, an integrated BIM approach [45.50] was targeted in this project, using Revit Architecture as a central BIM environment. The BIM model would then serve as a central reference model containing and providing information for all project partners. The construction company tried to be faithful to the BIM idea, but they gradually shifted to a more pragmatic software usage approach. A BIM model was

engineered and maintained as a reference model by the construction team in charge of the whole construction process. Depending on the background and software usage approach of the project partners, the information in this BIM model was interpreted and provided to the related project partners according to the semantic structures they were using and the medium in which they were working. Communication of information thus included, for instance, Excel spreadsheets, PDF documents, and partial 3-D models in various file formats. In importing and exporting these documents to and from the modeling environment, human interpretation was required in the form of manual conversion efforts. Nevertheless, this human interpretation step produced a desirable result within a foreseeable and plannable time span.

The pragmatic software usage approach outlined here and in [45.60] requires a very good balance between automatic (technological reformatting) and manual procedures (human interpretation steps). The information structures of applications can be integrated either by implementing project-specific software components or by manual modeling. The key to a pragmatic usage of (semantic) modeling applications is finding the right balance between these automatic and manual procedures (Fig. 45.10), so that it fits the current design situation.

Similar approaches appear to be followed in other large architectural firms that concentrate on geometrically or semantically complex architectural projects. In most cases, the balance shifts towards the usage of automatic methods, as larger and more complex projects often benefit from automatic procedures in terms of

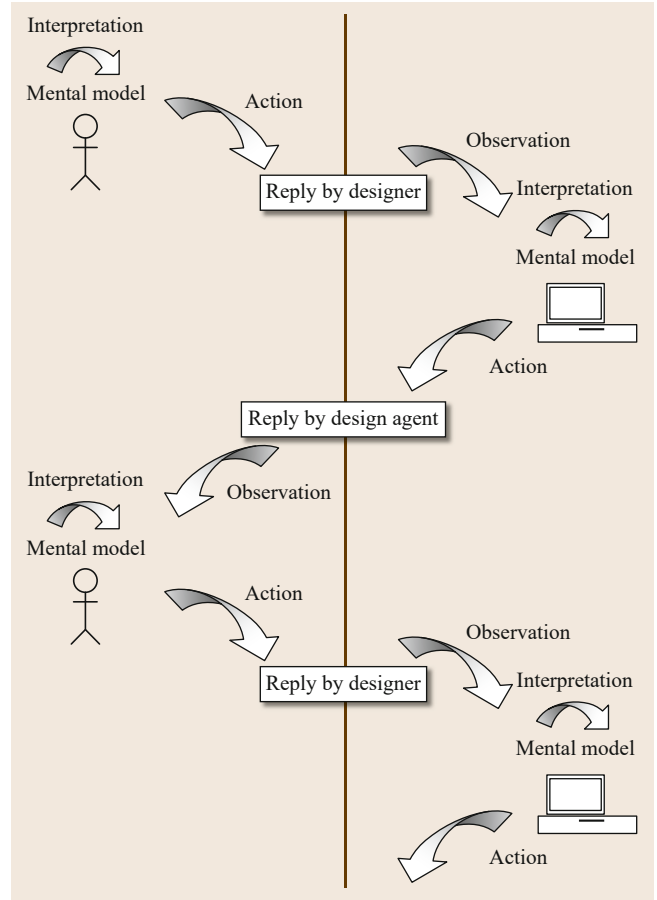

**Fig. 45.10** Indication of the balance between advantages and disadvantages of using manual and automatic procedures in information-handling in the Port House architectural design project (after [45.60])

efficiency or return on investment. A good example is the Specialist Modelling Group (SMG) in Foster + Partners, which is a group that appears to concentrate on optimizing information exchange and complex modeling for specific projects [45.61]. It appears to be confirmed in [45.60] that this not necessarily requires a standard information management approach. Pragmatically constructing a common agreement between project team members and combining manual and automatic methods with an expert group of programmers, process modelers and/or communication specialists can prove to be just as effective.

### 45.3.2 The Usage of Design Agents or Assistants

Thus, for architectural designers and construction specialists, the better option in using information technologies is to consider these technologies as yet another set of available media with which they can interact as part of their reflective practice. As with all media, there are certain rules, advantages and disadvantages that characterize each medium. One should thus carefully consider what medium to consider for what purpose. Something that all media have in common, nonetheless, is that they can all capture but a fragment of our in-mind abstract knowledge.

One might wonder whether there really is no alternative, whether information systems will really not be capable, almost as if by definition, to capture an abstract model similar to the way in which human beings do so. As indicated in the first section of this chapter, there is only one thing that stands in the way of such a development and that is the element of *interpretation*, *analogical reasoning* or *abductive reasoning* (see Fig. 45.5). This seems to be one of the main capacities that distinguishes man from computer. Key design actions require interpretation, including: the mapping of incoming semantic information to its own semantic structures, or the construction of context-specific and purposeful shape

**Fig. 45.11** Our original schema of the design process, adapted in order to communicate how the interaction between designer and computer-based agent could be taking place

grammars and creation of appropriate design decisions while relying on and continuously adapting this shape grammar, or the performance of multidimensional optimization or satisficing of design constraints. In order for a computer to perform these actions, it will first have to be able to interpret incoming information and understand it using a mechanism that involves a form of abductive, analogical or appositional reasoning.

If this is ever realized, it will result in the third of three realms of software usages in architectural design and construction support, as they were originally identified by Lawson [45.62]. We have seen the first two in the previous sections, namely, (1) the computer as a rigid problem-solving and all-knowing oracle, and (2) the computer as a draughtsman, which is simply used as yet another interaction medium while the designer remains the only decision-making and interpreting agent. In a third scenario (3), the computer is to be used as a true design agent or assistant (see also [45.57] for more in-

formation about how this relates to the earlier outlined pragmatic approach). In this scenario, designers interact with autonomously reasoning computer-based agents, as if they would interact with any other medium. Both the designer and the computer-based agent would then interpret incoming information and learn from experience. Using our schematic format of the design process again, this interaction between designer and computer-based agent would likely look as depicted in Fig. 45.11, with processes of inquiry happening in the human mind (Fig. 45.11, left) as well as in the computer agent’s information system (Fig. 45.11, right).

For this scenario to be realized, interpretation as it functions in the human mind needs to be implemented. In this regard, some effort has already been placed in the automation or implementation of abductive reasoning. It is useful to consider the number of research initiatives in the domain of abductive logic programming (ALP) [45.63]. Second, we have already looked into some pointers towards CBR in brief [45.21–23]. Unfortunately, most of these research initiatives appear to lack tangible research results. Not one of the resulting software systems appears capable of reliably simulating an interpretation step as it is produced by any human agent in an autonomous and natural manner, let alone within an architectural design context.

Some researchers have taken a different approach and have primarily considered the larger cycle that people appear to go through in any interaction with an outside world [45.64–66]. This larger cycle resembles

the original *process of inquiry* as it was outlined multiple times by Peirce [45.42]. It is hereby considered useful to not only consider abductive reasoning, but to also look for the occurrence of inductive and deductive reasoning as they were considered by Peirce [45.42]. This implementation approach makes sense as it seems to be the only valid way to let an agent learn in an autonomous manner, yet enabling it to store previous experiences so that they can be reused in interpreting future observations. Additionally, combining abductive reasoning with inductive and deductive reasoning in an iterative cycle is required if the agent’s functionality is to remain true to Peirce’s idea of a process of inquiry. When relying on this interpretation of Peirce’s process of inquiry [45.64–66], we might be able to indicate where such a cycle resides in our earlier diagrams of the design process (Fig. 45.12).

One research initiative that appeared to take on the realization of this agent approach can be found in the work of King [45.67, 68]. In this work, the goal was to build a machine that can autonomously “discover new scientific knowledge” by its capacity to “devise a hypothesis, carry out experiments, to test it and assess results” [45.68]. This endeavor to enable a machine to go through these diverse stages is very much like building a machine that is able to go through Peirce’s process of inquiry, in the sense that in the case of King’s research, the main question was also whether they were able to build a “robot scientist that can actually accomplish the entire process” [45.68]. Eventually, a machine was built that is capable of successfully constructing hypotheses, devise appropriate experiments and test them, in the domain of functional genomics, a domain in which the relations between genes and their functions are investigated. These actions are made using a core body of knowledge, resulting from a “formalization that involves over 10 000 different research units in a nested treelike structure, 10 levels deep, that relates 6.6 million biomass measurements to their logical description” [45.67].

In any case, even if this autonomous agent-based approach proves valid and a useful implementation of such an autonomous reasoning agent can be realized, it will take years before this agent takes on a form that can provide help to an architectural designer as it was theoretically outlined by Lawson [45.62]. Namely, it requires at least 25 years for brilliant human agents to learn this capacity and there is no reason to assume that computer-based agents might be able to outperform this human capacity. So, to conclude, we are best off, for now, with following the pragmatic software usage approach as it was outlined earlier in this chapter and keep relying on the architectural designers themselves as reflective practitioners and decision-makers.

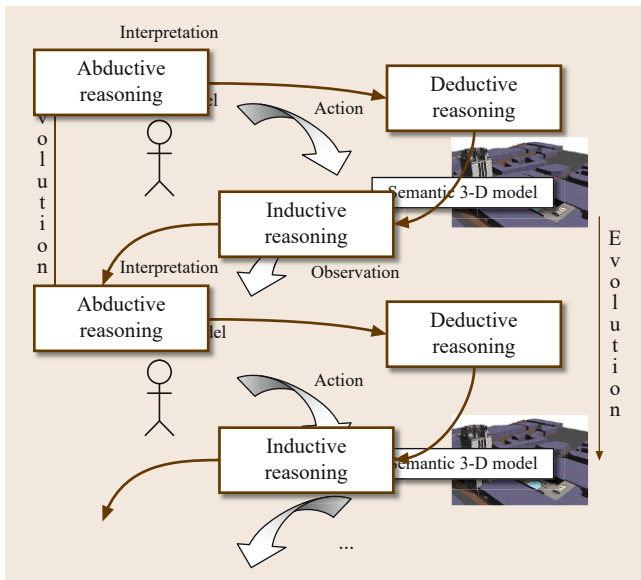

Fig. 45.12 Our original schema of the design process, with an overlay of where the abductive, deductive, and inductive reasoning might be taking place

## 46. Representational and Experimental Modeling in Archaeology

Alison Wylie

I distinguish, by specificity and representational function, several different types of archaeological models: phenomenological, scaffolding, and explanatory models. These take the form of concrete, mathematical, and computational models (following Weisberg's taxonomy), and they exemplify what Morgan describes as the *double life* of models; they vary significantly in the degree to which they are intended to accurately represent a particular target, or are media for experimental manipulation of idealized cultural processes. At the phenomenological end of the spectrum, representational models of data include typological constructs that selectively represent variability in archaeological data on several dimensions: formal (material), spatial, and temporal. Archaeologists also build phenomenological models of data drawn from nonarchaeological sources – cultural and natural – that are relevant for interpreting archaeological data as evidence. Assemblages of these target and source models provide the necessary scaffolding for building and evaluating more ambitious explanatory and experimental models of cultural systems and processes, actual and hypothetical.

Archaeology is nothing if not a modeling discipline. Archaeologists model the data they recover from the archaeological record, the sources on which they draw to interpret these data, the specific events and activities that produced the surviving traces, and the encompassing social, cultural, ecological contexts and processes in which these events and activities took place. And yet there has been persistent ambivalence among archaeologists about models and modeling practices. Early advocates of modeling in archaeology were aligned with the emergence of a self-consciously scientific research program in the late 1960s and 1970s, the New Archaeology. But the defining commitment of the New Archaeology – to move beyond mere description of the record and interpretive speculation about the past; to realize genuinely explanatory understanding of the

past – was most influentially articulated in terms of a vernacular logical positivism [46.1, Part 2]. The explanatory goals of scientific inquiry were characterized in terms of covering-law models, and a programmatic commitment was made to design inquiry as a program of hypothetico-deductive testing; law-like generalizations about cultural systems and processes were to be systematically tested against archaeological data or, if established on other grounds, applied as explanatory principles to archaeological cases. In practice, however, it is typically models that even the most ardent archaeological positivists build and test, not isolated theoretical or factual claims, much less systems of laws or law-like propositions. They routinely make use of models, framed at a number of different levels of specificity, to explain events and conditions in

the cultural past in terms of underlying mechanisms and historically specific processes rather than by subsuming particulars under general regularities. It is more productive, I argue, to think about archaeological practice as a genre of empirically grounded, investigative reasoning with and through models – a perspective elaborated by recent advocates of a *model-based archaeology* [46.2].

This shift in analytic frame may seem straightforward enough but things quickly become complicated when you consider the range of constructs that archaeologists count as models; these are radically heteroge-

neous on a number of different dimensions. The task I take up here is to address the question: What are archaeological models? I propose a taxonomy of the kinds of models archaeologists build and use, distinguished by specificity and representational function. In the process I address two further questions: What do archaeologists use models to do? And, how do they learn from models? I take this to be scaffolding necessary for the normative epistemic task, which lies outside the scope of this chapter, of addressing questions about what makes for a better or worse models and modeling practice in archaeology, given their diverse purposes.

## 46.1 Philosophical Resources and Archaeological Parallels

In framing a taxonomy of archaeological models I draw on a point made with particular clarity by *Morrison and Morgan in Models as mediating instruments* [46.3]: that modeling practice is not well understood if you think of models primarily as tools for operationalizing theory, derived top-down from theory or constructed as *models of theory* for application to real world systems, or as simplified descriptions of phenomena that function as tools for systematizing data built, bottom-up, from the analysis of a specific body of data. Archaeological models are no exception; they are rarely constructed in either of these ways, and even when they approximate to these types of modeling practice their content is often much more complex. In Morrison and Morgan's terms, key classes of archaeological models are autonomous; they incorporate content that is not derived from or reducible to the data they represent or the theories they interpret. As such, they put archaeologists in a position to learn things about an archaeological subject that they could not have learned either from direct empirical investigation or by manipulating – testing, refining, applying – existing theory. That said, I find it useful to think of archaeological models as falling along a spectrum of degrees of abstraction (or idealization) and empirical specificity, with resolutely descriptive, data-systematizing models at the phenomenological end of the spectrum and highly idealized, theoretically motivated models at the other.

*Morgan's* recent discussion of the *double life* of models is a second useful resource, in this case for understanding the variability of purpose evident in archaeological models [46.4]. She makes the case that models in economics figure both as objects of investigation and as tools for investigation; they support experimental as well as representational uses. As I will show, an important class of archaeological models is

quite explicitly designed to support experimental manipulation; they are objects of investigation in Morgan's sense, rather than strictly representational tools. This is a point made in especially compelling terms by *Kohler and van der Leeuw* when they argue that the value of models, as constructs that mediate between "the real world and ourselves," is that they support the "joint exploration of the model and its target system" [46.2, p. 4].

Finally, I draw on an older philosophical literature on models that anticipates, in some respects, recent philosophical thinking about models in science exemplified by *Weisberg's Simulation and Similarity* [46.5], but is particularly useful in an archaeological context because of its focus on the role of analogical reasoning in the construction and use of models. The account of modeling developed by *Harré* [46.6] and by *Hesse* [46.7, 8] brings into sharp focus the complexity of models themselves, and of the relationships that hold between models and their targets and sources. The taxonomy of archaeological models that I outline here presupposes their argument, now much expanded by Weisberg, that sentential and formal, mathematical models by no means exhaust the range of models that figure in the sciences. Iconic or *picturing* models, including what Weisberg describes as concrete models, play a crucial role in empirical inquiry: they "stand in for [...] mechanisms of nature of which we are ignorant"; they allow researchers to "picture possible mechanisms for producing phenomena" *Harré* [46.6, p. 54]. Especially relevant here is the distinction *Harré* draws between two basic types of iconic model: homeomorphic models, in which source and subject are the same; and paramorphic models, in which these are different. A key feature of paramorphic models, where archaeological practice is concerned, is that they may be *multiply connected* [46.6, pp. 47–49]; they in-

corporate elements drawn from a number of sources relevant for modeling different aspects of archaeological subjects that have no comprehensive contemporary analog.

In developing this taxonomy of archaeological models and modeling practices, I am influenced as well by the magisterial analysis, “Models and Paradigms in Contemporary Archaeology” [46.9] offered by the British archaeologist, *Clarke*, as the framework for an early and prescient collection of essays *Models in Archeology* [46.10] and by the distinctions drawn by *Kohler* and *van der Leeuw* in connection with the case they make for a *model-based archaeology* [46.2]. Both recognize the purpose-specific, partial nature of models. *Clarke* emphasizes the different functions served by models pitched at different levels of abstraction, lying on a continuum much like that posited by *Morgan* and *Morrison* for economics and the physical sciences. Archaeological models include what *Clarke* calls *mind models* that function like Kuhnian paradigms; operational models that interpret these orienting conceptual models in observational terms; and models that systematize (selectively and economically) complex bodies of data, serving as heuristic devices for visualizing, manipulating, organizing, and comparing observations [46.9, pp. 2–5]. Together, *Clarke* argues, models of these various kinds are a crucial resource for generating and articulating explanatory hypotheses. Taking up the

cause of archaeological modeling 35 years later, the explanatory function of models is primary for *Kohler* and *van der Leeuw*: “a model here is just a candidate explanation” [46.2, p. 1]. However, invoking *Levins* on the impossibility of simultaneously maximizing generality, realism, and precision [46.11], they also recognize a range of scales and degrees of abstraction in the models archaeologists devise to answer “*how* and *why* questions” [46.2, pp. 1, 7]. These are primarily marked by degree of aggregation; the key contrast for *Kohler* and *van der Leeuw* is between a new generation of agent-based models and earlier systems models (more of this ancestry shortly). *Kohler* and *van der Leeuw* also make a point that figures prominently in *Clarke*’s brief for model-based modes of practice and converges directly on *Weisberg*’s taxonomy of scientific models: that models come in a great many different forms. Their roster of mental, verbal, physical, and formal (mathematical and simulation) models is reminiscent of *Clarke*’s argument that models can be constructed as physical *homomorphic parallels* between model and target or can take the form of formal (mathematical) representations of abstract systems of relationships inherent in the target [46.9, p. 41]. In short, despite an emphasis on discontinuities, these programmatic arguments for *model-based* archaeology reflect significant continuities in evolving archaeological practice to which I hope the taxonomy proposed here does justice.

## 46.2 The Challenges of Archaeological Modeling

Some advocates of the explanatorily ambitious New Archaeology did make the case for what they described as a *systems* rather than a *law and order* approach which put modeling at the center of archaeological inquiry [46.12, 13], which in some respects anticipated arguments made with considerable force in the UK by *Clarke* [46.9]. In the discussions of modeling associated with the New Archaeology the emphasis was initially on theory-driven, *whole system* models, usually of an explicitly eco-determinist cast; these were intended to capture the essential causal and structural features of distinct types of cultural systems and the processes by which they adapted to the ecological contexts in which they took shape and evolved over time. But from the outset the constraints on *whole system* modeling and on the mathematical and simulation modeling techniques used to operationalize archaeological theories of cultural process were recognized to be all but insurmountable in explanatorily interesting cases. In a classic statement dating to 1975, echoed in a number of later assessments, *Doran* and

*Hodson* identified three pivotal problems. First, they observed, “models which are mathematically tractable are too simple for most archaeological problems” [46.14, p. 315]. This is not just a technical constraint. Although computer technology was, even then, making possible simulations that could better cope with the computational challenges of modeling whole systems, a second more fundamental problem is that these models require a level of understanding of the conditions and processes modeled that is “only rarely met in archaeological work” [46.14, p. 315]. Finally, an inescapable problem for archaeological modelers noted by *Doran* and *Hodson* and reiterated many times since is the “fundamental noisiness” of archaeological data which makes it difficult to empirically assess the descriptive and explanatory claims about the cultural past captured by or derived from these models [46.15, p. 230].

Despite this early pessimism about the prospects of ever realizing the explanatory ambitions of the New Archaeology by means of modeling approaches, models

are ubiquitous in archaeology. As Kohler and van der Leeuw put it, archaeologists [46.2, p. 3]:

“have drifted *in practice* toward what philosophers of science call a *model-based* (Giere 1999) or *semantic* (Lloyd 1988; Suppe 1977 [...]) approach to the task of explaining what happened, and why, in prehistory.”

This in part due to the proliferation of fast, cheap computer technology but, even with the promise that Doran and Hodson’s first problem might be resolved, the archaeological models that now answer the call to explanatory understanding are typically much more narrowly circumscribed than the whole system models initially advocated by allies and critics of the New Archaeology. This reflects, in part, a growing appreciation of the complexity of the human, social *ecodynamics* by which cultural systems modify as much as adapt

to their environments [46.2, p. 10]. If anything, this makes Doran and Hodson’s second two concerns even more acute. In response, archaeologists have shifted their focus to building and refining models of specific conditions and processes that are, or that could have been, responsible for specific types of event or forms of life to which the archaeological record bears witness. As Kohler and van der Leeuw describe the mandate for a *model-based archaeology* at this juncture, it is to understand “relatively small-scale” human systems, but to understand them in something closer to their full complexity: as “embedded within [...] the environments they inhabit and alter” [46.2, p. 2]. At the same time, a broad cross-section of archaeologists have embraced a wide range of more prosaic modeling practices that are resolutely descriptive and phenomenological, but that are no less crucial to the broader explanatory goals of contemporary archaeology.

## 46.3 A Taxonomy of Archaeological Models

With these conceptual resources in hand, consider some of the types of work-a-day models that abound in archaeology.

### 46.3.1 Phenomenological Models of Archaeological Subject and Source Data

One prevalent use of models in archaeology is to characterize, in systematic terms, various types of archaeological data, and the diverse experimental and ethnohistoric sources on which archaeologists rely to interpret these data as evidence. These models take a range of forms: mathematical, computational, and in some cases concrete, to use Weisberg’s categorization [46.5, Chap. 2]. They are typically homeomorphic models designed to represent variability in the target or source domain. As such, they lie at the phenomenological end of the spectrum of model function marked by Morgan and Morrison although, I will argue, they incorporate much often unrecognized theoretical and interpretive content.

#### Models of Archaeological Data

Models of archaeological data typically represent variability on three dimensions: formal, material variability; the spatial distribution of artifacts and features within sites, or of sites and assemblages of artifacts across a region; and chronological trends in the appearance, frequency, and disappearance of artifact types, architectural styles, and cultural formations over time.

Material, formal variability in archaeological data is captured by descriptive typologies, ranging from highly specific artifact typologies aimed at systematizing local variability in material culture to expansive classification schemes that delineate trans-historical cultural formations and trans-regional cultural horizons. At the artifact-specific end of the spectrum, ceramic and lithic (stone tool) typologies have been especially crucial in many contexts as chronologically and spatially sensitive markers that came to anchor the characterization of *archaeological cultures* [46.16]: distinctive assemblages of archaeological material – for example, stylistically distinctive artifacts, house forms, burial rites and subsistence practices that consistently co-occur – that were presumed to be the expression of distinct cultural configurations. So, for example, the late Neolithic culture(s) of western Europe that came to be known as the *Beaker people* were characterized archaeologically by a *package* of artifacts associated with a characteristic type of pottery, and the hunting-intensive Paleo-indian cultures of central North America were named for the distinctive Clovis and Fulsom projectile and spear points in terms of which they were first identified in the 1920s and 1930s. Broader syntheses of archaeological cultures, of the kind posited by Willey and Phillips for the Americas [46.17], and by Childe for Europe [46.18], characterize broad cultural horizons based on the sequence of appearance and distribution of these co-occurrent classes of archaeological evidence.

The presumption that formal (material) variability of this kind has inherent cultural significance has

been a matter of sharp contention within archaeology since at least the 1940s and 1950s, when *Brew* and *Ford*, and later *Spaulding*, articulated opposing views about what these models of data represent: that they are selective, purpose-specific impositions by the analyst [46.19, 20], as opposed to culturally salient features of the archaeological record that archaeologists *discover* (Spaulding [46.21, 22] and see *Adams* and *Adams* [46.23] and *Wylie* [46.1, pp. 42–51] for analysis of this debate). To illustrate the contingency and purpose-specificity of typological systems, Ford offered a thought experiment: a variety of house forms on the fictional Island of Gama Gama characterized by a range of different traits (e.g., roof style, construction on stilts, size, layout) whose variability is continuous across time and space. Although regularities in the distribution and association of these material traits can certainly be identified empirically (indeed, *statistically discovered*, as Spaulding had insisted), it is possible to carve material culture at different joints. Shifting the selection of traits will yield different patterns of association and spatial/temporal distribution, and often enough their variability is continuous so that different boundaries can be drawn between types [46.24]. Ford's point was that archaeological typologies are tools of analysis, constructed as needed to address particular archaeological questions. The typologies that served archaeologists initially in modeling spatial and temporal relations within and between classes of archaeological data may not be a plausible proxy for cultural identity, or useful in tracking shifts in technologies, subsistence practice, trading relations or social status, to name just areas of archaeological interest.

Spatial distribution models vary dramatically in scale, target, form, and purpose. They include, for example, spatial auto-correlation models that delineate artifact drop-zones around hearths and in activity areas, and a range of other models that capture the spatial relations between key features within archaeological sites. Classic examples are models that represent regularities observed in the orientation of burials and associated grave goods in mortuary sites (see the example of a Roman period cemetery in the UK discussed below), and the patterned clustering of functionally distinct rooms in Southwestern pueblos that was the basis for *Hill's* posit of generationally stable households at Pueblo [46.25], an early demonstration project for the New Archaeology. They include, as well, models of an architectural *grammar* of the kind developed by *Glassie* for Middle Virginia folk housing: an inventory of geometric forms structured by a basic unit of measurement (the diagonal constitutive rectangles and squares) and a set of grammatical rules for assembling these into canonical house forms [46.26]. At a regional

scale archaeologists develop formal and computational models of the distribution sites or visible features on the landscape, now facilitated by widespread use of geographical information systems (GISs). For example, spatial packing models (imported from quantitative geography) were developed to capture the proxemics of settlement hierarchies which, in turn, were the basis for positing regional chiefdoms in Neolithic Europe [46.27]. More recently, landscape archaeologists have developed richly interpretive spatial models of the sacred (rather than political) landscapes in which Neolithic and Bronze Age monuments like Stonehenge are embedded [46.28, 29]. A related example that incorporates experimental elements (of which, more below) is *Llobera's* delineation of corridors of movement between Neolithic Galician mamoas, identified both in terms of ease of movement, given regional topology, and the viewscape afforded travelers along these pathways [46.30]. In these cases, digital repositories of spatial data and the analytic power of GIS analyses are a crucial resource; predictive modeling of where archaeological sites of various kinds are likely to occur is now a key component of cultural resource management [46.31].

Chronological models represent the appearance and disappearance, and related changes in the form and frequency of specific types of material culture over time, and at scales ranging from individual artifact types, cross-type styles and assemblages, to broad cultural formations. The locus classicus for such models is *Kroeber's* decidedly nonarchaeological seriation of changes in fashion in which he determined that, despite the perception of rapid and dramatic change, the proportions that define what is fashionable change very slowly and predictably; his test case was the evolution of styles in women's formal wear from 1845 to 1915 [46.32]. Influential examples developed to illustrate these seriation principles in archaeological terms include *Deetz* and *Dethlefsen's* classic analysis of changes in the frequency of decorative styles in New England tombstones; they demonstrated the same regular *battleship curve* in stylistic changes over time as had *Kroeber* [46.33]. Another example that continues to be used as a basis for building finegrained chronologies in historical archaeology is *Binford's* formal model of a regular pattern of change in the mean bore hole diameter of clay tobacco pipes produced in Europe and North America between 1600 and 1900, described as *deterministic and mathematical* by *Clarke* [46.9, p. 18]. Although physical dating techniques are now predominantly the basis for archaeological chronologies, tradition-specific seriation models continue to be a key resource in many contexts. Indeed, although it was widely assumed that local, *relative* chronologies

would automatically be replaced when radiocarbon dating was introduced – the *first radiocarbon revolution* (initiated by Libby in the 1950s) – in fact, discrepancies between these systems have been pivotal in raising questions about the accuracy of absolute chronologies that generated the painstaking, 60 year process of calibrating radiocarbon dating curves – the *second radiocarbon revolution* [46.34, pp. 130–140].

The challenge of establishing spatial-temporal control dominated the initial construction of typological systems in most contexts of archaeological research, but this by no means exhausts the purposes for which they are used. As *Boozer* observes in a discussion of the “tyranny of typologies” [46.35], once these phenomenological models were developed, practitioners often lost sight of the purposes they were designed to serve. They became entrenched as the dominant medium of communication within archaeology; they configure reporting conventions and set the framework for the comparative analyses that were the basis not only for regional models of cultural diversity and evolution, but also the fine-grained analogical comparisons that underpin interpretive claims about the evidential significance of archaeological data. Often they persist even when accumulating data undermines the distinctions they draw and as focal questions change, requiring analysis in terms of traits that track other dimensions of variability. As the disconnect between these models of data and evolving research agendas becomes increasingly strained, the central point made by Brew and Ford in the mid-1950s is more relevant than ever: that in constructing typologies archaeologists must choose among a great many observable, measurable traits, so any one selection necessarily reflects specific investigative purposes. In analysis of a problematic typology of domestic Romano-Egyptian house forms, *Boozer* draws attention to the ramifying downstream consequences of failing to keep the contingency of these models of data clearly in view, reifying them as representations of a fundamental cultural reality and treating them as the framework within which all subsequent research must be conducted [46.35, pp. 104–106].

#### Models of Nonarchaeological Sources

A second important genre of phenomenological modeling in archaeology is of the data drawn from nonarchaeological sources on which archaeologists rely to interpret archaeological data as evidence. These are also typically homeomorphic models, in this case of natural or cultural processes that are presumed to be responsible for (or that could have been responsible for) the production, deposition, and preservation or degradation of the types of material that make up the archaeological record: *N-transform* and *C-transform* models, to use

language introduced in the 1980s by *Schiffer* in connection with widely influential account of archaeological inference [46.36].

Archaeologists rely on an enormously broad range of other fields, from ethnography and history to biomedicine, ecology, and physics for the background knowledge necessary to build these models. But as useful as these resources are, often archaeologists find that the cultural and/or natural processes of interest to them have not been intensively studied, or not studied at scales or in contexts relevant to archaeological questions. The fields of experimental archaeology and ethno-archaeology have grown up in response to these limitations. At the C-transform end of the spectrum, the Kalinga Ethnoarchaeological Project is one example of a long-running research program in which archaeologists have undertaken their own ethnographic research with the aim of documenting methods of production, exchange networks, and patterns of cultural transmission, in this case, of ceramic technology [46.37]. A recent report on this project includes a directional graph of household pottery exchange: a phenomenological model of ethnographic data relevant to the question of whether shifting patterns in ceramic production and exchange can serve as a proxy for intensification in a craft-based agricultural economy [46.37, p. 43]. N-transform modeling includes, for example, the uses archaeologists make of well-established geological models of soil formation and erosion processes to understand archaeological deposits. But here again archaeologists often develop their own models of the impact that, for example, the activities of burrowing animals and insects can have on archaeological features and stratigraphy: “bioturbation” and “faunalturbation” [46.38, pp. 271–276]. A classic example is *Stein’s* model of the rate at which earthworms can completely turn over an archaeological midden, obscuring archaeological features and redistributing cultural material [46.39]. A number of experimental archaeologists have taken this a step further, building concrete models designed to provide insight into the processes by which particular classes of artifacts could have been produced or transformed over time into distinctive types of archaeological deposit. Bell [46.40] describes a number of experimental projects in England and Europe that involve full-scale recreations of key archaeological features, like earthworks and mounds, house structures and middens, which are then monitored, sometimes over decades, for patterns of collapse and erosion. The identification of weed complexes that are diagnostic of different types of early Neolithic farming practices in Europe (described below) depends on phenomenological models of bioecological conditions under which weed and food crop species co-occur, and the results of agri-

cultural experiments designed to model the impact on these plant assemblages of different plant husbandry regimes [46.41, 42].

Recent developments in archaeometallurgy, dietary studies, and radiocarbon dating, among other areas, also illustrate the complexity of putting external resources to work in archaeological contexts, particularly when this requires modeling physical or biochemical processes that are affected by and that reciprocally shape human activities. For example, *Pollard and Bray* [46.43] make the case that provenience studies of European Bronze Age metal artifacts has run aground; the complexity of the chemical composition of these artifacts undermines a long-running program of analysis aimed at linking individual artifacts or assemblages to particular sources of raw material. Rather than persist in the attempt to disentangle a signal linked to origin from the noise of degradation – an approach they describe as narrowly scientific – they argue for an alternative that takes as its point of departure the assumption that the chemical components of these objects are themselves dynamic, the product of jointly social and technological/material histories of circulation, reuse, repurposing. To this end they identify distinct types of copper based on the presence or absence of trace elements that reflects the differential effects on them of oxidation and interaction under conditions of repeated melting, mixing, and recycling: a phenomenological model of variability in the chemical composition of this class of material [46.43, pp. 118–120]. Similarly, complex phenomenological modeling is required to make use of stable isotope and trace element analysis of skeletal material as a basis for reconstructing dietary profiles. In an example discussed below, this involved modeling the clines in the chemical composition of groundwater across England and Europe in order to estimate the geographical origins and lifetime travels of individuals buried in a late Romano-British cemetery. Finally, the process of refining radiocarbon dates likewise depends on integrating evidence relating to physical, climatic, ecological conditions that can affect the ratio of radioactive to stable carbon in organic matter recovered from archaeological contexts: for example, fluctuations in atmospheric carbon levels, carbon sinks, patterns of carbon uptake, sources of contamination. While these N-transform models focus on factors affecting the radiocarbon signal itself, the characteristic approach of the *third radiocarbon revolution* has been a *pragmatic Bayesianism* ([46.34, pp. 140–141], [46.44, pp. 217–218]): a strategy of modeling the probability distributions for a range of radiocarbon dates that could have been produced by an organic sample. This approach takes into account not only N-transform processes that affect the measured ratio of stable to radioactive carbon in a sample,

but also multiple lines of archaeology-source evidence including, for example, stratigraphic superposition and seriation.

These examples of phenomenological models – models of data associated with archaeological subjects and sources – illustrate the now well-established point that seemingly straightforward descriptive, representational models are actually quite complex conceptually. Even when, on the face of it, they seem to be abstracted directly from the phenomena, and their source and subject is ostensibly the same, they incorporate substantial purpose-specific theoretical and interpretive, as well as descriptive, content.

### 46.3.2 Scaffolding Models: Measurement Tools and Guides to Interpretation

The complexity of phenomenological models arises, not just because their targets and sometimes their sources are complex, but because their purposes are complex; they are intended to serve a number of inferential and investigative purposes beyond systematizing the data they represent. Models of source data are intended to capture projectable relations between the physical traces that survive in the archaeological record and the antecedent events, conditions, and processes that produced them. Well constructed, they are mediators in a rather different sense than that introduced by Morgan and Morrison; they function in archaeological interpretation as auxiliary hypotheses that mediate the interpretation of archaeological data as evidence relevant for positing and testing hypotheses about the archaeological target of interest: cultural events and activities, conditions of life, systems, and processes. Here are two examples in which archaeologists make use of phenomenological models of source and subject data in this scaffolding sense, as *measurement tools or interpretive guides*.

*The Roman Diaspora Project.* In this project archaeologists make sophisticated use of an array of N-transform and C-transform models to specify the likely origins and lifetime travel of individuals buried in a late period Roman cemetery in Winchester and York, UK [46.45, 46]. The catalyst for this study was an interpretation, dating to the 1970s, of the formal traits of burials in this cemetery – skull morphology; epigraphy, statuary, and associated artifacts; and patterns of spatial orientation and distribution – that were taken to be markers of cultural affiliation and status associated with degree of *Romanization*, resistance to Roman rule, and North African or Eastern European origins as *incomers*. The Diaspora project team undertook to develop dietary profiles based on isotope and trace element analysis of

bone marrow and dental cores that allowed them to determine where individuals were likely born and spent their early years, as well as where they had lived and traveled. This analysis depends crucially on two types of phenomenological models mentioned earlier: models of cross-continent clines in the mineral composition of groundwater, and of the isotopic signatures of various types of diet. The upshot was that several individuals who had been identified originally as incomers had most likely been born and raised in the vicinity of the cemetery where they had been buried; others who most likely originated in North Africa were buried in graves that had been interpreted as elite; and several children proved to have originated outside the region where they were buried. These scaffolding models were, then, the basis for characterizing the status and mobility of individuals buried at Winchester and York in terms that pose a substantial challenge to the earlier interpretation of their remains and the canonical, text-based accounts of population diversity and mobility in the Roman Empire that had informed this interpretation [46.45, 46].

*Farming practice in Neolithic Eastern Europe.* The objective of this project was to adjudicate between competing models of the farming practices that had been adopted in various locales as agricultural subsistence patterns were taking shape in Eastern Europe through the Mesolithic to Neolithic transition 10 000 years ago [46.41]. Each of these models had some support, and each had different explanatory implications for understanding the impact of this major transition in subsistence practice on settlement patterns, material culture, social relations, and population mobility. It had proven difficult to discriminate between these competing models not least because the contemporary analogues for each type of practice involve suites of plants – cultigens and weeds – now adapted to ecological settings that have been continuously reconfigured through millennia of intensive human activity. To determine which types of farming practice were adopted at various junctures and in different locales Bogaard developed a series of scaffolding models of functional plant ecology that incorporate the phenomenological models of experimental and bioecological data mentioned earlier. These scaffolding models represent the distinctive complement of weeds associated with each type of crop and crop management, for example, intensive rather than extensive agriculture, shifting rather than fixed-plot cultivation, and spring rather than winter cropping [46.41, pp. 154–159]. The background knowledge from plant science and archaeobotany provided an initial set of posits about these weed complexes, refined through a program of experimental archaeology designed to recreate hypothesized Neolithic farming practices and document their ecological viability, labor

demands, yield, and archaeological signatures. Bogaard thus constructs archaeological proxies for the major crop husbandry models on offer and uses these lower level scaffolding models as the basis for systematically assessing the representational plausibility of each of them in specific prehistoric contexts.

In these two cases archaeologists build an assemblage of homeomorphic phenomenological models of source as well as archaeological data that, together, serve as scaffolding for the interpretation of archaeological data as evidence of specific past events and practices. As interpretive scaffolding, these models serve as the basis for analogical arguments that make possible systematic comparisons between the sources of interpretation (natural and/or cultural processes observed in the present) and the archaeological targets or subject of interpretation [46.47, 48]. While no one line of evidence based on scaffolding models is likely to be decisive, they can be used very effectively, in combination, to build and test broader reconstructive and explanatory claims about the past. The principle at work here is that such *cables* of argument will be compelling to the extent that the scaffolding models used to construct distinct lines of evidence are causally and epistemically independent of one another; this “vertical independence” is the key to ensuring that they have the capacity to be mutually constraining [46.49, p. 387], [46.50].

### 46.3.3 Reconstructive and Explanatory Models

As these examples suggest, assemblages of scaffolding and phenomenological models are the basis for building explanatory models of the cultural past of the kind that are identified as the central goal of archaeology. These last are *complex paramorphic models* either of particular archaeological targets (specific past cultures) or of generalizable types of cultural system or cultural process. Consider three reconstructive models that address explanatory questions, and that bring into sharp focus two key dimensions on which archaeological modeling varies: in degree of idealization as opposed to representational fidelity to a specific subject past; and in the nonrepresentational use of models in an experimental mode, as objects of investigation.

*Representational models: the Desert Archaic simulation.* This is a classic whole-system simulation of prehistoric subsistence practice in the Great Basin (US) known as the “Desert Archaic” that was developed by *Thomas* [46.51], in the spirit of the New Archaeology, to determine whether the Shoshone seasonal round documented in the 1930s could be projected back in time: whether it could be treated as, in effect,

a homeomorphic model of the subsistence practices of antecedent, archaeologically identified cultures in the region. Thomas' strategy was, first, to develop a computational model of the source: *Steward's* 1938 ethnographic account of the seasonal round of Shoshone foragers in the Great Basin [46.52]. He then "reduce[d] the activities [modeled] to their correlative tool assemblages", ran this single year model a thousand times, corrected for the impact of less frequently available resources, and in this way generated aggregate patterns of artifact deposition for the region. He then tested the model output against the results of archaeological surveys in the region, establishing that drop patterns for most artifact classes did conform to expectations, most strikingly in case of sites located in open areas where they had not previously been archaeologically documented. This process also threw into relief several empirical and inferential weaknesses inherent in his model, for example, the tool types differentiated by edge angle proved not to be reliably diagnostic of the functionally different types of site posited by the model. In short, one result of testing the expectations generated by his simulation of the Shoshone ethnohistoric seasonal round was to make it clear that the lithic typologies on which archaeologists conventionally relied in this region – phenomenological models of this class of archaeological data – were too coarse-grained with respect to tool function to be reliable scaffolding for the interpretation of these data as evidence relevant to questions about subsistence practice.

This reconstructive, explanatory model is explicitly representational and homeomorphic, at least aspirationally; it is intended to capture *how actually* Shoshone foragers exploited the resources afforded by the Great Basin over the 1000 year period precontact. It is credible to the extent that the models of data (source and subject) used to generate test outcomes are themselves well established and fit for purpose, and to the extent that they are also causally and epistemically independent of the overarching model they are meant to test. The principle at work here is that the material signature posited for each element of the Shoshone seasonal round should not nepotistically ensure that archaeological data will conform to expectation; I describe this elsewhere as a requirement of "vertical independence" [46.49, p. 381].

*Hybrid representational and experimental models: Gila Naquitz* (the early Mesoamerican village). This is a more sophisticated computational model of the evolution of the foraging and farming practices of a hypothetical microband developed by *Flannery* and *Reynolds* in the mid-1980s [46.53]; it answers *Flannery's* earlier call for attention to modeling approaches when the New Archaeology was taking shape [46.12]. One goal

of this modeling exercise was to simulate the process of incremental change in subsistence practices evident in the archaeological record of a cave site in the Oaxaca valley (8700–6600 BC). The simulation developed was, in this respect, a representational model built up from an assemblage of subsidiary homeomorphic scaffolding models; *Flannery* and *Reynolds* report that they did "everything we could think of to make the model realistic" with respect to the climate and paleoecology of Gila Naquitz, and the "wide spectrum" repertoire of foraging resources exploited by its late Holocene occupants that had been documented archaeologically [46.53, p. 436]. In addition, however, this model incorporates a crucial experimental component; *Flannery* and *Reynolds* manipulate key elements of the model to test the impact of different intergenerational processes of community learning from trial and error in face of fluctuating climatic and ecological conditions [46.53, p. 441]. *Flannery's* larger purpose is to assess the credibility of competing explanatory accounts of how and why agriculture developed, apparently independently, in a great many locales around the world at roughly the same time (10 000–5000 BC). He argues that archaeological and paleo-ecological evidence calls into question conventional appeals to exogenous forcing factors like environmental crisis, and urges archaeologists to consider the explanatory potential of accounts that posit more gradual processes by which incipient agriculture emerged as an extension of foraging practices, driven as much by internal social processes as by pressures to adapt to climatic variation in the early Holocene.

*Flannery* and *Richard's* strategy was to develop a computational model in two stages, simulating first the evolution of wide spectrum foraging in the area of Gila Naquitz, and then the emergence, in this context, of incipient agriculture. To make these models as realistic as possible, the repertoire of subsistence activities represented in each of these two stages was based on archaeological data that establish what resources were being exploited when the cave at Gila Naquitz was occupied; the climate was modeled as generating wet, dry, and average years randomly, based on paleoclimatic data; and the assignment of values to such variables as availability, yield, labor requirements and dietary return for the dozen key sources of food exploited by the microband was based on scaffolding models of region-specific archaeological and paleoecological data. In addition, *Flannery* and *Reynolds* developed several hypothetical subroutines to model the information-sharing and decision-making practices by which the hypothetical foragers could learn from trial and error experimentation with different resource collecting schedules and modifications to their repertoire of collecting strategies. This jointly realistic and

experimental simulation was initially run for foraging strategies alone and showed rapid improvement in efficiency until, after about 500 iterations, it proved hard to improve on the established pattern; at this point positive feedback for change shifted to negative feedback encouraging conservatism. Then they introduced several archaeologically documented incipient agricultural strategies to the repertoire – for example, clearing thorn forest to allow weedy plants (beans, and squash) to colonize, and deliberately planting maize and squash seeds – and simulated another learning process. In this second stage simulation the foraging strategies of the hypothetical microband gradually shifted, incorporating the full suite of agricultural strategies until they reached stable performance in 550 iterations.

The adequacy of the model as a representation of the real system should be evaluated in two ways, Flannery and Reynolds argue. First, as with Thomas' model, it should be assessed in terms of the correspondence of model outcomes with actual outcomes documented archaeologically – specifically, outcomes not built into the original simulation. Key measures of success were congruence in the relative emphasis on each plant species exploited for both models; the order in which changes in practice and shifts in emphasis emerge in the case of incipient agriculture model; and in the time frame for stabilization in both models. Second, Flannery and Reynolds add an assessment of model robustness that depends on experimental manipulation of model parameters and inputs. For example, to assess the role and plausibility of the multigenerational learning processes they had built into the foraging model they disabled the information feedback loop and found that performance peaked early but then oscillated in a manner quite unlike anything suggested by the archaeological record. They also changed the environmental conditions and population density under which agricultural strategies were adopted and found that the random alternation of wet, dry, and average years is a crucial stimulus for the experimentation and learning processes that, in the simulation, give rise to incipient agriculture. Under conditions of substantially greater climatic or populational stress the hypothetical band proved to be more conservative, while under conditions of lower stress the band's subsistence strategies fluctuated without the directional intensification of practice observed archaeologically.

This, then, is a computational paramorphic model poised between modeling *how actually* and *how possibly* incipient agriculture took shape in the Oaxaca valley. It incorporates a number of subsidiary homeomorphic models – analytic and descriptive models of climate, ecology, subsistence strategy – but reaches beyond them to model archaeologically enigmatic socio-

cognitive factors. As such, this model is autonomous in the sense outlined by Morgan and Morrison [46.54] and, given this autonomy, it manifests the double life of models discussed more recently by Morgan [46.4]. The simulation developed by Flannery and Reynolds serves both as a tool for investigating the archaeological subject, for which representational adequacy is key, and as an object of investigation in its own right. Experimental manipulation of the model generated a number of insights into causal dynamics of the system that could not be directly investigated, and suggests that intergenerational learning from trial and error can result in extensions of foraging practices that ultimately transform them into agricultural practices. In short, exploration of the hypothetical world of the model provides at least preliminary support for their more general contention that you do not necessarily need to posit a prime mover external to the system to account for major cultural transformations; these may well be explicable in terms of incremental changes in a number of interlinked social practices and ecological conditions.

Sophisticated models designed to simulate complex, path-dependent interactions between multiple causal and ecological factors, including decision making processes and social dynamics, have since been developed in a number of connections. In a recent optimal foraging model of the Pleistocene colonization of Sahul (Australia-New Guinea), O'Connell and Allen are explicit in rejecting *minimalist* models that downplay the cognitive and technological sophistication of these incoming foraging populations [46.55, p. 5]. Their model incorporates ethnographically and ecologically informed submodels of decision-making that had reciprocal impact on the complex environments they entered, under conditions of short-term climatic instability [46.55, p. 12]. Contributors to *Model-Based Archaeology* [46.56] likewise emphasize the complexity of the processes by which human populations modify their environments and, in turn, reconfigure their practices and technologies in response to environments they have in part created [46.57, p. 61]. Their agent-based models are built up from a great many scaffolding models that are as realistic as possible, given available archaeological and paleoecological data, but also incorporate what Kohler et al. refer to as “cultural algorithms” [46.57, p. 89]. These models are then a platform for simulating the impact of various types of stress and shifts in social organization or learning process. For example, Wilkinson et al. [46.58] develop a baseline model of an Early Bronze Age Mesopotamian settlement that they describe as a plausible, but “static view of settlement and land use” [46.58, p. 192]. They then build agent-based simulations that incorporate a number of key behavioral patterns (reciprocal exchange, kinship and subsistence

activities) in order to explore the effects of chronic or acute labor shortages and disease on settlement population and household viability. These simulations are not representational, but they provide an insight into factors that affect settlement sustainability “from the standpoint of the individual household agents” rather than at the level of the settlement as a whole and its “aggregate properties” [46.58, pp. 201, 203]. They illustrate “different evolutionary trends that households can follow” within the same socio-ecological environment, and in the process bring into focus conditions under which aggregate system behavior can abruptly change as a consequence of agent-level decisions that push the system toward “a hidden resource threshold” [46.58, p. 206].

*Experimental models: Hopi agriculturalists in the US Southwest.* This is a suite of even more hypothetical “how possibly” models developed by *Hegmon* [46.59] and *Robertson* [46.60] to explore the impact of different food sharing practices on the survival rates of households in a small-scale farming community, and the potential for (some of) these practices to generate stratification [46.60, p. 13]. Although they rely on well established phenomenological and scaffolding models of the paleoecology, settlement patterns, and social organization in the prehistoric Southwest, their purpose is not to model the dynamics of any particular ancestral Hopi farming community. Rather it is to investigate various properties and dynamics of the model itself. *Hegmon*’s initial model is a highly idealized computational model designed to simulate the survival rates of a dozen households in a hypothetical farming community that practices traditional ethnographically documented Hopi-style maize farming on three different kinds of fields under typical Southwest conditions of crop yields in wet and dry years. She asks what the survival rates for individual households would be if, rather than sharing food in dry, low-yield years, each household kept its own produce to itself, if they shared only in years of scarcity, or if all households consistently pooled their produce. For multiple runs of 20-year simulation cycles she found that households had only a 45% survival rate if they relied exclusively on their own produce. By contrast, on a *restricted sharing* scenario the survival rate was 80% for households in communities of four or more households. Pooling all produce generated equivocal results.

A related model developed by *Robertson* [46.60] relies on the same basic set-up but simulates the effects, over time, of two different sharing arrangements: an egalitarian, *credit-dispersing* strategy by which the shortfall of individual households is met through redistribution of a pool of total community surplus, and a *credit concentrating* procedure by which the household with the largest surplus has the first opportunity

to redistribute, starting with households with the smallest shortfall and meeting the needs of as many deficit households as its surplus permits. *Robertson* finds that [46.60, p. 13]:

“restricted sharing practices not only enhance household survival rates but also have the potential to lead to the growth of rather high levels of both debt and credit without any overt political maneuvering.”

For 100 runs of 40-year simulation cycles most households canceled out their credit or debt to one another, but some households did significantly better than others. Crucially, *Robertson* reports that these results were not tightly correlated with differences in the quality of the fields allocated to a household, and that they are robust even under the credit dispersing strategy, with some amplification under the credit concentrating strategy.

Despite their reliance on realistic, if highly idealized, baseline models of the regional ecology and of ancestral Hopi farming practices, these models are constructed primarily for purposes of experimentation, not to simulate the dynamics of any actual archaeological community as in the case of the models developed by *Thomas* [46.51], *Flannery* and *Reynolds* [46.53], or *Wilkinson* et al. [46.58]. The value of these models is heuristic; they allow *Hegmon* and *Robertson* to test hypothetical claims about the cumulative effects that different social arrangements could potentially have on the distribution of wealth in Southwestern communities that cannot be directly tested archaeologically. In the process, they show that significant social stratification can emerge without having to introduce the mechanisms of a chiefdom-style political formation. *Kohler* et al. [46.57] describe similar goals in connection with an agent-based simulation of the performance of farming households in the context of a suite of highly realistic, archaeologically constrained resource models of the environment in which prehispanic settlement patterns would have evolved in southwestern Colorado (600–1300 AD). Their ultimate goal is to understand archaeologically documented cycles of colonization, settlement concentration, and depopulation in the region [46.57, p. 63] but their primary interest in the simulation is in “abstract properties of the simulated exchange systems” [46.57, p. 96]. They defer assessment of the archaeological plausibility of these simulations, noting that their discussion of factors that make a difference in this simulation “is purely hypothetical”; the value of the simulation is its “power [...] to show us alternative worlds” which, even if they did not exist, “may be able to tell us many things about the worlds that did” [46.57, pp. 99–100].

## 46.4 Conclusions

I draw three conclusions from this taxonomy of archaeological models.

First, the diversity of archaeological modeling practices reinforces analyses developed in other contexts, most pointedly, in philosophical terms, by *Weisberg* in *Simulation and Similarity* [46.5], and by *Kohler* and *van der Leeuw* in their brief for model-based archaeology [46.2]. What counts as adequacy in model construction depends fundamentally on what the model in question is meant to do, and this is an irreducibly pragmatic issue: a matter of research priorities, technical capabilities, empirical and interpretive resources.

Second, reconstructive and explanatory models of the cultural past are assemblages of smaller scale phenomenological and scaffolding models that, together, represent specific factors, variables or processes presumed to constitute the archaeological target, whether this is a particular event, a local set of practices, or large-scale cultural systems and long-term processes. Taken as a whole, these assemblages are multiply connected paramorphic models; they are constructed analogically, and their content derives from homeomorphic models of subject-domain archaeological data and of source-domain data drawn from a diverse array of other fields.

Finally, models at one scale, or models of one dimension of a cultural system or life-world, are the basis for testing and refining models pitched at other scales or that represent other dimensions of the target. Claims about the empirical, theoretical credibility of an explanatory account of the past typically concern the credibility of model components, themselves narrowly specified models of particular aspects of the past cultural context or process or system under study. On a modeling approach, evidential constraints are thus diffuse, impinging on archaeological understanding of the cultural past at a number of points; testing model outputs against source data or archaeological data may suggest the plausibility of the model as a whole, but more immediately it establishes the credibility of specific elements of the assemblage. The hypothetico-deductive account of confirmation and testing that was vigorously advocated by New Archaeologists and still influences programmatic debate in archaeology captures little of what matters in this process of building, refining, manipulating, and assessing explanatory models in archaeology. When these models are compelling, their credibility arises from mutually constraining and reinforcing relations among subsidiary models rather than from any one self-warranting epistemic foundation.

# Models and Ideology

## 47. Models and Ideology in Design

Cameron Shelley

Models play a number of roles in design. Models may assist designers in the solution of technical problems. In addition, models may assist designers in achieving ideological goals. Ideological goals of designers could include respect for cultural norms, such as the distinction between masculine and feminine, or adherence to a design paradigm, such as modernism. In this latter role, design models could be compared to model citizens, that is, community members of exemplary character. Use of such models helps designers to produce solutions that fit with the prevailing norms of good design and to promote the standards of design paradigms. For example, the Ville Savoye house was designed by Le Corbusier using ships as models both to solve technical problems of accommodation but also to visibly promote the modernist design paradigm. The purpose of this chapter is to review examples of models that serve this last ideological function. Design ideologies reviewed include revivalism, modernism, industrial design,

and biomimicry. Each of these paradigms is characterized by a set of values that designers seek to reflect and promote through their works. There is no finite or canonical list of design ideologies but this set is widely known and acknowledged. So, these examples illustrate how models may serve ideological functions in various design disciplines.

### 47.1 Design and Ideology

In his history of modern design, *Forty* [47.1] considers several explanations for the increasing differentiation in design of consumer products from the nineteenth century forwards. For example, product design increasingly varied according to the gender of the intended purchaser. This trend was manifested in various articles, including wristwatches [47.1, p. 65]:

“In wristwatches, the disparity in size between those for gentlemen and those for ladies exceeded that between male and female wrists, and a lady’s watch usually had more delicate features and face. Being smaller, ladies’ watches have generally been more expensive, but when they can be compared to men’s watches of a similar price, the ladies’ models are still more ornamented. In the 1907 Army and

Navy Stores catalogue, the men’s watches were all calibrated with Roman numerals, while the ladies’ watches all had Arabic numerals, whose form – curvilinear rather than angular – may be judged more delicate.”

These differences in wristwatch design have little to do with any physical differences between the arms and eyes of men and women and more to do with differences in their social roles. As the social spheres of men and women diverged, so did prevalent ideals of the masculine and feminine. These ideals then came to be embodied in the design of consumer goods that, in turn, served as confirmation that the ideals reflected an objective reality. In other words, as *Forty* [47.1, p. 66] points out, the design of objects such as men’s and

ladies' wristwatches reflects an ideology in which *masculine* versus *feminine* is a crucial distinction. Design, along with fiction, education, and religion, helped to make this ideology manifest, thus both making it visible and material and also reinforcing its veracity.

## 47.2 Models and Ideology

Given the importance of ideology in accounting for designs, there remains the issue of how ideology exerts its influence. One way in which ideology participates in design is through the use of models. Designers frequently rely on models in order to address design problems.

For example, in the original version of the Calculator app for its iPod and iPhone, Apple designed the interface to recall the signature Braun ET-44 calculator created by legendary designer Dieter Rams [47.2]. The rounded buttons with convex, raised centers were a distinctive design element of the original calculator. Even though the flat, touch-sensitive surface of the iPhone could not accommodate raised buttons, the crisp and candy-like appearance made the interface attractive and inviting.

Apple's designers had at least two reasons for using the ET-66 as a model. First, it was a borrowing from a proven design, aimed to make the calculator app straightforward and pleasant for users, regardless of their familiarity with the original. Second, it was an homage to a design classic; Steve Jobs' admiration for Rams is well known [47.3]. By imitating the ET-66, Apple's designers connected their work to an honored design tradition. In brief, Rams' ET-66 stood as a model for the Calculator app in two respects, as a guide to resolving an interface challenge and as an assurance of right-mindedness of their design philosophy.

The term *model* itself exhibits an ambiguity between these two senses:

1. A model can be a *model solution*, that is, something that exhibits how a particular problem can be solved correctly or optimally.
2. A model can be a *model citizen*, that is, someone who embodies right thinking and good conduct and is thus worthy of emulation.

A model solution provides a solution to a problem that can be applied analogically to other problems of

The role of design in both manifesting and reinforcing ideology is demonstrated in other social conceptions as well, such as *juvenile* versus *adult*, *middle class* versus *working class*, and *master* versus *servant* [47.1, p. 67ff].

a similar nature. A model citizen embodies the values of a community and inspires others to act in accord with those same values.

Rams' calculator served as a model for the Calculator app in both senses. It saved Apple designers the trouble of trying to design a calculator interface from first principles. It also provided them with a standard of design excellence that their own work could strive to live up to.

The role of models as model citizens in design more clearly reflects their role in the ideology of design. That is, model citizens represent an ideal of social standards and behavior that designs tend to reify and reflect. So, to further understand the place of ideology and models in design, we must examine models in design as model citizens.

To explore this subject further, it will be convenient to look at design as practiced in a number of ideologically informed, modern design movements. Each movement exemplifies a different ideology and illustrates how models have been used as model citizens in design. The design movements discussed are as follows:

1. *Revivalism*: The Gothic Revival of the nineteenth century looked to the European Middle Ages for models of good design.
2. *Modernism*: The Modernist movement of the early twentieth century looked to contemporary heavy industry for models of good design.
3. *Industrial design*: Consultant designers of the mid-twentieth century looked to forecasts of future industry for models of good design.
4. *Biomimicry*: Engineers in the later twentieth century looked to biological organisms for models of good design.

In each case, the ideological aspects of models, in the sense used by *Forty* [47.1], are explained and discussed. From this examination, the importance of ideology in model selection will become more clear.

## 47.3 Revivalism: Looking to the Past

In general, revivalism refers to the use of elements from an historical design style in contemporary designs. One of the best-known revivalist design movements was the Gothic Revival, which reached its height in Britain in the nineteenth century. The Gothic Revival began in the eighteenth century, after the antiquarian Horace Walpole wrote the medieval romance, the *Castle of Otranto* in 1764, and another book about his old house, Strawberry Hill in 1774. The latter book described how Walpole renovated this house with elements from medieval buildings, such as pointed arches, crockets, quatrefoils, and so on. This book helped to raise general interest in the architecture and design from medieval Europe [47.4].

In the years after the Napoleonic Wars, the government Church Building Commission undertook to subsidize the construction of hundreds of churches throughout Britain. The general idea was to knit back together the social fabric that had unraveled somewhat under the pressures of the prolonged and ideologically charged conflict. Many of these churches were built in a Gothic style. That is, they often applied design elements from Gothic structures, in the spirit of Walpole's version of decoration [47.5]. See the Gothic Revival St. Peter's church, built under the auspices of the Commission in Fig. 47.1 for an example.

Some architects criticized the Commission's approach to architecture. Among them was Augustus Welby Northmore Pugin (1812–1852), most famous for his work on the Palace of Westminster in the 1840s. Pugin objected that, oftentimes, Gothic elements such

as pointed windows and buttresses were simply tacked on to structures that were essentially classical in design, having the basic form of Greek temples. The resulting hybrid structures were not truly Gothic at all in his eyes. Compare St. Peter's to the neoclassical St. John's church, built under the auspices of the Commission, in Fig. 47.2. Note how St. Peter's imitates the roof profile and basic layout of the neoclassical model, except with Gothic-style buttresses and accoutrements in place of classical ones.

Pugin had formed a strong attachment to medieval buildings and churches in particular. He had converted to Catholicism in 1834, in part as a result of his experiences studying medieval churches in England and northern France. He saw a strong connection between medieval architecture and proper, Christian faith. As his biographer puts it, for Pugin, “the Catholic Church is the true church, Gothic architecture its revealed form, true in the sense of absolute, a divine, revealed form” [47.6].

For Pugin, the ideology of the Gothic Revival contained at least two social ideals, those being *authenticity* and *conservatism*. Being authentic did not mean, of course, that a building had to be a genuine medieval structure. Instead, it meant that a building should be a close facsimile of genuine buildings of the earlier era. Studies of genuine structures in England and northern France served as models that could guide the revivalist architect in this matter.

**Fig. 47.1** St. Peter's Church, Blackley, UK. Designed by E. H. Shellard, ca. 1845. The church has the basic form of a Greek temple but is dressed up with Gothic features such as pointed windows and superfluous buttresses. Photo by David Dixon

**Fig. 47.2** St. John's church, London, UK. Designed by Francis Octavius Bedford ca. 1824. Photo by The Voice of Hassocks

An important aspect of authenticity, then, was *localism*. That is, revivalist structures should use local materials and building methods that imitated the methods used in the Middle Ages by builders in the vicinity where the new building was to stand. In the Middle Ages, the transportation infrastructure of northern Europe was neither efficient nor developed enough to allow for the shipment of large volumes of materials over long distances. As a result, medieval buildings tended to be made of materials acquired in the local area. Similarly, poor infrastructure meant that the builders hired to construct buildings were also recruited from the local area. This situation facilitated the existence of local idioms in design. That is, each region tended to see the rise of design traditions within the region and different from the traditions that arose in other regions. For authenticity in a building to be situated in a given region, Pugin thought it best to observe the local building traditions that characterized genuine, medieval buildings nearby.

From an instrumental standpoint, this emphasis on localism was not always optimal. In the nineteenth century, it would often be more economical to ship materials and workmen from other areas of the country by rail or canal. Pugin's emphasis on localism was motivated on ideological and not instrumental grounds.

Beyond authenticity, Pugin's careful imitation of medieval design was motivated by religious conservatism. Contemporary Protestant churches tended to be spatially simple in the sense that their interiors were relatively undifferentiated spaces in which the congregation and minister gathered together. A Catholic church from the Middle Ages was a microcosm of the medieval worldview, a hierarchical arrangement of separate spaces, each with its own appropriate functions and occupants. Pugin's church designs persisted in this traditional divided arrangement of spaces. For example, Pugin's church designs usually contained a *rood screen* to separate the nave from the chancel, thus keeping the altar and choir apart from the congregation. This

separation had an important function in the medieval ceremony of mass but had fallen out of favor among Anglicans and Catholics by the nineteenth century. Pugin designed the screens for his churches as a way of advocating for the return to medieval forms of worship, which he regarded as worthier. A controversy ensued that was settled, in the end, by an appeal to the Vatican, which sided with Pugin's opponents. As a result, many of the rood screens in his churches were subsequently removed [47.7].

So, authenticity and religious conservatism were important social ideals in Pugin's version of the Gothic Revival. First, the continued presence of medieval Gothic architecture in the country supported the view that such architecture was an authentic expression of Englishness. Study of regional variations in medieval Gothic architecture in England only served to reinforce its authenticity. By reviving the Gothic style, then, Pugin was not introducing a foreign element into English life.

Second, Pugin could point to the models as evidence of the Englishness of the Catholic Church. Britain was officially Anglican and had only recently passed a law tolerating Catholicism and allowing Catholics to hold public offices. Pugin hoped to turn this tolerance into broader acceptance of Catholicism, even reconciliation with the Anglican Church. People's attachment to these medieval buildings, reinforced through Pugin's own works, might lead them to reconsider their separation from the Church of Rome.

The Gothic Revival shows how models can play a role in the ideological side of design. Design is undertaken not merely to solve a given problem but to reflect a worldview. In the Gothic Revival, historical authenticity and religious propriety were dominant ideological values that informed design. Practitioners of the Gothic Revival, such as Pugin, naturally looked to surviving instances of Gothic architecture as models of solutions to technical design problems and also as embodiments of their social ideals.

## 47.4 Modernism: Transcending History

Historical structures are an obvious source of models within a design ideology that seeks to reinstate or reinvigorate past modes of living. By the outset of the twentieth century, some designers had decided that revivalism was not a tenable ideology. Technological advances had brought with them new challenges and those challenges called for new approaches. Thus, appropriate design ideology had to be divorced from attachments to the past.

The designer who perhaps most embodies this form of modernism is Le Corbusier. Born as Charles Edouard Jeanneret (1887–1965) in Switzerland, Le Corbusier trained in engraving but made his mark in architecture and urban planning. Le Corbusier set up his practice in Paris towards the end of World War I and advocated modernist housing as a means of quickly rebuilding the housing stock destroyed in the war. He published a collection of essays, *Vers une*

architecture [47.8], discussing his views on architecture.

In this book, Le Corbusier famously promoted his view that the design of contemporary industrial objects formed the best source of models for architecture. In particular, he described a house as “a machine for living”, meaning that houses should be designed just like cars, boats, or other mass-produced objects. His most famous house, the Villa Savoye built in 1928–1931 near Paris, was designed in this manner (Fig. 47.3). It was made of modern materials, reinforced concrete, steel, and glass, with no attempt at disguise or decoration. The use of steel and concrete structure meant that there was no need for load-bearing walls, so interior walls were eliminated or minimized. Thus, the interior was largely open space. Each of the four exterior walls contained long ribbon windows, reducing the distinction between inside and outside. The roof was flat, not peaked, and contained a garden for the occupants to use, rather like the recreation deck on an ocean liner. In fact, the design of the house was inspired by the design of the decks of ocean liners such as RMS Aquitania, a picture of which was featured in Le Corbusier’s book (Fig. 47.4).

**Fig. 47.3** La Ville Savoye, Poissy, France. Designed by Le Corbusier ca. 1930

**Fig. 47.4** Deck of the RMS Aquitania. Detail of photo by Library of Congress

In urban planning, Le Corbusier’s early ideas are conveyed by the *Ville Contemporaine* exhibit that he mounted at the Salon d’Automne in Paris in 1922 [47.9]. This ideal city contained a central district consisting of glass skyscrapers and apartment buildings arranged in a grid pattern. Connecting the buildings with each other and the surrounding countryside were a network of highways. At the center where the highways met would be a seven-level transportation hub including levels for railways, highways, subways, with an airport on the top layer. The buildings were to be raised off the ground on stilts so that the ground level of the entire city could be a large green space.

Each component of the design is dedicated to the fulfillment of a single function. The buildings in the central core were for white-collar workers who would run the city. Blue-collar workers and industrial facilities would be placed in areas outside the central district. Some buildings in the core were for work, others for housing, others for commerce. Some spaces were dedicated to transportation, for example highways and airports, whereas others were dedicated to recreation, for example rooftops and the ground-floor green space. In order to transition from one activity to another, a person would drive a car along the highway to the space designed for that activity.

This initial design was generic. However, Le Corbusier later exhibited a design of this type specifically for Paris at the *Exposition des Arts Decoratifs* in 1925. It was called the *Voisin* plan after the automobile and aircraft manufacturer that sponsored Le Corbusier at the event. In this plan, Le Corbusier suggested razing the central district of Paris and replacing it with a grid of eighteen sixty-story skyscrapers connected by highways. Important monuments like Notre Dame would be retained but, otherwise, the core of the city was to be entirely rebuilt. The traditional but chaotic layout of Paris, with its maze of medieval streets, was to be eliminated in favor a functional and efficient grid of massive buildings and roads.

Le Corbusier’s ideas become influential particularly after World War II, when building and rebuilding projects took off all over the industrialized world. Highways were built, old neighborhoods were bulldozed to make way for expressways and apartment blocks, and the downtowns of big cities filled with slabs of concrete, glass, and steel. Note the resemblance of the Co-op City buildings in Fig. 47.5, constructed ca. 1970, to those envisioned by Le Corbusier.

A great virtue of modernist design is that it made efficient use of industrial materials, allowing infrastructure to be built rapidly and affordably. A great problem of the modernist approach is that it could be overwhelming and inflexible, treating people somewhat as

**Fig. 47.5** Co-op City, the Bronx, USA. Photo by Jules Antonio

goods to be stored and moved about as required by the design of their infrastructure [47.10].

The main social ideals of Le Corbusier's modernist view are *functionalism* and *conformity*. Functionalism identifies the analytic approach to design adopted by the modernists, embodied in the expression *form follows function*. In brief, design should be approached from perspective independent of history. To a functionalist designer, it is of no relevance how buildings or anything else were designed in antiquity or the Middle Ages. All that matters is the problem to be solved and the means available to solve it with. Le Corbusier took a Platonic view on which the activities of living and the architectural forms for building are regarded as a set of timeless forms. His buildings exhibited a preference for simple geometric figures and solids in combination.

In terms of analysis, modernist designers sought to disaggregate the various activities that would occur in the use of the design. When designing a house, or machine for living, the process of living should be broken down into its subprocesses and some space designated for each. The remaining task was to place the spaces for each activity in the correct relation to each other. In the Villa Savoye, the ground floor contained spaces for auxiliary functions, including the entrance, the garage, and rooms for chauffeurs and maids. The main floor contained the bedrooms for sleeping, the kitchen for cooking, and the salon for interacting. The roof contained the garden for relaxation and recreation. In the Voisin plan, activities such as resting, recreating, working, and moving were each assigned a separate space. Highways were used to allow people to move from one activity to another with as little hindrance as possible.

Besides disaggregation, functionalism also implies a kind of universalism. Just as the relevance of historical antecedents is minimized, so is the relevance of region-

alism. Functionalist design tends to focus on the basics. Living in a house, for example, is analyzed to an almost biological level: eating, sleeping, exercising, interacting. These functions are universal ideals that apply to all people. In contrast, cultural preferences, such as having a porch or enlarged foyer to lend importance to the front entrance, are minor considerations.

In addition, another important component of functionalism is honesty [47.11]. That is, the aesthetic value of a modernist design should come from its construction instead of from add-on decorations that serve no basic purpose. In the Victorian era, designers might use iron as a structural element of Gothic buildings, as Pugin did for the Palace of Westminster. However, the iron would be hidden from view. From a modernist perspective, this practice is dishonest. A building made of steel, glass and concrete should display these materials. Furthermore, its construction should be such that nothing further is required to make the building look good.

Besides functionalism as such, modernist designs also tend to require *conformity* from their users. A modernist building, for example, does not invite later modification. If the building's form resulted from a correct application of timeless ideals, then no modifications should be necessary. In the Voisin plan, residents were not to be invited to customize their spaces to suit themselves. In some cases, this attribute of modernist design may be put down to the narcissism of the designers. In many cases, however, conformity was an implication of the modernist view of industrial production as the ultimate state of civilization. The efficiencies of industrial design and production would drive out suboptimal or idiosyncratic architecture, replacing it with universal design. In that event, people would have to accommodate themselves to their designed surroundings, rather than the reverse. This view is admirable in its egalitarianism, that everyone should enjoy the same, amenable standard of living. However, it is also objectionable in the sense that it aims to achieve this end through imposition of a rigid mode of life.

In any event, models were important to the development of modernist design. The influence of ships, in particular, on Le Corbusier was noted above. The ability of passenger ships like the Aquitania to efficiently accommodate hundreds of people on long voyages clearly impressed him. In his architecture, he sought to apply the lessons of ship design, as he saw them, to the design of houses and even cities. The efficiency with which modernist designs could provide accommodation for large number of people, using modern, mass-produced materials such as concrete, steel, and glass, made it a highly suitable building regime for the post-World War II construction boom.

Of course, modernist models had their limits. After all, ships (and cars and airplanes, other sources much admired by Le Corbusier and contemporary modernists) are not themselves machines for living but machines for transportation. The arrangements made in such vehicles for people to travel in them temporarily are not necessarily appropriate for structures where people expect to live permanently. The conformity required in arrangements for air travel, for example, is more of an imposition in a house or a neighborhood.

However, such limitations might be overlooked because industrial models also served their ideological function. That is, living in industrial surroundings would accommodate people to the industrialized world that they inhabited. In his way, then, Le Corbusier was just as concerned as Pugin for the authenticity of his architecture. However, cars and ocean liners served him as guarantors of authenticity and the good life in place of the medieval cathedrals favored by his predecessor.

## 47.5 Industrial Design: The Shape of Things to Come

Besides looking to the past for inspiration or to the present, it is also conceivable to look to the future for models suitable for the purposes of good design. Although such a perspective may sound paradoxical or even impossible, it was characteristic of a third design movement that I wish to examine, that being industrial design.

Strictly speaking, industrial design is not a movement but a profession. It arose as a result of the industrial revolution and the mass production of goods. Before the revolution, household goods were typically produced by craftsmen who worked in local design traditions, producing a given item from raw materials. With industrialization, craftsmen were replaced by semiskilled laborers who did not participate in the design process. Goods were designed either in imitation of previous craft traditions, or they were designed by their inventors. By the early twentieth century, both these approaches had proven inadequate for the novel technologies that were being mass produced. A group of professionals arose whose occupation was giving proper form to these new technologies. These were the industrial designers.

In spite of the fact that industrial design was, and continues to be, a profession, its first practitioners shared a set of social ideals that informed their work. Thus, the profession also constituted a design movement with a characteristic ideology. Perhaps the key values of this ideology were *progress* and *consumerism*.

The value of progress in industrial design was most clearly captured by Raymond Loewy, perhaps the most famous industrial designer of his era. Loewy (1893–1986) was born in France and received an education in technology in a preparatory school in Paris. He served in the French Army Corps of Engineers during the World War I. After the war, he emigrated to the United States where he made a living applying his artistic talents as a window dresser for New York department stores and as an illustrator for fashion magazines. His

first break in industrial design came with the commission to redesign the Gestetner duplicating machine in 1929. Afterwards, Loewy established a successful design consultancy and participated in the design of a variety of industrial objects, from cigarette packages to cars, locomotives, and refrigerators.

In his autobiography, *Loewy* tries to capture some of the lessons he had learned over the course of his career [47.12]. One of the key lessons is embodied in what he calls the MAYA principle. *MAYA* is an acronym for the phrase *most advanced yet acceptable*. In his view, a well-designed product should appear to its users to be technologically advanced but also comfortably familiar. Loewy had observed a tension in people's minds about what they expect from the things they use: On the one hand, people expect technology to improve over time, so that a newer product should outperform older ones. As a result, they expect the design of their gear to change over time. On the other hand, people like to stick with what they know or are used to. Thus, change in design can be discomforting or unwelcome. The *MAYA* principle suggests that industrial design has to balance people's expectation of innovation with their need for stability.

Consider Loewy's redesign of the Gestetner mimeograph machine [47.13]. The Gestetner was an industrial contraption with an exposed mechanism and perched on an ungainly metal frame. Loewy enclosed the mechanism in a streamlined case and streamlined the machine's appearance and footprint. By enclosing the machine's workings, Loewy made it less dangerous, for example, the user's tie and fingers were not likely to get caught in its gears and its toner was less likely to splash the user's skin and clothing. The new appearance also made the machine more approachable.

Loewy's redesign of the Gestetner provides a good illustration of the *MAYA* principle. The new design was advanced in the sense that it brought the productivity of an industrial device into the office space. Beforehand,

the ungainly and mechanical look of the Gestetner had caused users to categorize it as industrial equipment. Thus, it was treated like a furnace or a boiler and hidden away from the office spaces where its duplicating function was most useful. Afterward, by making the Gestetner look and feel much like a file cabinet, Loewy caused office managers to think of it as a piece of office furniture, to be kept in the workplace itself. Thus, the new design was advanced in the sense that it brought industrial productivity to the office, and acceptable in the sense that it looked right at home next to the file cabinets and desks already situated there. After the introduction of the new design, the Gestetner sold well as a piece of office furniture.

The MAYA principle illustrates the importance of progress to industrial design of this era. Advancement, on this principle, is an indispensable part of the design of new goods. That is, one of the jobs of a good designer is to provide customers with goods that will outperform previous designs, thus making the work of customers more productive, and their lives more pleasant. As a practical matter, the MAYA principle also instructs us that progress is best served up in moderate doses. This view stands somewhat in contrast with the view among some current designers that advancement should come in the form of game-changing or disruptive designs.

Consumerism is also part of this picture, although not one that is explicitly noted in the MAYA principle. If there is to be advancement in design, then existing designs must become obsolete. New designs can make old ones obsolete in at least two ways. First, new designs may perform a given job better than old designs. A new engine, for example, may burn fuel more efficiently than older designs. Second, new designs may appeal to people more than old designs. The practice of changing the style of cars each year provides a good example: people may get rid of an old car in favor of a new one not because the new one is technically superior but because the appearance of the new car makes them feel unhappy about the appearance of the old one. This mental phenomenon is known as *psychological obsolescence* [47.14].

One example of how industrial design could be applied to psychological obsolescence is provided by Loewy. One of Loewy's best-known designs was a streamlined pencil sharpener. The sharpener was designed in the shape of an aerodynamic tear drop, with the hole for insertion of the pencil tip at the round end and the handle to turn the mechanism at the pointed end. *William Gibson* describes the sharpener as follows [47.15]:

**Fig. 47.6** Petipoint streamlined iron, made by the Weverly Tool Co. of Sandusky, Ohio, ca. 1941. Detail of photo by Tomislav Medak

“The Thirties had seen the first generation of American industrial designers; until the Thirties, all pencil sharpeners had looked like pencil sharpeners; your basic Victorian mechanism, perhaps with a curlicue of decorative trim. After the advent of the designers, some pencil sharpeners looked as though they'd been put together in wind tunnels. For the most part, the change was only skin-deep; under the streamlined chrome shell, you'd find the same Victorian mechanism. Which made a certain kind of sense, because the most successful American designers had been recruited from the ranks of Broadway theater designers. It was all a stage set, a series of elaborate props for playing at living in the future.”

The point is that the mechanism of the sharpener has not changed. Loewy has simply made the casing more up-to-date.

This application of industrial design encourages consumerism in the sense that it invites users to confuse technological innovation with stylistic innovation. In the case of the pencil sharpener, this confusion could lead users to dispose of their existing goods in order to purchase new ones that do not sharpen pencils any better.

*Gibson* also observes that industrial design of the era allowed people to *play at* living in the future. This point is key to see how the use of models fits into this version of industrial design. Designers like *Loewy* could not, of course, actually see into the future and take from there the models they needed for the present. They could, however, take current trends in technology and extrapolate them. One trend they could extrapolate involved *streamlining*, that is, the use of aerodynamic shapes. Industrial designers of that era felt that air travel was the transportation of the future for all [47.16]. Thus, industrial designers took existing aircraft as models, imagined how they would look in the future, and then

applied these ideas to the design of various contemporary goods, even such slow-moving objects as pencil sharpeners or irons [47.17] (Fig. 47.6). Thus it was that industrial designers could look to the future, as it were, for models to apply to contemporary design problems.

As with revivalists or modernists, industrial designers of the early twentieth century used models in order to address design problems. Their models were selected not merely for their ability to answer questions of function but because they embodied the ideals of the movement. Central to the ideology of that movement were the ideals of progress and consumerism.

## 47.6 Biomimicry

Designers typically look to artifacts to find models for their work. Of course, it makes sense to seek one artifact to be a model for another. Yet, the natural world also provides models for designers. On the face of it, this observation seems odd since the natural world is not an artifact. However, the process of evolution has produced organic forms that can be treated as designs, that is, as solutions to problems posed by the environment. For example, many early airplane designers looked to birds and other flying organisms in order to work out their designs [47.18]. As is the case with artifacts, organisms such as birds can serve as model solutions but also as model citizens.

In fact, several design movements have taken organisms as models in different ways. In art, the Art Nouveau movement often used plants as models for its curvaceous forms. Designers interested in sustainability often look to organic systems for inspiration, such as the *Cradle-to-Cradle* paradigm espoused by *McDonough* and *Braungart* [47.19]. Others adopt organic models based on the biophilia hypothesis of *Edward O. Wilson* [47.20], on which human beings simply have a profound need of, and liking for, natural forms and systems. Each movement has a distinct ideology associated with it.

Another design movement taking organisms as models, known sometimes as *biomimicry*, views organisms as marvels of engineering. The efficiency and optimality found in organic forms serves as a model for engineering designs [47.21]. Biomimicry is the paradigm explored here. In particular, the exposition of biomimicry given by *French* [47.22] is used because its ideological content is presented clearly.

Like the modernist architects, an important ideal of biomimicry is *functionalism*. That is, design should be dispassionate and analytic. Like *Le Corbusier*, who

sought to separate architecture from nostalgic attachments to historical forms, *French* holds that good engineering is the result of cool calculation, for which evolution provides an instructive example [47.22, p. xii]:

“Living organisms are examples of design strictly for function, the product of blind evolutionary forces rather than conscious thought, yet far excelling the products of engineering. When the engineer looks at nature he sees familiar principles of design being followed, often in surprising and elegant ways.”

The forces of evolution are blind in the sense that they respond only to the problems of the present and are not sentimental about the past or, for that matter, concerned with their legacy for the future.

The anti-sentimental stance of biomimicry focuses the attention of the designer on the products of evolution through natural selection. In many treatments, natural selection is the only kind of evolutionary scheme discussed, for example [47.18].

Other evolutionary forces are set aside. *Darwin* [47.23] argued that, in addition to natural selection, the form of organisms could be explained by sexual selection. The extravagant tail of the peacock, for example, could not be explained by a struggle for existence as it hardly improves the peacock’s ability to fight, fly or feed. However, it could be explained by the need of male birds to impress choosy females. The focus on aesthetics involved in sexual selection is not compatible with the functionalist outlook of biomimicry.

Biomimicry also exhibits the other aspect of functionalism shown by modernism, namely an emphasis on efficiency. *French* notes how organisms display adherence to a principle of economic efficiency, namely the

division of labor. In classical economics, an economy functions most productively when each of its members simply does what they do best, and nothing else. A similar principle holds in the organic world [47.22, p. 3]:

“The division of labour is but a special case of a more general principle of functional design, the *separation of functions*. Thus, simple single-celled organisms have to provide all their functions in one cell, whereas higher animals and plants have many different kinds of cell for special purposes, carrying sap, extracting water and minerals from the soil, transmitting signals, secreting digestive juices, etc. The early steam-engines, following Newcomen’s design of 1712, had a cylinder in which the steam did work and in which it was also condensed. Watt’s engine, fifty years or so later, separated the functions of working cylinder and steam condenser, so greatly increasing the efficiency.”

Organisms evolve to display this economy of organization, thus providing models for engineers.

As before, this characterization of the natural world diverts attention from organic structures that serve multiple functions. The feathers on a bird’s wings, for example, may help that structure to create lift, but also play a role in creating thrust, and supplying a platform for decorative features important in the competition for mates.

Also like modernist architects, although biomimicry involves suspicion of ornament, it shows an aesthetic concern through attention to elegance. A design, like an organism, can achieve elegance simply by being thoroughly functional [47.22, p. 14]:

“One characteristic of functional design is elegance. Most people find a buttercup beautiful, and many would say that the locomotive was at least pleasant to look at. However, the buttercup has an essential elegance, much more fundamental than its mere appearance. It is an elegant solution to a difficult problem in functional design.”

This approach to aesthetics is *reductionist* in the sense that it holds that a kind of beauty, namely elegance, can be achieved by adhering to nonaesthetic values such as dispassionate analysis and economy. This kind of beauty is exemplified by organisms like buttercups but also, to a lesser degree perhaps, by artifacts like locomotives. French’s treatment of elegance is thus much like the modernists’ treatment of honesty in functionalism.

A salient difference between biomimicry and modernism is that the former allows an ideal of *plurality* instead of *conformity*. Modernists like Le Corbusier held that their views on design applied fundamentally

and universally. As such, there is no room for other design paradigms.

Biomimicry, however, admits the (limited) applicability of other approaches to the use of natural models in design. French contrasts the field of engineering with that of architecture, which has a different ideology and occasionally produces good results [47.22, pp. 5–6]:

“However, in much architecture the functional aspects are very secondary to aesthetic ones, and, moreover, rather readily met (or indeed, neglected altogether, as in some badly-designed buildings which have nonetheless won awards). Another defect of architecture as a training ground for functional design was that often the economic constraint, so powerful throughout nature and engineering, was virtually absent, the patrons caring more for glory than the public good (which was the public’s loss then, but is sometimes our gain now).”

Clearly, French’s pluralism is graded and grudging. That is, he places engineering above architecture in terms of the typical quality of its results. Nevertheless, architects sometimes produce works that are both artistic and sound. A medieval cathedral, for example, may be ornamented in beautiful sculptures of people and animals that no engineer would ever produce. Yet, it also includes a broad roof and sturdy buttresses that make it sound and lasting.

One other ideal of biomimicry of the type described by French may be termed *masculinity*. Hofstede [47.24] defines masculinity in a culture as a gender role that emphasizes self-orientation, assertiveness, and ambition over feminine values such as relationships, communication and caring. The preference for masculine features of evolution is suggested by the emphasis placed on natural selection as a competition for survival amongst individuals, a kind of war of all against all. Attention is paid mostly to features that animals have for obtaining food, fleeing predators or fighting rivals. Features that animals have for more feminine tasks such as forming groups, cooperating with others and raising offspring are less often examined. Consider this description of the severity of conditions to which natural designs respond [47.22, pp. 265–266]:

“The difficulties of a hostile environment are added to by those of growth; many organisms must fend for themselves from an early stage; for example, fish may be all on their own when only a centimeter or so long, though they may eventually reach a meter in length. The caterpillar-pupa-butterfly and tadpole-frog metamorphoses are familiar. If the caterpillar is eaten there will be no butterfly;

each stage must be viable. Insects and other arthropoda, such as crabs and shrimps, have a hard outer skin which cannot grow with them, and must be moulted periodically as it becomes too tight; until the soft new armour hardens, they are relatively defenceless.”

Adaptations that animals possess for feminine functions are mentioned briefly and as an afterthought [47.22, p. 266]:

“One of the devices used to cope with the extreme severity of the design problem of living creatures is a very high production rate, so that out of millions of embryos a handful may survive. But some less wasteful approaches have appeared in the course of evolution, principally, the protection of the young by adults among the higher animals and termites, ants and bees.”

## 47.7 Conclusion

Design paradigms exhibit ideological characteristics. That is, they adhere to a set of ideals about what good design is and is not. The selection and use of models in a design paradigm is duly affected by the prevailing ideology. Within a design paradigm, models are selected both because they are model solutions, providing answers to design questions, and because they are model citizens, properly reflecting and reinforcing the ideals of the paradigm.

The ideologies of four design movements have been explored and exhibited. Revivalism, modernism, industrial design, and biomimicry have all been important

approaches to design problems. Each exhibits a characteristic ideology. Each ideology is reflected in the selection and use of models in each case. In this way, each ideology assists in the process of innovation of solutions to design problems, and produces artifacts that bear out the soundness of the ideology.

It seems fair to say that biomimicry concerns itself primarily with those aspects of animal bodies that are most closely associated with culturally masculine activities. As with any ideology, biomimicry tends to be self-reinforcing. That is, models for artifacts may be located in nature according to the ideals described above. Subsequently, the success of artifacts designed in this way attests to the validity of the ideology. For example, perhaps the most famous instance of biomimicry is velcro [47.18, pp. 268–270]. Swiss engineer George de Mestral investigated how burrs stuck so tightly to his coat and his dog’s fur. He went on to devise an artificial equivalent made of nylon that is still a popular fastener. Burrs are the seed pods of burdock plants, which use their adhesive function in order to spread the seeds around as a part of the struggle for survival. Thus, the continuing fame of this example attests to the functional and masculine ideals of biomimicry.

approaches to design problems. Each exhibits a characteristic ideology. Each ideology is reflected in the selection and use of models in each case. In this way, each ideology assists in the process of innovation of solutions to design problems, and produces artifacts that bear out the soundness of the ideology.

## 48. Restructuring Incomplete Models in Innovators Marketplace on Data Jackets

Yukio Ohsawa, Teruaki Hayashi, Hiroyuki Kido

Innovators Marketplace, a market-like workshop where cards showing existing pieces of knowledge in various domains are combined to create ideas of services/products and thrown into demand-driven communication to choose practical ideas, has been extended to a setting of the market of data. This extension is called Innovators Marketplace on Data Jackets, a workshop in which each prepared card called a data jacket represents the digest knowledge about a dataset, that is, a kind of metadata. Data jackets are disclosed, whereas the corresponding data are not, and participants of the workshop create ideas for combining and analyzing data using the visualized correlation of data jackets. In this chapter, this workshop is described as a systematic process for reasoning on incomplete models, where each data jacket is regarded as an incomplete local model in the domain of the data, and communication is launched for satisfying requirements in the market (regarded as incomplete global models) by restructuring and combining local models. The data jacket may initially include atoms and terms in the domain, not connected via complete causal relations. Via the communication, however, links including causal relations appear and are revised toward obtaining a *glocal* model corresponding to a solution to satisfy requirements in the marketplace. In this process, the local model corresponding to each element is also revised to obtain useful knowledge digesting the corresponding data.

One century passed since Schumpeter suggested the concept *innovation* as a creative activity by which the economy jumps up to a new state, and that this creativity is to be realized by a novel combination of industrial resources [48.1]. After half a century, *Rogers* pointed out that leading consumers play the role of *innovators* [48.2]. That is, an important idea cannot become an innovation without innovators who are not only those who produce products/services but also consumers who discover new values of products in using them and diffuse the discovered values to the majority. Here lead-

ing consumers can also invent, not only use and diffuse technologies [48.3]. Thus, innovation came to be a term referring to the thoughts and the interaction of stakeholders in the market, involving inventors in companies, sensitive and communicative diffusers, and also consumers. As a result of their interaction, novel dimensions are to be introduced for evaluating and improving the performance of humans' activities in the real life, as in *Drucker's* redefinition of innovation "a change that creates a *new dimension of performance*," which urged him to discuss *do's* are essential paths to innovation [48.4, 5].

## 48.1 Chance Discovery as a Trigger to Innovation

In this chapter, we aim at showing the potential contribution of model-based reasoning to modeling the process of data-driven innovation. For this, we introduce *chance discovery* that means to discover a chance event – an uncertain event significant for making a decision, as in the definition since 2000 [48.6]. Especially if the chance event is rare or novel, the attention to the event may trigger the creation of a novel performance dimension to the human life, as Drucker's above definition of innovation. In fact, users of methods for chance discovery went beyond their previous achievements in data-based decisions, as exemplified in the next section. In successful cases [48.7, 8], chance discovery has been understood as innovation by enhancing humans' activities with value sensing [48.9] and sense making [48.10, 11], taking advantage of tools for data visualization positioned and used in the process for decision making. Areas such as evidence extraction and link discovery (EELD) [48.12] shared this basic idea, but the point of chance discovery was unique in the sense we focused on the effect of communication with sharing a graph visualizing the correlation of events in data for creating scenarios of actions that satisfy stakeholders' intentions and constraints, by connecting frequent patterns via chance events.

In this chapter, first we review some basic approaches to chance discovery. Then Innovators Marketplace (IM) [48.13] will be introduced as a methodology of workshop for chance discovery, where participants are aided to communicate from individual viewpoints reflecting their roles in the market, reason with combin-

ing pieces of basic knowledge as elements for creation, and communicate to introduce various aspects and knowledge for improving presented ideas and choosing practical ideas. Then in the latter half of this chapter IM will be extended to IM with Data Jackets (IMDJ), recently developed in order to fulfill intentions of business people by social data sharing without violating constraints of stakeholders.

From the aspect of model-based reasoning, each element to be combined in IMDJ initially includes a set of atoms and terms in its *local* domain, which are not yet connected via causal relations. Links including causal relations are to be given via reasoning and communication to combine the elements, to embody and realize consumers' requirements casted as a *global* model, in the sense the requirements are not restricted to a definite relevant domain. In this process, the local model corresponding to each element is revised, with constructing and reconstructing *global* models that mean the links between local and global models, via the idea-revising communication as shown later. Here stakeholders externalize intentions and constraints via communication, so that latent values are externalized and scenarios of actions for realizing those values are created. Strategies to combine and/or analyze data are obtained, as solutions for the requirements, as a result of choice from these scenarios. A logical framework for guiding this process of reasoning in IMDJ is shown in this chapter, on which we propose a new procedure of IMDJ where participants shall obtain feasible solutions to satisfy requirements of data analysis users.

## 48.2 Chance Discovery from Data and Communication

Data mining recently tends to be regarded as a method for showing objectively useful knowledge, as far as people read application cases of data mining superficially. This is a reasonable trend, because large amount of data are collected via sensing systems such as POS (position of sales) registers, RFID tags, events in a networked system, etc., without interruption of subjective thoughts of humans. Furthermore, the importance of attention to the volume, the variety, and the velocity of changes in data is coming to be widely and concretely conceived in businesses and sciences.

### 48.2.1 Chance Discovery as a Problematic Child of Data Mining

These features of recent data are, however, really casting a serious problem. A number of variables in data

increases with the growth in the variety, and the volume of data embracing changes reflecting the changes in the real world is making it hard to choose essential attributes (which may be called variables). For example, suppose the features of animals have got collected in huge data corresponding to the overall history of evolution. Via evolution, anus and urethra have been developed and came to be separate for almost all mammals, not for birds or reptiles. Thus, the number of holes at the bottom of the body may be regarded as a useful attribute for defining mammals as a separate class from others. To define mammals, however, this attribute cannot be regarded as the most essential because other attributes may take place. For example, the stability of blood temperature, that is, monothematic or not, is a feature regarded as typical for mammals. Attribute selection methods have been developed for explaining

classes simply and correctly, on selected essential attributes without such a redundancy [48.14, 15].

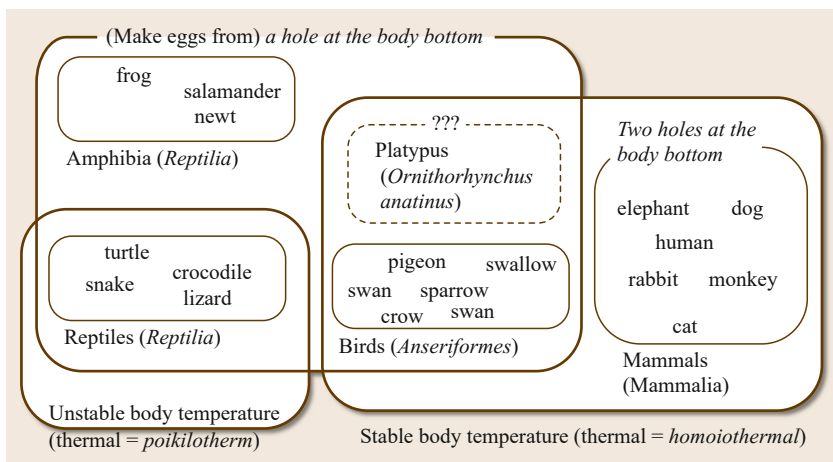

On the other hand, recently the attention of users (rather than researchers) of data mining came to be paid to a new problem – explanation of the boundary between classes. For example, some rare species are hard to be classified into mammals or reptiles or birds, because they have features that cannot be covered in a single class as far as we apply such attributes as above. Platypus has one hole at the body bottom that works both as anus and urethra, but has a stable blood temperature, that is, homoiothermal. This makes platypus be positioned at the boundary between mammals and reptiles/birds. Here we should now restore the importance of the number of body bottom holes for classifying animals into two large classes (mammals, and reptiles/birds) and also explaining the outstanding feature of the rare samples of homoiothermal animals positioned between the two classes. Although platypus in Fig. 48.1 has been finally classified as a member of mammalia, such a rare sample in data has been ignored as a noise in quite classical methods of data analysis, whereas other studies highlighted predicting rare events [48.16, 17], extracting exceptional patterns [48.18, 19].

On the other hand, in the approaches to chance discovery under the definition of a *chance* as an event significant for human’s decision, we stood on the principle that a decision is to choose one from multiple scenarios of actions/events that can be taken in the future. Based on this principle, a chance can be regarded as an event at the cross point of multiple scenarios, may be transient and rare, after which the forthcoming sequence of events is uncertain. The cross point is an important candidate of chance if it means a trigger of contextual shift, that is, an event that occurs in transition from one established scenario to a scenario that occurs

in a new context. This is understandable by relating the dimension of performance in Drucker’s definition of innovation to the *context* here. That is, a noteworthy chance should be at the boundary of contexts, such as platypus for biologists desiring to explain the history of evolution. Symptoms at the boundary of disease progress and recovery [48.20] and products at the boundary of different contexts of consumptions [48.7] have been obtained in cases of chance discovery. Chance discovery can be positioned as a data-driven guidance of humans’ attention to black swans [48.21].

An important point here is that not all cross points of scenarios are necessarily noteworthy chances. Thus we need a method to choose a useful event, even if we can be informed about all events at contextual bounds based on data available. For doing this, one way may be to count up all possible sequences including candidates of chances, and compare their evaluated utilities. This, however, is inefficient even for a computer if we have a large number of observations corresponding to the large number of events and their attributes in data. Considering this point, we focused efforts to developing methods to take advantage of human’s sense to choose high-utility scenarios and events, borrowing computer’s power to visualize a map showing the complex structure of event–event co-occurrences (actions of humans have been counted as events).

However, even if one has got a sophisticated software for visualizing big data, it is not easy to learn to sense the utility of a sequence of events without embedding one’s body in the real-world situation and acquire experiences of gain/loss due to various sequences of events and actions. In other words, the process of acting on/for thoughts with manipulation [48.22, 23] is required for enabling data collection and interaction with the environment, toward opening one’s mind to inconsistencies and questions. As a result, hidden events are

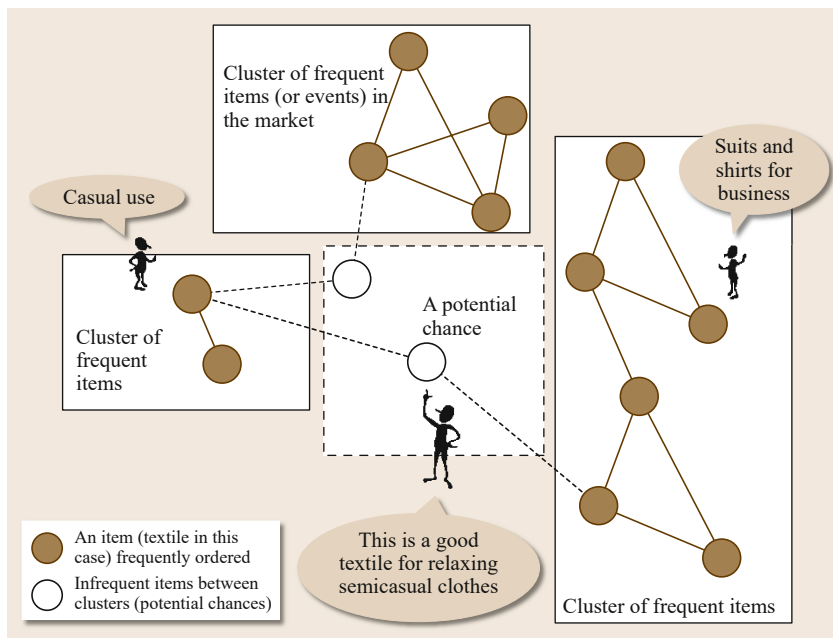

**Fig. 48.1** A novel/rare, event or item, guiding to the discovery of useful variables for explaining the boundary of classes. Such variables give insights for modeling hidden causalities

revealed and *variables* – identical to *attributes* above such as the number of holes in the animal body in the example above – are highlighted. From the collected data, scenario communication of humans [48.8, 24] aided by data visualization works in externalizing latent criteria for evaluating an event as a candidate of chance. Such externalized criteria may come to be regarded as latent variables, of which the contribution to the utility of an event (or of the scenario including an event) had been discounted. In this step, analogy [48.25, 26], insight with reframing [48.27, 28], and metacognition came to be argued as bases for realizing chance discovery as a systematic process toward perceiving useful information for decision making. In projects we conducted with industries, teams of marketing or product developing acquired novel awareness of valuable parts of their markets they had not taken into consideration. For acquiring the awareness, such tools for visualization as KeyGraph [48.7, 20, 29–32] assisted decision-making users by showing a map of the market having (1) a set of clusters of items frequently co-selected, that is, items in each cluster have been chosen by the same customer at the same time, and (2) rare items at the boundary of these clusters, which may imply a latent market coming up in the future. In other words, we regarded such a rare item as a candidate of chance, because a scenario that is a sequence of actions and events to occur in a certain context is represented by events or items in each cluster. Items in (2) can be regarded as bridges between scenarios, at their cross points, or a significant chance to switch from/to sce-

narios as in the case of a biologist looking at animals in Fig. 48.1 with the desire to discover an explanatory scenario of history of evolution.

Here let us refer to a case presented in [48.7], where a map obtained by KeyGraph assisted chance discovery in business, which will be linked to IM in the next section. For this example, KeyGraph showed clusters in item (1) above, and rare items in (2) above which meant products in the niche not yet popular. The map obtained in a textile manufacturing firm from data of customers' choices of textile products, was as outlined in Fig. 48.2. Here, the black nodes linked by solid lines show clusters above. The white nodes and the dotted lines show items corresponding to (2) above and their co-occurrence with items in clusters respectively. Ten marketers in this textile firm attached real textile samples corresponding nodes in the printed map. The marketers, looking at the figure and touching the textile items on it, discussed about their new scenarios, that is, plans of business. First, they noticed the clusters corresponding to popular item sets mentioned in (1) above: The large cluster in the right means an established market of textiles for business clothes (suits, shirts/blouses for under suits, etc.), and the one in the left came to be interpreted as of casual (called *worn-out*) wear by multiple marketers. Then, a few marketers pointed out that consumers desire to change from one cluster to another. For example, when one moves from the place to work at daytime to a restaurant for dinner after working, one may like to change clothes from business suits to casual for relaxation. Interested in such consumers,

**Fig. 48.2** A successful use case of chance discovery. Each node represents a textile (*black*: frequent textile, *white*: infrequent), links co-occurrences in customers' ordering (*solid*: between frequent items, *dotted*: between a frequent item and an infrequent) (after [48.7])

the marketers came to pay attention to an item between the clusters, because they noticed and agreed that the item is suitable as a material of a new jacket to wear after working, without changing trousers, as desired by consumers. In this case of Fig. 48.2, their new scenario was to sell the new item at the center of the map that was not yet popular by that time, to suit manufacturers as a material of casual jacket office workers can wear fitting the trousers of suits to go out for dinner.

Such a creative communication in business can be regarded as a manner for externalizing latent knowledge, of marketers and developers of textile in the case of Fig. 48.2. As studied in requirement engineering, externalizing latent intentions and constraints of stakeholders are an essential step for designing acceptable products/services [48.33–35]. And, the latent (tacit dimension of) knowledge presented by *Polanyi* [48.36] behind activities of humans should be and can be externalized for and by enabling a creative process of collaboration in businesses [48.37]. However, we should also note that externalized or created knowledge cannot be always evaluated highly or accepted by others.

This point can be linked to sticky information [48.3, 38, 39], meaning information is to be localized to individual people who may be either industrial inventors or consumers. The information about consumers' requirements and the knowledge of inventors are hard to be transferred from/to each other, which may disturb the mutual understanding of all stakeholders including consumers. This happens even between developers of a product, so sometimes teamwork in a firm comes to be disturbed. In successful cases, even if useful information in a firm is sticky, users of a product may propose new designs from their own utility-intensive viewpoints whereas manufacturers may design products to improve the power efficiency from the solution-intensive viewpoints. This might be good enough if the proposal of user is easy to implement with techniques available for users or if users get satisfied by the technical improvement by manufacturer. However, this does not stand if users' ideas are not feasible or if technologies of inventors are not easy to understand or available for users.

A new approach of chance discovery to this problem can be found in the invention of *tsugology* [48.40], where the three-tuple hidden behind an action – *intention*, *preconstraint* (pre-existing constraint), and *postconstraint* (the constraint to be made after and due to the action) – is called a *tsugo* after a Japanese daily use word. People, living in social relationships, should externalize one's and others' *tsugoes* for choosing actions that are feasible, that is, for realizing an intention under constraints that sometimes emerge from the real life. A point of *tsugology* (studies for externalizing and connecting *tsugoes* of stakeholders of a problem

in face) is that constraints emerge dynamically. That is, post-constraints may emerge from one's action and may make a preconstraint on others' actions, in contrast to static constraints considered in design methodologies in the literature. For example, if Mr. X sells out data on consumption of foods and drinks, the preconstraint of consumers, such as their requirement to protect their privacy, may be violated. In this case, the leakage of information about privacy is a post-constraint for Mr. X that had not been considered before but got externalized in discussing the plan to find business opportunities from consumption data. By noticing such a constraint, Mr. X should think of a new action, such as using data without customers' IDs but just linking his data with other's data about weather, via date and time for realizing his original intention to sell beer efficiently to suitable consumers. This intention itself may also get externalized via speaking out his own thoughts in a workshop with neighbors and colleagues. As in [48.40], we found that the essential part of sticky information is relevant to underlying *tsugoes*, that is, intentions and constraints of stakeholders.

We can summarize the recommendable process to chance discovery [48.6], learned from successful and unsuccessful cases so far, as follows. The process should start from data collection based on user's (or users') interest. Then, one can visualize the data using suitable tools for chance discovery, and regard it as a map of the market. The visualized result aids in collecting stakeholders as participants of communication to discuss novel scenarios leading to a successful business. This process can be reinterpreted by the four-step spiral below:

1. *Sensing external events*: Keep sensing events in the environment, and collecting data on events that are beyond individual human's sensing capacity.
2. *Recollection*: Try to recollect and explain scenarios from the past. These are sequences of events and actions, explained with the background context. For this step, *subject data*, that is, text about one's and teammates' thoughts of actions and *tsugoes*, should be collected to visualize thoughts as an itemized list of sentences, drawn images, or a graph of word-to-word correlations. Individual's meta-cognition of one's own awareness is thus accelerated.
3. *Scenarization*: Extend the scenarios about the past into scenarios as plans for the future, applying analogy, and explain the scenarios as done in step (2). Data visualization here aids participants' building of scenarios based on the visualized connections of events and items.
4. *Co-evolution of scenarios*: In creating, by combining, scenarios in (3) participants speak out to

externalize variables, that is, embodied criteria to evaluate the utility of created scenarios. Variables relevant to tsugoes of stakeholders are to be externalized here from awareness of inconsistencies between scenarios of participants. Crosses of scenarios are obtained as a result of this step.

Via these steps, the following three effects are expected:

*Effect I: Representing basic knowledge*, that is, the preparatory knowledge to be explained in step (2) above and combined for innovation mainly in step (4). The knowledge should be represented by individuals in order to enable the reasoning for novel combination and explanation of scenarios. This requirement for step (2) urges individuals to discuss latent contexts behind events in step (1).

*Effect II: Reasoning with combinations and analogy*: The extension with analogical transplantation and combination in steps (3) and (4) of basic knowledge, possibly with changing minor parts, are executed. For this, participants are urged to find similarities between the bases (problems for which basic knowledge worked previously) and the target (the present

problem) and explain them as common features of the past and the future, which work as candidates of common variables of scenarios to be combined. For example, *relaxing* in the center of Fig. 48.2 can be a variable to explain an obtained use scenario of the new item which is a candidate of potential chance.

*Effect III: Communication with presenting users'/inventors' conditions*: Individuals speak, reflecting each one's living condition, facing conflicts. Such a communication is relevant to step (4) above, urges awareness of latent conditions which should be considered for reaching consensus about the scenario to choose in decision making. For example, the requirement to fit the trousers of suits could be considered in modifying the color of the new textile in the center of Fig. 48.2.

Note that items above show our viewpoints to highlight the link between chance discovery and our methods of workshops for innovation. For more general principles of innovative collaboration, reader is referred to references on collaborative design approach [48.41–43], to find processes to evaluate and discover values of existing and emerging items.

### 48.3 IM for Externalizing and Connecting Requirements and Solutions

Here again let us confirm that this chapter has been written to show the utility of model-based reasoning in data-driven innovation. For this purpose, the method IMDJ to be introduced in Sect. 48.4 plays a role of environment setting for communication toward data-driven innovation based on the methodology of chance discovery, by which we propose a model-based explanation of reasoning to combine and analyze data. And, in this section, we introduce IM in preparation for Sect. 48.4.

IM is a gamified workshop where ideas are created by *inventors* who combine elements, that is, existing technologies and pieces of knowledge, and evaluated by players who play their roles as *consumers*. IM can be regarded as a method for chance discovery. That is, IM is a workshop where each inventor presents one's own basic knowledge from the viewpoint of a member of the market (e.g., a provider/inventor of products), reason with combinations and/or analogy, and communicate with consumers, focusing and shifting contexts. The case in Fig. 48.2 can be regarded as an origin of IM, where marketers knowing different parts of the market and relevant technologies communicated to present emerging demands for creating a strategic scenario of business.

IM starts with a given set of *basic cards*, on which summaries of existing pieces of knowledge are printed. The cards are put on a game-board that is a graph, visualizing the correlations among contents of basic cards in order to aid the creation of inventors' ideas. As in Fig. 48.3, the inventor's tasks are to buy a preferable number of basic cards and combine some of those cards to present an idea for new business. Other inventors may propose the presenting inventor to start collaboration or share the created idea, with negotiating the dealing price. Here each can use a presented idea as a new element to combine with basic cards or other ideas. The inventor having got the largest amount of money at the halting time (a fixed length of time after starting) wins the game. On the other hand, each consumer plays one's own role, which is an occupation chosen from among a variety such as *housekeeper, farmer, medical doctor, power industry, aged people, students, manufacturer, transportation*, etc., and buys a preferable idea from some inventor for the price determined by negotiation, for improving the life quality of his/her own role. A consumer becomes the winning consumer if he/she obtains the highest value as a result of other participants' evaluation about his/her presenta-

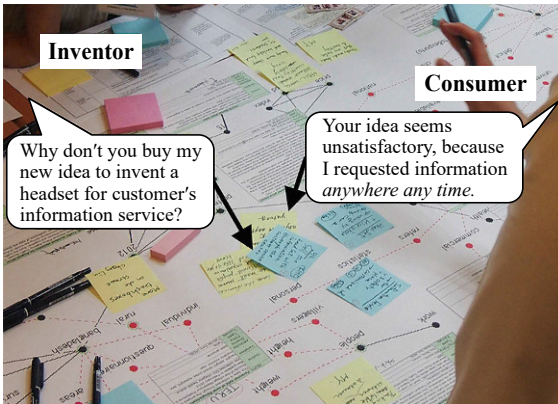

Fig. 48.3 A scene of Innovators Marketplace (IM)

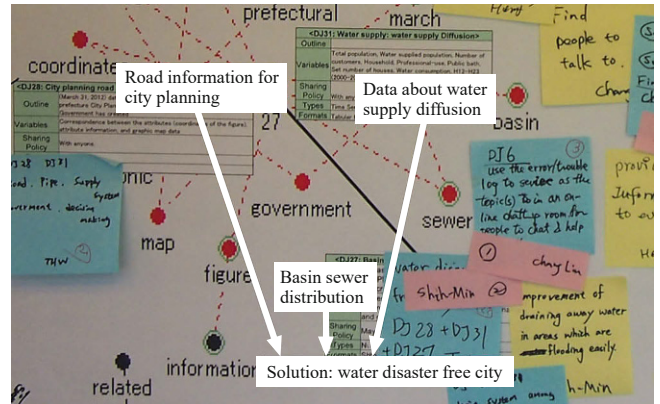

Fig. 48.4 Innovation game on the game board, made of KeyGraph

tion at the halting time. This presentation is about how the quality of life will be improved by the ideas the consumer bought in IM. IM has been introduced in industries and researches, for example, for strategies in businesses and for sustainable safety of nuclear power plants [48.13].

To make the game-board, the contents of basic cards are collected to make a text file and visualized with KeyGraph [48.29] or its extension such as data-crystallization [48.44]. Here KeyGraph shows the positions of not only existing knowledge but also of latent possibility that a new idea may emerge by combining pieces of existing knowledge connected or closely located in the graph. For example, the basic cards showing existing data in Fig. 48.4 (*DJ* here will be explained later in Sect. 48.4) are *DJ27: Basin sewer distribution* that shows the location of basic sewers in a city, *DJ28: City planning road information* that enables to investigate the traffic conditions on each road of the city, and *DJ31: water supply diffusion* that means data about quantity of water supplied at each point of the city. By combining these pieces of information, an inventor proposed the idea of *water disaster free city* that is to be realized by enabling to extinguish flooded polluted water and to supply clean water to citizens. Since this idea was evaluated highly by participants who attended as consumers, hereafter the participants came to be encouraged to apply data to reinforce disaster protection.

Reader interested in the details and the novelty of IM are advised to see [48.13], but let us show a very brief comparison of IM with another methods

of idea creation using stickers and/or cards. That is, the Kawakita Jiro (KJ) method (as introduced *Hambleton* [48.45], called Affinity Diagram) has been world widely used for half a century since it was invented. In KJ, collected pieces of information are put on cards, arranged on a two-dimensional space and classified hierarchically into clusters and subclusters, reflecting the concepts participants externalize. Then, lines between clusters are drawn with titles, corresponding to participants' ideas about relationships among the clusters. Finally the location of all cards and lines among them are observed. As a result, concepts and scenarios are acquired by tracing the lines and closely positioned cards. However, because visualization such as KeyGraph has not been employed in KJ, the bird-eye view of the associations of ideas, is not easily available in the early stage. As shown by *Ohsawa* and *Nishihara* [48.13], we published technical features of IM such as the effects of KeyGraph. It is more important, however, to learn the manner of communication in IM, borrowed from the market of products and services, where people interact competitively and co-creatively with evaluations of ideas using toy money. And, the example above (Figs. 48.3 and 48.4) is of a specific IM for combining and reusing data that is, of IMDJ to be mentioned below. That is, the novelty of Innovators Marketplace is not a point in this chapter where we focus on the logical structure of users' thoughts in IMDJ that is a specification of IM. In other words, we use IMDJ as a setting of collective intelligence for data-driven innovation, in order to discuss the meaning of model-based reasoning.

## 48.4 Innovators Marketplace on Data Jackets

The IMDJ method has an additional novelty to IM, which is the data jackets (DJ). The point of DJ is that it enables participants to show out the digests of data they own for evaluating the potential use value of data, without opening the content. DJ can be used as a knowledge unit as a card in IM to be used as an element to be combined with others in the workshop. Advising reader to see [48.46, 47] for some details, below let us briefly introduce IMDJ.

### 48.4.1 Marketplaces of Data

As in the previous work such as IM, we define stakeholders as people involved in the process to solve a problem. In order to realize creative communications for externalizing and solving problems they potentially share, stakeholders should share data to the extent they can. The market of data is a useful concept for realizing such a creative communication of stakeholders seeking innovation, in that the market is essentially a social environment where items are created and exchanged for reasonable conditions. That is, data in the market of data are created, valued, sold, opened free, shared after negotiation or based on some external guiding force such as the governmental control. In the on-line market of data [48.48, 49], a number of data digests are exhibited, similar to the catalogue of free-access open data (e.g., [48.50, 51]) except that prices are assigned to each dataset in the market. The effect of thus pricing data is significant. That is, potential users and providers of data are enabled, respectively, via pricing, to provide and choose suitable data to share. Furthermore, by estimating the utility of each dataset via negotiation to discount/raise the price, stakeholders can even discuss for improving use scenarios of data to fulfill new values in their businesses. For this purpose, data should be priced reasonably on fair negotiation of stakeholders – owners, analysts, users, and brokers of data.

Thus, the market of data is expected to be a place where the value of data are communicated with externalizing and sharing potential scenarios for combining and using data. In addition, analysts often need to learn techniques from each other. In order to analyze data in hand, it is an essential step for an analyst to import structural models of causality from domains of other analysts, and to choose a suitable model for explaining the latent causality in his/her target domain. This, in other words, is analogical learning of the basic knowledge structure [48.52] or of knowledge-use process from other analysts. In comparison with the diverting use of previous analysis, called transfer learn-

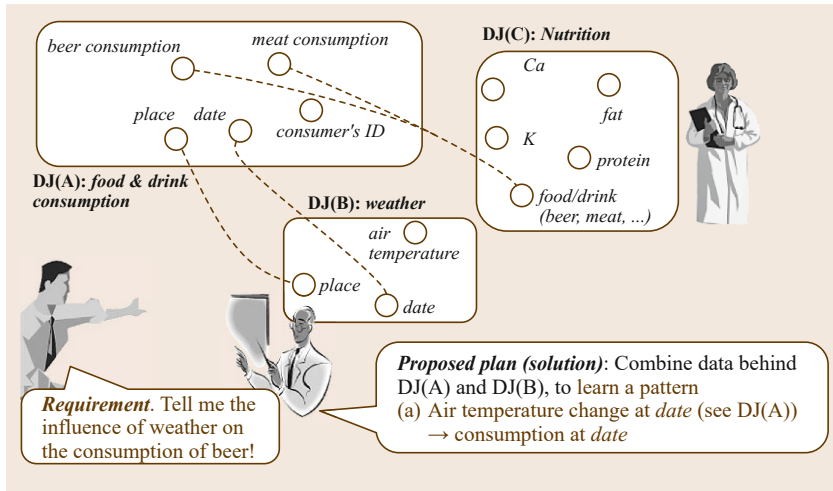

ing [48.53], the effect of the marketplace is to have humans, rather than machines, learn generic ideas from other analysts' experiences.

The thoughts for data-driven innovation in IMDJ, where values of data are externalized and shared in the wide society, can be explained as a model-based reasoning (MBR) as in this chapter. The basic idea of IMDJ comes from what customers and salesclerks do in shopping stores of media such as movie DVDs, where only quite superficial pieces of information in disk jackets are shown for advertisement or for exhibition to customers approaching shelves. On the other hand, the content of DVD – movies, music, etc. – should be hidden in order to reduce the risk that the details may be copied and used free by anyone who does not pay or by rivals. Such a policy may look like an attitude of data closure that may suppress data-driven innovation, but is a useful idea as the basis of IMDJ where each data owner takes part with filling in and disclosing only DJs, which are just small pieces of information describing the digest of existing data. These pieces work as the unit of knowledge in the logical reasoning.

### 48.4.2 The Procedure of IMDJ

IMDJ [48.46, 47] is a specification of the IM. IMDJ is a process where participants propose ideas to combine data, even if the data are confidential, by disclosing DJs that are digests of existing data or data to be collected in the future, and to analyze the combined data. In contrast to data contents, hard to collect or manage, DJs are easy to collect (just enter via [48.54], the entry sheet of DJs), and to describe links between data. DJs here correspond to elements to be combined in IM. For example, a DJ corresponding to weather data and another to data on consumptions in a restaurant can be disclosed, although the data contents should not be, and used for understanding the potential relevance of data about weather and about food consumption. Such an understanding will be urged by presenting *time* and *place* as common variables described in the two DJs. By communication with sharing attention to these variables, participants in IMDJ may propose a scenario to combine and analyze datasets via links of DJs, to discover reasons for new activities.

IMDJ is a gamified workshop, where winners are to be determined in the same manner as in IM. That is, one who earns the largest amount of money becomes the winning *inventor*, and one becomes the best *user* if having made the best presentation about how the solutions one bought in the game can satisfy the own requirements in the market, as customers in IM did. Each

**Fig. 48.5** The core step in Innovators' Marketplace on Data Jackets (IMDJ) (after [48.47])

participant listens to and evaluates others' utterances in order to buy practical and useful solutions in order to become the winning user, and tries to present solutions in order to be evaluated highly and become the winning inventor as in Fig. 48.5 [48.47], in the communication phase. For example, by combining two datasets, one about weather and the other about liquor consumption, a solution such as *one tends to drink one more bottle of beer if the air temperature is higher by 3° than the day before*, can be proposed. This idea may be interesting to a user working for a brewery, but may be criticized if not yet satisfactory to others. Criticisms are not easy to listen to, but urge improvements of solutions in IMDJ because participants consider them rather than being upset, in a gamified mood.

The utility of data may not be evaluated directly in IMDJ, because data are not necessarily disclosed. However, the utility can be evaluated reflecting the eval-

uation of ideas in DJ. That is, the evaluation of an idea reflecting its feasibility and utility, that is, coincidence with participants' requirement, will be reflected to the evaluation of DJs used for creating the idea. As a result, a user interested in a solution pays both to the inventor for the solution and to the expert, that is, provider of the DJ used, for the data used for inventor's creating the idea. This indirect evaluation of data during the playing time of IMDJ will be finally reflected to the condition in which the data get provided to analysts or users. Data corresponding to DJs used in creating an idea (solution), bought for a high price in IMDJ, are expected to be purchased for a high price after the session of IMDJ. On the other hand, even if the DJ has been used in many solutions, the owner of the corresponding data may decide to open the data free to the public in spite of the high evaluation in IMDJ, for the benefits of people in the society.

## 48.5 IMDJ as Place for Reasoning on Incomplete Models

### 48.5.1 Grounding Incompletely Defined Models Into Well-Defined Models

IMDJ can be expressed as a process to revise models of actions and events by coupling three types of information, that is, (1) of requirement from users, (2) of data from experts or data owners, and (3) of proposals from inventors. (1), (2), and (3) can be, respectively, regarded as a *global*, *local*, and *glocal* models, as follows:

1. A *global* model: The representation of desired knowledge that a participant playing the role of data user (corresponding to consumer in IM) expresses, as a requirement without restriction of the technical domain for solution
2. A *local* model: A set of atoms and/or terms in a domain of technology, which may be used for solving the requirement above but not yet connected via causal relations that are certain to be valid. These models are to be given initially as DJs
3. A *glocal* model: The representation of a connection between local and global models, represented by using elements in multiple local domains. Such a model is expected to be created as the result of inventors' reasoning

Requirement models of (1) above form an incomplete structure of demanded causality or relations among events. For example, a brewery's requirement to know the causality between weather and beer consumption can be put in natural language as *if weather changes, the consumption of beer may change* that is incomplete in that it is unknown which variables of weather should be included in the condition *if weather changes*. Such a causality can be described as an incomplete and uncertain model as

$$beer\_consumption \leftarrow ? weather\_change, \quad (48.1)$$

where the LHS of the relation represented by  $\leftarrow ?$  shows a tentative conclusion of the condition given in the RHS. Let us call this as a declared requirement, or goal  $G$ . Yet, the causality is not convinced or numerically evaluated in such a form as conditional probability  $P(beer\_consumption|weather\_change)$  because neither  $beer\_consumption$  nor  $weather\_change$  are defined as variables in data. The causality may be modeled as in (48.2), on the other hand, via the analysis of data combining data about beer consumption and about weather. That is, some model may have been described by the expert of each dataset, as the *local model*, over functions such as  $air\_temp(date)$  and  $beer\_percons(date)$ , where  $date$  means the variable in the form of  $dd/mm/yyyy$  appearing both in data  $beer\_percons$  and  $air\_temp$ . If so, the proposed model in (48.1) can be concretized as in (48.2) via data analysis and become a candidate of solution that embodies the requirement represented. This is a glocal model because this connects the goal in (48.3) and local models that is, data given in local domains such as beer consumption and of weather. The local model is made complete by data supporting.  $l$  and  $K$  respectively mean liter and Kelvin.

$$\begin{aligned} beer\_percons(date) &> 0.31 \\ \leftarrow air\_temp(date) - air\_temp(date - 1) &> 2 K \end{aligned} \quad (48.2)$$

The grounding from the incomplete model as in (48.1) to the well-defined model as in (48.2) should occur based on the knowledge of expert about data, via the communication between experts and inventors in IMDJ and analysis of data if applicable. Below we aim at formally describing the systematic process where the requirement, that is, the user's goal as in (48.1), is to be externalized and the solution to the requirement as in (48.2) can be obtained based on experts' local models corresponding to provided data. The three stakeholders, that is, experts, inventors, and users of data should interact for restructuring the local, glocal, and global models, respectively, in IMDJ in order to realize such

a process. In this section we aim at describing the constraints we should realize as a social system where the process is to be realized.

*Innovators Marketplace on Data Jackets, described as a list of constraints*

$DJ_i (i \in [1, N])$ : The  $i$ -th DJ, among those collected before or created in IMDJ

$DJ_i := \{F_i, P_i, V_i, \}$ , where elements are defined as follows:

$F_i$ : the set of variables in  $DJ_i$ , expressed as functions over other variables in  $DJ_i$

$P_i$ : the set of predicates (relations of variables) in  $DJ_i$

$V_i$ : the set of other variables in  $DJ_i$  than  $F_i$  or  $P_i$ .

$G$ : The goal, that is, the requirement incompletely defined as the relation over informal terms corresponding to events/features as in (48.1).

$T$ : The theory, that is, a model described by a set of clauses represented by a combination of defined predicates in  $P_G$  below.  $T$  is given by  $T(P_G, F_G, V_G)$ , that is, a relation over elements  $P_G, F_G$ , and  $V_G$ , of a set of DJs in  $DJcom(G)$  defined as in (48.3), which satisfies (48.4) where  $[v]$  for variable  $v$  means the defined domain range of the value of  $v$  and also satisfies *Conditions I and II* mentioned below. Below, we list a part, rather than all clauses, of  $T$ , in exemplifying  $T$ .

$$\begin{aligned} DJcom(G) &:= \{DJ_a, DJ_b, \dots, DJ_L\} \\ &\subseteq \{DJ_1, DJ_2, \dots, DJ_N\} \text{ where} \end{aligned}$$

$$\begin{aligned} P_G &:= P_a \cup P_b \cup \dots \cup P_L, F_G := F_a \cup F_b \cup \dots \cup F_L, \\ V_G &:= V_a \cup V_b \cup \dots \cup V_L. \end{aligned} \quad (48.3)$$

$$\begin{aligned} \exists v \in V_G [\forall V_x \in \{V_a, V_b, \dots, V_L\}, \\ \exists v_x \in V_x ([v] \cap [v_x] \neq \emptyset)]. \end{aligned} \quad (48.4)$$

*Condition I*:  $\exists G' [G \supseteq G' \Leftarrow T]$ , which means goal  $G$  subsumes a conclusion  $G'$  derived by theory  $T$ . Here, subsuming means there is a substitution to elements in  $G$  that implies  $G'$ , and substitution here means to rewrite terms in  $G$  using defined functions in  $F_G$ , variables in  $V_G$ , and predicates in  $P_G$ . This is a generalization of substitution to variables, for the grounding of informal (in natural language) expressions of a goal.

*Condition II*:  $T$  is *completely defined* (this concept is defined just after here) and consistent with data  $D_a, D_b, \dots, D_L$  corresponding to DJs in  $DJcom(G)$ .

$\{DJ_a, DJ_b, \dots, DJ_L\}$ , put  $DJcom(G)$ , is the DJ set, the combination of which satisfies  $G$ .

*Completely defined  $T$*  above means a completed glocal model, which is a logically consistent relation between  $G'$  defined in *Condition I* and theory  $T$ . Let us

here restrict  $G'$  and  $T$  to be a set of Horn clauses described by one head (conclusion) and body (conditions) for simplicity. The example of  $G'$  and  $T$  below is used only for this explanation of *completely defined*  $T$  in this subsection.

$$G' \text{ beer is consumed (city, date)} \\ \leftarrow \text{air temperature rises (city, date)}. \quad (48.5)$$

$$T: \text{beer is consumed (city, date)} \\ \leftarrow \text{air temperature rises (city, date),} \\ \text{people are rich (city)}. \quad (48.6)$$

$$\text{air temperature rises (city, date)} \\ \leftarrow \text{Typhoon is coming (city, date)}. \quad (48.7)$$

Then the relation  $T$  is *completely defined* for  $G'$  is defined as follows:

- i)  $G'$  is derived by  $T$  and existing data, that is, the head of  $G'$  should be included in the head of some clause in  $T$ , and all predicates in the body of  $G'$  should be in the body of some clause in  $T$ , with satisfying (ii) through (iv).

*Example:*  $T$  above derives (i. e., resolves)  $G'$  above if it is believed to be true that people are rich and Typhoon is coming as in (ii) below.

- ii) All clauses and bodies of clauses in  $T$  are supported by data if any, corresponding to DJs in  $DJcom(G)$ , and other clauses in  $T$ .

*Example:* *people are rich* and *Typhoon is coming*, as well as (48.6) and (48.7), must be supported by some data for deriving  $G'$ .

- iii) In each clause in  $T$ , all variables in the head must appear in some predicate in the body. This is the range restriction constraint in clause logic.

*Example:* *city* and *date* are included in the bodies in all clauses above.

Combining this condition with condition (ii), the theory comes to be based on data. That is, all variables appearing in predicates derived from  $T$  are certified to be in some DJ(s) in  $DJcom$ , as in (48.4).

- iv) All predicates in the body of each clause must share some variable(s) with some other predicates in the same clause, for the resolution in deriving a predicate in the head of a clause.

*Example:* *city* is shared between the two predicates in the first clause in  $T$  above. This variable should be also shared with *Typhoon is coming* in the second clause, to be resolved with *people are rich (city)* in deriving  $G'$ .

This condition is formalized as in (48.4), a point of which is that the names variables may differ across data, but the existence of common values in the

defined domain ranges is regarded as a reason for believing the two variables can be unified. Such a common variable is essential for enabling comparison or combination of data. However, the value common to variables, for example, a variable  $v_x$  in  $V_x$  and  $v_y$  in  $V_y$ , does not have to really exist in neither  $D_x$  nor  $D_y$ . This is because the analysis may result in finding sheer difference in the values of  $v_x$  and  $v_y$  rather than a pattern linking variables in  $D_x$  and  $D_y$  to be learned using common values of  $v_x$  and  $v_y$ . In this sense,  $[v]$  in (48.4) is defined as the domain range of variable  $v$ , not the values really taken in data.

Note we have at least two alternative subconditions for *Condition II-(ii)* as follows

$$\text{Condition II-ii(a):} \\ \exists D \subset D_a \cup D_b \cup \dots \cup D_L \{T \Rightarrow D\} \quad (48.8)$$

$$\text{Condition II-ii(b):} \\ D_a \cup D_b \cup \dots \cup D_L \Rightarrow T \quad (48.9)$$

*Condition II-(a)* means  $T$  explains some part of the data, and *Condition II-(b)* means  $T$  is a necessary theory for the data in  $DJcom$ . A noteworthy point is that the contents of data are not necessarily available in advance or in the initial state of IMDJ. In such a case, the data are analyzed after the data trading after workshop. And in the analysis, statistical validation for evaluating the support, that is, the extent of satisfying *Condition II-ii(a)*, or the confidence that is, the extent of satisfying *Condition II-ii(b)*, of the theory proposed in IMDJ is to be executed. If a theory – regarded as a glocal model in this chapter – is not acceptable according to the evaluation, the revision of the model will be considered, and new rules will be explored by data mining applied to data in  $DJcom$ .

### 48.5.2 Abductive Reasoning for Thoughts and Communications in IMDJ

Let us return to the example of (48.1) and (48.2), in order to present the process of reasoning to obtain satisfactory models. The breaking of (48.1) into (48.2), is to be realized here via the substitution below.

*Transforming goal  $G$  to  $G'$ :* put *beer\_consumption*  $\leftarrow ?$  *weather\_change* as in (48.10) by substituting *beer\_consumption* with *beer\_consumption (date)* and *weather\_change* with *air\_temperature\_change (date)*. This and the next step to describe (48.11) and (48.12) are to be executed by considering words' meaning.

$$G' : \text{beer\_consumption (date)} \\ \leftarrow \text{air\_temperature\_change (date)} \quad (48.10)$$

Definition of predicates in  $G'$ : for undefined constants  $\alpha$  and  $\beta$ ,

$$\begin{aligned} \text{air\_temperature\_change}(\text{date}) \\ := \text{air\_temp}(\text{date}) - \text{air\_temp}(\text{date} - 1) > \alpha K \end{aligned} \quad (48.11)$$

$$\begin{aligned} \text{beer\_consumption}(\text{date}) \\ := \text{beer\_percons}(\text{date}) > \beta 1 \end{aligned} \quad (48.12)$$

$G'$  is thus interpreted as (48.13)

$$\begin{aligned} \text{air\_temp}(\text{date}) - \text{air\_temp}(\text{date} - 1) > \alpha K \\ \leftarrow \text{beer\_percons}(\text{date}) > \beta 1. \end{aligned} \quad (48.13)$$

And, parameters  $\alpha$  and  $\beta$  in (48.11) are embodied using data below, brought in by experts of weather and of beer, respectively, modeled by functions as

$\text{air\_temp}(\text{date})$  :  
average daily air temperature for each day  $\text{date}$   
 $\text{beer\_percons}(\text{date})$  :  
average consumption of beer per consumer for date

As a result of validation on these data, parameters are substituted with values as  $\alpha = 2$  and  $\beta = 0.3$ , so that (48.2) is obtained as the solution, which is a completion of the theory as glocal model in (48.13).

As shown above, the initial and informal model  $G$  of requirement *globally* rules the overall knowledge processing from a general viewpoint, that is, without fixing variables in any data (such as  $\text{date}$ ) to use for reasoning. Then, the *local* models in (48.11) and (48.12) corresponding to data in local domains are chosen and applied, to connect  $\text{beer\_consumption}(\text{date})$  and  $\text{air\_temperature\_change}(\text{date})$  in  $G'$  of (48.10) via variable  $\text{date}$  and the clause created in the glocal model. As a result, the incompletely defined goal  $G$  is put into an expression of first-order logic (FOL) with defined predicates.

Here we should note the goal could not have been translated into such a well-defined FOL without having experts' knowledge for modeling their data. Also here we find inventors' reasoning to combine experts' models as in (48.11) and (48.12) worked in substituting words in the global model, that is, the informally suggested goal  $G$ , with predicates to be defined on variables in available data. Without this contribution of experts' knowledge, (48.2) and (48.13) may have lost the *completely defined* nature especially *Condition II-(iii)*, and put as in (48.14) due to choosing data on the superficial

similarity to terms in  $G$  and variables in data, without checking the meaning or values of variables.

$$\begin{aligned} \text{beer\_consumed}(\text{month}) \\ \leftarrow \text{weather\_condition}(\text{week}) \end{aligned} \quad (48.14)$$

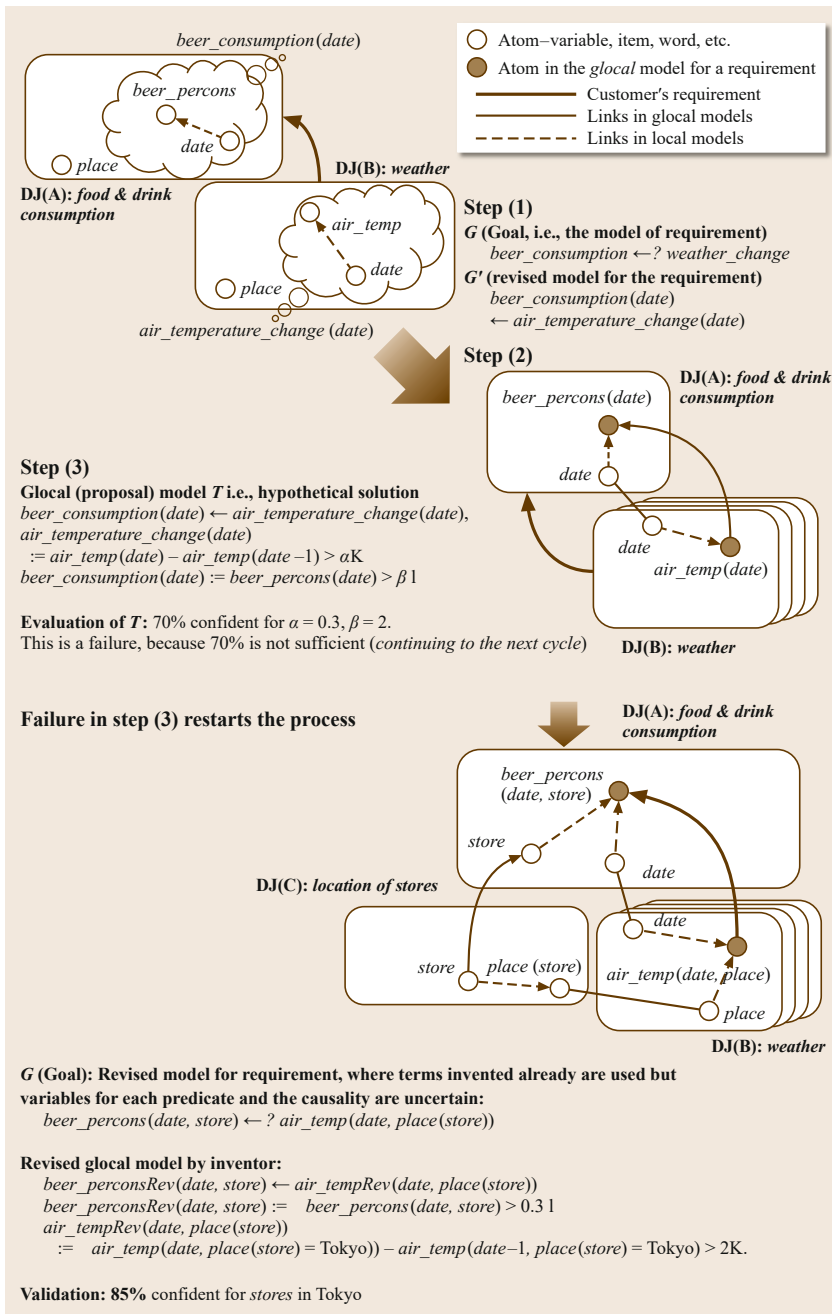

In (48.14), variables are not shared between the head and the body. Thus we can regard the inventors' models as *glocal*, that is, the result of interaction between the global model and local variables in  $V_G$  in data. On the other hand, in the successful example to derive (48.2) above,  $\text{date}$  worked as the common variable in  $V_G$  between the used two datasets, playing the role to connect data on weather and on beer consumption. The utility of this variable is evaluated and supported by comparing the values in  $\text{date}$  in the data including  $\text{air\_temp}(\text{date}1)$  and the data including  $\text{beer\_percons}(\text{date}2)$  to find the existence of common values between  $\text{date}1$  and  $\text{date}2$ , as meant by (48.4). As a result, it is confirmed that  $\text{date}$  can be in  $V_G$  and used for resolution of the two predicates.

As in this case, the requirement should be presented by a data user. Then, in order to translate the requirement into FOL, the elements in the requirement should be put into predicates or functions corresponding to variables in existing data. A set of data, including these variables and share variables such as  $\text{date}$  in the above example, should be collected here. For this, experts having models of data may be invited for presenting local models for these data, for using/collecting data corresponding to local models that may derive the global requirement model if combined by the glocal model of inventors' proposal. An alternative set of data may be proposed here, described as  $DJcom$ , if a set is not satisfactory for describing the requirement. This goal-driven process of reasoning can be regarded as abduction, and itemized as steps below. It is clear from this list that the organization of IMD provides with the reasoning and communication required for satisfying constraints proposed in the previous section.

### A Process of Abductive Reasoning with Communication for IMDJ

*Step 1* (goal setting): Users of data or of analysis results express requirement  $G$  as a model  $G'$  in FOL, with predicates invented with the assistance of experts. Here experts describe local models for DJs with inventing predicates (functions are translated into predicates as in (48.11) and (48.12)), reflecting the interpreted relations of attributes in each DJ, and make  $DJcom$  a set of DJs including attributes or predicates in  $G'$ .

*Step 2*: Inventors check the existence of common values of variables in different DJs in  $DJcom$  (for this,

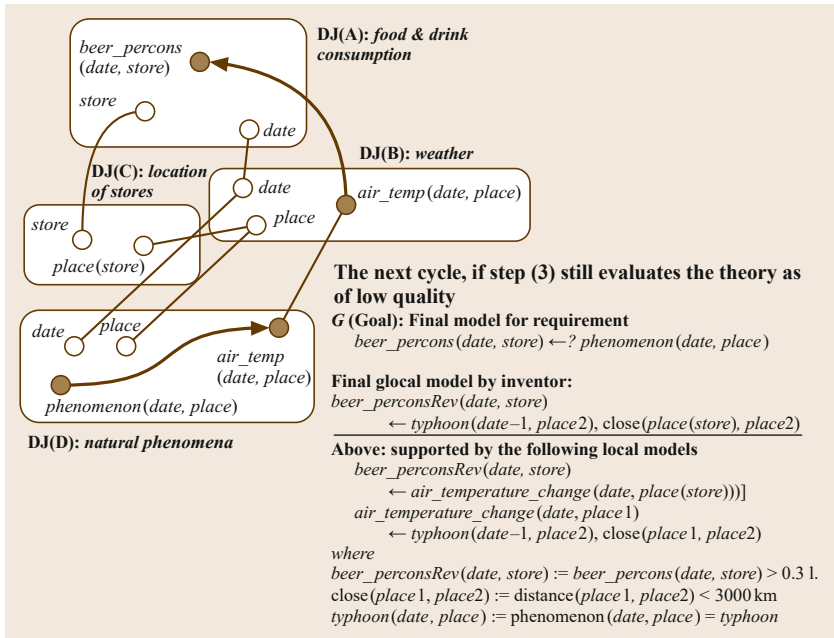

**Fig. 48.6** The abductive reasoning based on incomplete models in IMDJ

it is recommended that experts declare the defined domain range of variables in describing DJs in advance).

*Step 3* (abduction as the main step): Inventors explore hypothetical theory *T*, which derives *G'* and include only predicates and attributes obtained in steps so far.

If such a hypothetical theory *T* exists, *T* is evaluated subjectively on users' interest, or objectively on data, if available, corresponding to DJs of which attributes and predicates are in *T*. If the evaluation of *T* is higher than a predefined threshold, it is regarded as the solution. If the evaluation is lower, discard *T* and restart *Step 3*.

**Fig. 48.7** An abductive reasoning, where local models are added (continuing from Fig. 48.6)

Otherwise (if no hypothetical theory  $T$  derives  $G'$ ), call experts for adding DJs (including attributes missed for deriving  $G'$ ), and restart from *Step 1* since the failure to derive  $G'$  means the global model is not supported by the current local models.

Thus, each hypothetical theory  $T$  turns out to be a global model combining local models obtained in *Step 3* to explain  $G'$  of *Step 1*. The criteria for the evaluation of theories on data corresponding to DJs, in *Step 3*, should differ for different goals. For example, data on beer consumption per day in all districts will be desired for validating (48.13) precisely, if covering all districts by beer market is desired. For this purpose, a DJ for inventing  $T$  and the data for evaluating  $T$  should include *address of consumer* as a variable. On the other hand, this variable will not be reflected neither to invention nor evaluation of  $T$ , if the goal is to check the total consumption of beer all over a country. In a different case, the user may evaluate the novelty of  $T$ , in spite of its low precision and small coverage in the market, if he seeks to discover a clue for creating new market of beer.

Figure 48.6 shows a modification of the last example, in that the model once obtained in *Step 3* is here as insufficient (70% of confidence) with substituting  $\alpha$  with 2 and  $\beta$  with 0.3. This is superficially a failure but is a case of requirement externalization, in that the result of data analysis made the user notice his/her own latent desire to predict beer consumption by higher confidence.

As a result, participants will consider to add data about the correspondence between liquor store and its location given by the variable *place*, so that expert(s) owning such data creates a new function  $place(store)$  for explaining his knowledge about additional data (the latter half of *Step 3*). This can be regarded as an invention made because the insufficient confidence as a result of the previous analysis is attributed to the insufficient consideration of attributes, which may explain beer consumption, such as the liquor store selling beer. By adding the attributes, that is,  $(date, store)$  or with  $(date, place(store))$  in *Step 3*, participants obtain a model as more confident proposal, as in the last step of Fig. 48.6. Here, the store selling beer and its place are connected due to adding DJ. This case shows the nonmonotonic nature of abduction in the procedure.

Figure 48.6 is still a simplistic example. More generally we may iterate abductive reasoning further. For example, additional data about extraordinary natural phenomena including disasters, may be used as in Fig. 48.7 for learning such a causality as *if typhoon is active in China, the air temperature in Tokyo increases*. This causality will be obtained by finding a corresponding pattern from data inventing predicate *typhoon* as

$$\begin{aligned}
 &air\_temperature\_change(date, Tokyo) \\
 &\leftarrow typhoon(date - 1, China) \tag{48.15}
 \end{aligned}$$

Furthermore, by inventing predicate *close* with collecting facts for other places than Tokyo and China, the goal

may be revised to (48.16), meaning one should be concerned about the influence of natural phenomena such as typhoon for predicting the beer consumption per consumer

$$\begin{aligned} &beer\_perconsRev(date, store) \\ &\leftarrow typhoon(date - 1, place2), \\ &close(place(store), place2). \end{aligned} \quad (48.16)$$

## 48.6 Conclusions

In the Innovators Marketplace on Data Jackets (IMDJ), small pieces of information called Data Jackets containing abstracts of confidential data, that is, data that cannot be disclosed, are submitted. Then the process of IMDJ goes as a gamified workshop where participants create and propose ideas to combine and/or analyze data corresponding to DJs. The ideas are evaluated, on the matching of requirements and the utility of the expected knowledge or action scenario to be obtained from the proposed analysis.

This chapter proposed a formalization of the process of IMDJ as of abductive reasoning, and derived a proposal of refined process of the workshop to iterate cycles of steps for communication, reasoning, and sharing DJ. By this formalization, the link of IMDJ to a logical framework in model-based reasoning and to a feasible procedure of innovation came to be clearer by introducing the co-evolution of global, glocal, and local models. These models correspond respectively to the requirements of data users, the proposals of inventors of analysis plans, and the knowledge of experts of data domains.

Such a logical formalization from the viewpoint of model-based reasoning is of high use value, in two

The real intension of user may have been to validate an idea like (48.16), rather than the uttered one as in (48.1). On the way of communication in IMDJ, such a real intention tend to be externalized. As in these examples, participants concretize local and glocal models from goals given as abstract global models and various datasets, by revising and combining local models in the abductive reasoning to derive the goal.

senses, that is, (a) the presented three steps are expected to save IMDJ organizer in explaining the procedure without ambiguity, (b) we may consider in the future to automate a part of the whole process with developing computational methods to cope with the complexity of nonmonotonic reasoning [48.55] such as abduction.

In the future, our direction will be to realize logical IMDJ, mainly in the sense of (a) above, toward humans' logical and creative data-based decision making. An essential problem addressed to the future is how we can support a beneficial real act of participants of IMDJ. That is, they tend to invent new, rather than just adhering to given, requirements as pointed out in the last section, motivated by the communication in the workshop. The frequency of this act cannot be explained by just adding Step 0 before the whole procedure presented in this chapter, nor should be suppressed just for following this procedure because this act results in inventing data reuse plans with novelty and utility.

**Acknowledgments.** This study has been supported by JST CREST, and discussions with Kozo Keikaku Engineering Inc. and other major collaborators have been reflected to this chapter.

# 49. Models in Pedagogy and Education

Flavia Santoianni

Pedagogy is a discipline concerned with theories and practices of education. Its epistemological model is complex. It may be considered as qualified by two structural directions: *pluralism* and *dialecticity*.

The pluralism of pedagogy is represented by its possible theoretical routes, by the different levels of sharing of disciplinarity and by a multiplicity of aspects. It involves empirical and experimental research, historical and philosophical dimensions, and epistemological and metatheoretical lines. The theoretical plurality of pedagogy concerns subjects, ages and places of education, languages and research methods, and actual directions and interpretative issues. The multidisciplinary plurality of pedagogy distinguishes it in pedagogical sciences, educational sciences, and educational developmental sciences. The disciplinary multiplicity of pedagogy is expressed by the diversity of pedagogical sciences that belong to general pedagogy. Even if pedagogical sciences are multiple, social pedagogy, history of pedagogy and special needs education are disciplines specifically related to the field of pedagogy.

The dialecticity of pedagogy expresses its controversial nature divided between science and philosophy. The scientific approach to pedagogy

evolves from systematicity to complexity. It develops, namely, in parallel with the construction and the reconstruction of the very idea of science. The systematization of educational sciences strengthens the philosophical role of pedagogy. The so-called *identity crisis* of pedagogy will bring it to rediscover the sense of its own reflexive intentionality. The relationship between theory and practice makes pedagogy a science of education, in particular a theory of educational development processes.

Pedagogy is a discipline concerned with theories and practices of education. The etymological meaning derives from the Greek language and means to guide ( $\alpha\gamma\epsilon\iota\nu$ ) the child ( $\pi\alpha\iota\varsigma$ ), that is, education. Pedagogy today relates to all the ages of humans and to a plurality of relational contexts.

From an epistemological viewpoint, the discipline is characterized by a complex model. As introduced by Cambi [49.1], this model shows two structural directions: pluralism and dialecticity.

## 49.1 Pluralism

The pluralism of pedagogy is represented by its possible theoretical routes, by the different levels of sharing of disciplinarity and by a multiplicity of aspects.

From a pluralistic viewpoint, it is possible to distinguish three coexisting aspects:

1. Empirical and experimental research, related to the model of the hard sciences.
2. Historical and philosophical dimensions, anchored to specific values and perspectives.
3. Epistemological and metatheoretical lines, which express the critical and regulative role of the discipline.

### 49.1.1 Theoretical Plurality

Pedagogical theoretical routes concern a plurality of subjects, the ages of education, the places of education, the languages, the research methods, and several interpretative directions.

#### Subjects, Ages, and Places of Education

The subjects of education have individual biological, psychological, and relational differences [49.2], which modulate their own ways of learning in a wide range of possibilities including cognitive discomfort and specific learning disorders [49.3, 4]. There are studies on gender [49.5] and social differences [49.6] regarding economic, environmental, and cultural deprivation. An emerging field concerns ethnic, linguistic, and cultural differences, which triggered intercultural studies [49.7, 8].

Learning is seen as an on-going process throughout the course of an individual lifespan [49.9]. For this reason, pedagogy concerns multiple ages: basic education for children and youths until university, with the processes of literacy and schooling; continuing education for adults, and educational proposals for seniors. Education is about the cycles of life – in a pedagogical and andragogical perspective – to implement lifelong learning, continuing education, adult education, and theories of adulthood [49.10]. The methodology of these approaches is based on the analysis of experiential contents and on the encouragement of self-management of learning processes. The teacher as a facilitator becomes an organizer of resources [49.11]. Adult education is continuous because it includes different stages of individual life. Adult education encourages change, through transformation and reorganization impulses, for a constant renewal of the person.

The places of education interact with individual and social development [49.12]. Family is the context of pri-

mary socialization, where learning is both explicit and implicit. School is the place of formal education and of self/guided reflection, even if the teaching and learning relationship can be influenced by implicit learning also here [49.13]. Moreover, institutions and associations that manage cultural activities – such as museums, libraries, and theaters – are considered places of nonformal education [49.14].

Also, technologies may be interpreted as a context of education [49.15]: for example, the instruments of social communication, as traditional media (cinema, television, radio, telephone) and electronic media (computer and social networks).

#### Languages and Research Methods

Pedagogy uses different languages. Explicative, analytical, and descriptive language – preferred by scientific pedagogy – coexists with narrative, and interpretative language by which personal stories are analyzed. The philosophical language of axiological nature defines the epistemological scope and the content value of the discipline, while everyday life and common sense language is usually utilized to solve concrete problems. Finally, there are the nonverbal languages [49.16], as the proxemics of communication, and the disciplinary languages [49.17], specifically used by the disciplinary didactics.

Research in education is multifaceted: it may be theoretical research, basic, formal, and structural research, which deals with the relationship with other sciences; at the same time it may be experimental research, which uses observation and measurement to improve teaching practices. It may be historical research, which deals with the evolution of educational institutions, and comparative research, which compares different territorial and national models of pedagogical organization.

Methods of educational research are several: nomothetic, idiographic, experimental, grounded theory, action research, historical, comparative, narrative, and clinical methods. They are quantitative and qualitative [49.18], they connect the scientific and philosophical areas of the discipline, and are often considered interpretative paradigms more than scientific methods.

#### Directions and Interpretative Issues

Pedagogy discusses either recurring and structural issues or emerging issues. Among the recurring and structural issues is the question of the relationship between education, instruction, training, and educational development: what are the mutual influences? A related issue is the question of the relationship between means and ends: which are predominant, from time to time, in

different historical situations? Another theme is related to the critique of educational institutions: what is their role and their more effective work?

Also, there are issues that affect pedagogical antinomies. These can be formal – science and philosophy, theory and practice, knowledge and skills, technology and art. Or these can be theoretical/practical – authority and freedom, culture and professional training, rupture and continuity in education. Pedagogical antinomies can also be practical/educative, such as those concerning the relationships between teacher and students. Other issues relate to the set of educational skills: which one should be the better training? Moreover, the links between pedagogy and politics: what relationships subsist with ideology?

Emerging issues relate to forefront issues, such as how to define the concept of educational development, how to prepare the young on the complexity of the current situations, and how to educate them to respect differences, especially in multicultural societies. Also, how to discuss the concept of value in postmodern societies, and how to dig deeper on the topic of subjectivity and its global interpretation through the concept of the persona, to focus on its role in education and school.

This entails recognizing the relationship between body and mind, and the cognitive, affective and organismic dimensions that are intertwined according to a comprehensive and holistic vision. Another aspect is to implement guidance procedures in learning pathways, within a process of care and taking charge of the learner.

In this sense, the role of the school is significant: how can and should it be autonomous and selective, how should it be influenced by technology? Which positions should be taken towards students in situations of great difficulty towards learning: for instance, the meaning of rejection of school. How about the intention of educating for community participation and critical thinking? Moreover, the openness and inclusion towards students in trouble, with specific learning disabilities or with physical disabilities, as well as towards students from other cultures.

Culture is another topic of interest: to recognize the role played by culture in the school, to affirm a pluralistic and dialectic culture, to educate the young towards a crosscultural mind, to recognize the role played by humanistic knowledge as by scientific and technological ones.

This discourse includes a reflection on communication technologies. The on-going debate on information and communication technology today asks not just what are the chances of access to knowledge through networks of communication, but rather how pedagogy can

render effective the opportunities for learning and sharing in a relational network from an educational point of view. Communication technologies may alter the space-time dimension, so pedagogy needs to reflect on the meaning of virtual experiences. Moreover, these experiences should be joined to traditional routes. New methods of distance education are studied and the criteria by which e-learning can be effective for learning is expanded. Media education explores the use of media and even their social, psychological, and communicative power and their possible individual and collective influences.

Particular attention is given to the concept of freedom, seen both as subjective realization, personal emancipation and as a competent and active citizenship in a supportive community. Finally, attention to the environment is given either as research on learning environments design, in all its diversity, or as ecological education.

### 49.1.2 Multidisciplinary Plurality

Of how many domains may pedagogy consist? The knowledges that compose it, or which are around it, can be distinguished in pedagogical sciences, educational sciences, and developmental sciences [49.19].

#### Pedagogical Sciences

Pedagogy is divided into pedagogical sciences, which all have general pedagogy underlying. These sciences can be numerous and are constantly developing, increasing according to the specialization of knowledge; in particular: social pedagogy, history of pedagogy, special needs education, didactics and experimental pedagogy. Experimental pedagogy, such as didactics, is seen as a theoretical, methodological, and practical framework in a close relationship with general pedagogy [49.20].

#### Educational Sciences

Educational sciences are disciplines that study the general and local conditions of education and the educational situation; they accomplish a general reflection on education [49.21]. Educational sciences include the historical, epistemological, psychological, sociological, and didactical fields of investigation. Therefore, they include disciplines such as history of education, educational epistemology, psychology of education, sociology of education, anthropology of education, and teaching.

In this interpretative framework, philosophy of education can be considered at the border of educational sciences, because it plays a regulatory and mediating role of a metareflective nature in relation to sciences of

education. Hence, it supports general education from an epistemological point of view.

### Educational Developmental Sciences

Educational developmental sciences represent a *trait d'union* with other disciplines that, in the humanities or in the natural sciences, study the development of the human species.

What relationships are between pedagogy and other areas of knowledge? What are the relationships that pedagogy develops with other disciplines [49.22] and which fields and levels of these relationships may be concerned [49.23]?

The pluralistic nature of pedagogy leads it to borrow research objects and methods of investigation from other disciplines; for this reason, sometimes there are chances of confusing its disciplinary identity with other ones. Relations between the different types of knowledge can be multidisciplinary, interdisciplinary, and transdisciplinary [49.24]; these are connections of increasing interdependence.

The relationship between pedagogy and science of education should be multidisciplinary. In this case, different disciplines, with different epistemological stances, with various research methodologies and sectorial operational tools, can share research hypothesis of mutual interest and then collaborate together without losing their disciplinary specificity. Pedagogy is a model of science in itself [49.25].

### 49.1.3 Disciplinary Multiplicity

The multiplicity of aspects that compose the educational pluralism can be represented by the diversity of pedagogical sciences that belong to general pedagogy. Pedagogical sciences are multiple; some ministerial subdivisions refer to the social pedagogy, history of pedagogy and special needs education as disciplines specifically related to the field of pedagogy.

#### Social Pedagogy

Social pedagogy applies the educational theories in operational form to various social contexts and reflects theoretically on these issues [49.26]. Its role is to weld the educational activities in the territories, within their local dynamics, in a transformative and emancipatory way for all the partners involved and the communities to which they belong.

The task of the social pedagogy is to build an integrated educational system between the school and the nonformal agencies such as the family, the church, the working world, the associations, the local authorities, and the informal systems, such as multimedia networks.

Social pedagogy uses a systemic-relational model of education that allows the placing of local interpretative patterns within more global visions. Through this model it manages to connect theory to practice and vice versa, by reformulating from time to time, in a participatory way, practices and theories in relation to the educational needs of the communities in which they are highlighted.

The disciplinary knowledge cannot be separated from the contexts but rather should be able to understand their specificity, the existential experiences that develop in them, and their social emergencies through participatory action research [49.27].

#### History of Pedagogy

History of pedagogy also relates to the history of educational institutions. After the 1970s of the twentieth century, the history of pedagogy gradually interacts with the history of education, since this includes more detailed attention towards the educational systems [49.28].

History of pedagogy studies how the concept of education has developed in the course of the history of humanity [49.29]. The diachronic dimension of the concept of education has developed in the transition from the Greek *paideia*, the free human development through culture, with aims of universal validity, to the *bildung* of the nineteenth century, unitary and not fragmented education, linked to the composition of several domains, from science to art, through which subjects shape their own image, *bild*.

In the Greek *paideia*, education takes place according to perspectives of universalization and interior harmonization through culture. Although there is a dualism of educational models, because intellectual work and manual labor are separated, *paideia* represents the ideal of the human, the global expression of the individual in its full manifestation. The *paideia* embodies the encyclopaedic tension of the classical world, the openness to all knowledge, the idea of humanities as areas of study. Education consists both in the personal relationship between the teacher and the student, both in the competitive tension which affects the corporeal dimension, the physical appearance, shaping itself as practical education within the *polis*, a pedagogical community in a global sense.

In the Greek enlightenment, culture becomes more critical, technical, scientific, and democratic. *Paideia* becomes more attentive to human problems and to the techniques of speech, to the use of words. Education is moral, rhetorical, and historical, increasingly tense to the principle of *kalokagathos*, the beautiful and the good, the cultivation of the specific aspects of humanity through the study.

In Socrates' thought, education is considered as *episteme* and not just as *ethos* or as *praxis*. Education therefore becomes *paideia*, the universalization of the subject through rational discussion, education of mankind through culture and civilization – maieutical, dialogical, and dialectical. An education in which the *humanitas* is the result of a focused education to the *know thyself*. The range is from a pragmatic to a theoretical dimension of educating.

In Platonic *paideia*, education of the individual under the control of reason takes place through the contemplation of ideas (the man is imprisoned in the *cave* of the body and of the *doxa*, of the opinion). The aim of the *paideia* is the recognition of the spirituality of the soul and of its contemplative identity; virtue is identified with knowledge. Political *paideia* is born, which is activated according to the different social classes and their different ways of education (technical learning for manufacturers, training courage for warriors, dialectical education for rulers).

*Paideia* embodies a blend of *musaica* education (gymnastics, poetry, and music) with literary education, thus representing an overall process. However, in this time arises the dichotomy between a rational and philosophical model of education, regarded as superior, and a lower model – technical, professional, and productive – of education. This dichotomy will be destined to last in Western society.

In Aristotelian *paideia*, men realize themselves according to their own shape, defined by the intellectual activity (*nous*). The aim of education is to achieve the virtue of wisdom through the educational mastery and the control of the body. Man is a social animal that develops in a concrete and real way.

In Roman civilization, education becomes literary education but even moral education, civic virtue, respect for tradition, for *patria potestas* and *res publica*. The educational model is based on the values of heroism, dignity, and courage; also piety, and sacrifice. Education acquires the rhetorical character of *humanitas*, the study of the liberal arts, *Humanæ litteræ*, as an introduction to the virtues of the orator, an ideal figure from an ethical standpoint.

The Latin *humanitas* switches to Middle Ages *paideia* Christi. After the conquest of Greece and the contact with the Hellenism, the Roman culture is transformed and acquires the Hellenistic character of education as self-care, self-control, inner balance, literary culture, use of the word, and consciousness of tradition. Ties with the Republican custom become loose: education is about man as universal expression of humankind and not just as a citizen.

By the Hellenistic influence, pedagogy gradually frees itself from the *ethos*, until the *romanitas* model

(which is based on the recognition of the state, on the rights, and on an hegemonic and universal culture) will be integrated with the educational model of the Christian culture, which advocates political and social values, different and *revolutionary* than the classic ones such as equality, solidarity, and humility.

*Enkyklios paideia* coexists with the educational vision of religion in a blend that lasts until the Middle Ages, when Christian *paideia* and its educational program, related to the Christian message – to its values of interiority, sublimation, transcendence – will overshadow the classical culture.

Middle Ages *paideia* turns into the humanistic and renaissance model of education, which is rooted in a man-centered secular worldview, whose author is *Homo faber* (either as an individual, and social subject). The key concepts are those of freedom, progress, emancipation, and rationalization.

Humanistic *paideia* returns to classical *paideia*: it becomes free human education in touch with culture and social life. Humanistic *paideia* resumes its aesthetic and scientific aspects from classical *paideia*, as its expression in the arts, its development in the techniques, its statement of thought as the study of the living and of the existing in a multiplicity of fields (from *created* to *constructed*), and its capacity to change reality.

The educational model is political; it revolves around a secular and civil education, worldly in its character, in controversy against subordination to theology, to encyclopaedism and formalism. It is, however, an aristocratic education, not directed to the middle and popular classes as, instead, the movement of the Reformation that encourages an autonomous approach to culture and its dissemination through a personal reading of the holy texts.

Pedagogy of the counter reformation promotes educational curricula inspired by a rhetorical and grammatical vision of education, characterized by detailed precepts and by strict rules. For instance, the *ratio studiorum*, the planning of educational activities governed by strict regulations, in line with the ethical and religious aims of the order of the Jesuits, whose cultural and educational model converges to the political and social models expressed by religious and civil authority.

In the late renaissance, education becomes more and more tense towards an encyclopaedic vision of the knowledge and becomes, in the late sixteenth and early seventeenth century, utopian pedagogy. Pedagogy aims to correlate a harmonic model of man, proper to humanistic pedagogy, with the design of ideal societies, in which the individual is a civil and social subject. At the same time, the seventeenth century is the century of the *new science*, in which the scientific method is born

and opens up the way for a rigorous foundation of pedagogy through a problematization of the methods and an experimental approach to practice.

In the eighteenth century, the concepts of education and socialization prevail over fragmentation of educational models and education is defined in a social and scientific sense. The bourgeois vision is affected by the political and cultural reformism of the secularized society: education acts as social homologation and a strengthening of civic consciousness for a promotion of the rational, free from prejudices and beliefs.

The modernity remarks the gradual emancipation of pedagogical knowledge from metaphysics – its progressive scientific investment and its consequent relativization – as confirmed by the links with politics and ideology.

The sociopolitical paradigm in pedagogy can be said to be characterized by the social philosophy of education, with ethical and political objectives, by the oscillation between the role of education on policy and vice versa [49.30], and by an historical, critical, and hermeneutical accuracy. The theory of education uses the social commitment as a model of the character of design of pedagogy, for a renewal of society; so it gradually moves away from any philosophy of education that reflects the dominant culture.

In the nineteenth century, *paideia* comes back as German *bildung* and its full educational expression. This century shows the link between education, society, ideology, and politics early but also between art and pedagogy; from an epistemological point of view, pedagogy becomes a rigorous, experimental, *positive*, and autonomous domain at the end of the century. The positivist scientific paradigm indeed brings pedagogy to social and institutional rationalization tasks.

In *bildung*, the human and cultural education interconnects individuality, science, and art to a model of man that elaborates its own internal shape, its image, *bild*. *Bildung* thus recovers the meaning of *paideia* as unification of knowledge against the fragmentation of culture and the influence of technology.

During the twentieth century, the deconstruction of the subject and the specialization of knowledge led to a rethinking of the ideal concept of *paideia*. The many directions taken by pedagogy share the idea of a new model of *bild* – synergistic, developmental, and dysmorphic.

Pedagogy is now *disenchanted*: it shares the issues related to the postmodern societies and attempts to address them. At the same time it does not give up the project of construction of identities and of re-

thinking of subjectivity. The involved categories are: deconstruction, interpretation, planning, responsibility, communication, and solidarity.

Through these categories, scientific and philosophical pedagogy find their meeting point in the idea of the subject as a person. Pedagogy becomes the science of the personal education, in the society of diffused knowledge.

The social dimension becomes collective sharing, solidarity in social practices, motor of local and global development that supports the individual, continuous and never predictable processes of internalization of knowledge. The postmodern neo-*bildung* is therefore a *bildung* without *bild* [49.31, p. 51].

### Special Needs Education

Special needs education is a research science that addresses the difference resulting from disability and deficit and the differences of gender and culture. These issues are also addressed by the pedagogy of gender and intercultural education. The purpose of special needs education is the integration, to provide appropriate responses to differences through special care that do not occur in separate contexts, but in educational shared places [49.32]. Special needs education is therefore integrated with general pedagogy, which deals with the concept of cognitive discomfort.

To go beyond separation towards integration does not mean neglecting special attention and professional figures able to meet special needs. In this sense, integration and special responses shouldn't be opposed. The specific needs of each individual, seen in her/his singularity, should be respected without providing answers to the needs of individuals grouped into categories. Special problems can be faced without control models that require special places and categories, but rather with open models that fit in with a variety of situations.

For this reason it is important to improve the vocational training in this area [49.33]. In particular, today it is required of teachers to take specific training to recognize, manage, and integrate students with specific learning disabilities in school settings.

A situation of disability is composed of multiple elements that interact with each other. The damage cannot be extrapolated from the historical, cultural and environmental context in which it is located. It is just the interaction with the contextual elements that can improve the quality of life and reduce the handicap relative to disability. Special needs education therefore develops special expertise in relation to the perspective of inclusion [49.34].

## 49.2 Dialecticity

The dialecticity of pedagogy expresses its controversial nature divided between science and philosophy – that is, between explanation and understanding, between theory and practice, between the various disciplines that comprise it, each of which offers its own educational theories.

Pedagogy is a discipline in progress, under construction and re-construction.

A discipline that is constantly renewed – like the phoenix, a fantastic mythological animal that is reborn from its own ashes, while retaining its unchanged nature, identitarian and dynamic at the same time [49.35].

Pedagogy always reconstructs itself in different ways, just because it is in search for more and more new interpretative hypotheses about the education of the human species. Every time, pedagogy is reflected in its pluralistic identity, in its holistic, rather than general, unity [49.36], and in its own disciplinary nature – dysmorphic, complex, and postmodern.

While renewing, pedagogy preserves in time the same architecture, consisting of two main epistemological axes.

### 49.2.1 Science and Philosophy

The relationship with the object of its own research, which makes it a science, a discipline with a defined epistemological status, is at the border between the humanistic and the scientific areas. In fact, in pedagogy, scientific and philosophical aspects that belong to the same entanglement may coexist.

#### Pedagogy as a Science

Along the course of the twentieth century, the reflections about the scientificity of pedagogy shift the epistemological axis from an idea of pedagogy as a *discipline* to an idea of pedagogy as a *science*, and farther, to an idea of pedagogy as a *science of education*, in the sense of a field of knowing with its specific objects and methods. The scientific approach to pedagogy evolves from systematicity to complexity. It develops, namely, in parallel with the construction and the reconstruction of the very idea of science.

The demand of pedagogy to be seen as a science, defining its disciplinary framework, is an idea gained in the course of its history. Its source seems to have been the emergence of the scientific paradigm in the eighteenth century, from Locke's empiricism and its reflections on the importance of experience in the processes of knowing.

In the nineteenth century, the scientific paradigm in pedagogy is enriched by the positivist considerations

on the interplay between theory and observation and by the verifiability of scientific statements in relation to the empirical observation of reality. It can be said that the debate on the scientific foundation of pedagogy started in 1806 with the volume of *Herbart* [49.37] *Allgemeine Pädagogik aus dem Zweck der Erziehung abgeleitet*, which highlights the necessity to consider pedagogy as a science, while allowing the antinomic nature of the discipline – both descriptive, and normative.

The demand for a scientific approach that runs through the course of the nineteenth century and is characterized by the positivist approach – axiomatic, nomothetic, and systematizing, as the scientific method of Comte – turns instead, at the beginning of the twentieth century, towards a more conscious reflection on the peculiarities of pedagogical discourse. In 1911, Durkheim compiles the entry *Pédagogie* for the *Nouveau Dictionnaire de Pédagogie et d'instruction primaire* and explains how pedagogy may be considered a science that reflects on education, a practical theory.

The term *science of education*, used at singular, occurs periodically in nineteenth century pedagogy – by Bain in England and by Siciliani, Ardigò in Italy. It is heard in the pedagogy of the second half of the twentieth century – in Germany, there are Brezinka, Lochner, Rohrs – but also in *Dewey*, in *The sources of a science of education* [49.22]. In Dewey's pragmatism, pedagogy may have a scientific and rigorous method, but it is not necessarily systematic. The pedagogical specificity is expressed in the rediscovery of a sense of intentionality, that can be recognized in all the other disciplines, seen as possible *sources* of a science of education. The *trait d'union* between them is represented by specific hypotheses of project intentionally expressed from time to time in educational direction.

Pedagogy as a science itself poses many questions. First of all, since by its nature it enters into a relationship with a variety of knowledge: what may its specific object of investigation (singular or plural, theoretical or applied) be? Secondly: What type of science should it be? The object of investigation of pedagogy is based around the education of men and women in their historical, cultural, and social contextualization. However, subjects, objects, and methods of pedagogy are always to be considered plural: they are indeed individual and social processes, contextually oriented, of multidisciplinary, plural and variable, nature. It is possible to establish relations of reciprocal interplay between them.

The search for an epistemological status for general pedagogy is unique because each discipline builds its own epistemology, its own way to be a science. During the twentieth century, pedagogy has tried to find an

epistemology that expresses its *proprium* and may justify it *iuxta propria principia*.

In the second half of the last century, the crisis of the concept of science has returned a problematic and complex image of it, focused on uncertainty, instability, disorder, diversity, evolution, and situativity [49.38]. The problematization of science and the criticism of its infallibility proposed by Popper, Kuhn, Lakatos, Feyerabend has overcome the traditional principles of intelligibility of classical science, the idea that science should be general, ahistorical, totalizing, regulated by laws, organizational invariants and constants; causal, linear, deterministic, acontextual, observer-independent, objective, and logical. The principles underlying the paradigm of complexity [49.39] rather represent a rethinking of science and, in particular, they propose the idea that science can be idiosyncratic and unique, as well as general, contingent, historical, irreversible, holistic and subject to feedbacks, to inter-relations and re-orientations.

Pedagogy is therefore a complex science and not a systemic one. Science “as an *attitude* and not like a *system*” as *De Bartolomeis* [49.40] wrote in *The pedagogy as a science* of 1953. Since the 1950s of the twentieth century, pedagogy catches both its fragmentation in multiple sciences and its unitariness between science and philosophy [49.41]. What links pedagogy to other sciences is a functional and pragmatic unity, not a systematic or a methodological one [49.42]. In fact, the scientific data of other disciplines involve pedagogy only if applied to specific working hypotheses, which will serve the educational aims.

Between the 1970s and 1980s, sciences of education are born [49.43]. The *Traité des sciences pédagogiques* [49.43], edited by *Debesse* and *Mialaret*, is now considered the official text of formalization of educational sciences. The *Traité* distinguishes between sciences of education and pedagogical sciences – the former more theoretical, the latter more methodological – and it affirms their mutual interdependence. Pedagogy is stated as a regulatory science across multiple sciences of education. To perform this role pedagogy highlights its philosophical dimension.

### Pedagogy as a Philosophy

The systematization of educational sciences strengthens the philosophical role of pedagogy. Since the 1980s of the twentieth century, the so-called *identity crisis* of pedagogy will bring it to rediscover the sense of its own reflexive intentionality.

Through the philosophical dimension pedagogy expresses its critical role.

The research object of the discipline is not only related to the processes of education, but also to the

metareflexive relations with other disciplines. Pedagogy then is shaped as a network of knowledge related to collaborative relationships, while retaining each of them a separate disciplinary autonomy.

At its core, philosophy of education is now recognized as an integrative aspect of the pedagogical expression in a variety of sciences of education. The philosophical approach, however, is no more analytical and systematic, but hermeneutic.

Philosophy of education plays a mediating and reflexive role both between the different domains and both between the various aspects that compose the complexity of pedagogy like its antinomy, historicity, and the openness to utopian models [49.44].

The metatheoretical inquiry uses second level reflections – the theory of theory – to analyze the dynamic relationship with the practice. Any theory of education in fact can not be an a priori nor dogmatic as it has an indivisible relationship with the practice that contributes to the definition of its historical, political, and social role.

The metatheoretical model explains the links between theory and practice through historically determined categories. In addition, the hermeneutic approach supports the pedagogical purposes expressed through the search for the meaning of its own philosophical dimension.

The philosophical aspects of pedagogy evolve from the macroparadigm of the modern to the postmodern.

## 49.2.2 Theory and Practice

The relationship between theory and practice makes pedagogy a science of education, in particular a theory of educational development processes.

Pedagogy is a theoretical and practical discipline, built on the ideal triangles theory-practice-theory and practice-theory-practice. Pedagogy indeed has a theoretical and projectual dimension to deal with the educational practice.

In practical dimension, theories pass an empirical verification and are confirmed, processed or falsified. This allows to review theories again and consequently to change practice.

Epistemological characteristics concerning the relationship between theory and practice in pedagogy are: dynamism, research, and retroaction.

### Dynamism, Research, and Retroaction

*Dynamism*, as it is an ongoing discipline, it is in continuous progress. The theory of education utilizes the theoretical construct of *antipedagogia* [49.45] as an indicator of the need for a continual renewal. Pedagogy, in this sense, becomes pedagogy of research.

*Research's* epistemological statute is flexible and based on inquiry, as it is a critical discipline. Although the various theories of education are many and different, in educational research there are some recurring concepts:

- The focus on the personal and social development of students and the deepening of their biological and psychological peculiarities.
- The promotion of the interests of students towards knowledge and disciplines of study; towards the environment, to sustain an ecological awareness; towards others to promote respect, communication, collaboration, solidarity, and emancipation.
- The use of the game. In its cognitive dimension, to empower the exploratory, constructive, communicative, and creative function that characterizes it. In its emotional dimension, because of the role of its symbolic and therapeutic function.
- The attention to individual and social differences of physical, mental, cultural, gender, and age nature to respect, promote, and enhance the diversity, as appropriate. It should also be necessary to educate for the diversity for aperture, encounter, and dialog.
- The respect of the individual autonomy as an evolutionary project, as an expression of personal identity, as a fulfillment of freedom as a potential for growth, as an opportunity for critical thinking, for the setup of the capacity for choice and for the development of active learning.
- The study of the individual singularity in its cognitive processing aspects, with particular reference to the plurality of facets of the cognitive prism, in its explicit and implicit levels and in the ways in which they interact: in their primary development, in their structural modularity and in their evolutionary compatibility.
- The development of the sensory and aesthetic dimension, to teach to enjoy the various forms of art but also to produce artistically in a creative way.
- The acknowledgment of the role played by the embodiment in the acquisition of knowledge, in particular the ways in which the field of embodied cognition interacts with the teaching and learning contexts.
- The recognition of the role played by the affective sphere and the strengthening of its balanced development, in relation to cognitive development. This research is intertwined with the psychological approach.

- The encouragement of social and ethical education, which fosters respect and responsibility, the concepts of coexistence, citizenship and solidarity, within the current multiethnic and multicultural societies.

*Retroaction*, as it is a recurrent discipline, which tends to reuse its own paradigms. Although theories of education are continuously overcome by later theories, the previous persist, update, redefine themselves and may even go back in use.

The different interpretative lines that compose the architecture of pedagogy define the relationship between instruction, learning and educability.

### Instruction, Learning, and Educability

The statement of instruction includes knowledge, skills, and methodological tools through which educational goals can be conveyed via explicit curricula such as school and institutional curricula or via implicit curricula such as nonformal and experiential ones.

Learning is an unavoidable process that can be activated independently of explicit purposes. It has a biopsychological and pedagogical value that can be driven by educational values but it does not necessarily depend on them.

Educability is the study of the education of the mind in the epigenesis; the study of the possibilities and constraints of education. According to the principles of educability, each individual activates diverse and dynamic learning that interact modifying themselves along the personal history of learning [49.46].

### Education, Training, and Educational Development

The concept of education is never neutral. Education has indeed an intentional, purposeful, and normative nature, which involves questions of philosophical foundation, as value and meaning.

The category of training and educational development is not only vocational training applied to specific contexts. Educational development underlines the subjectivity and its shaping in individually different ways and in several times and places. It may be considered interdependent in relation to education, and it is more operational.

The intertwining between education, training, and educational development may be outlined by applied models of education.

## 49.3 Applied Models

### 49.3.1 Traditional Models

Models of education influence teaching models [49.47]. Those that are currently used have been developed over the course of the twentieth century. Although some of them are dated, their positive characteristics make them still valid today. However, these models may involve negative aspects. For this reason, their understanding is basilar for teaching. In fact, only the informed use of models of education can effectively support their management.

Traditional models of education reflect different types of teaching. Among these models behaviorist teaching and cognitive teaching are included. Metareflective teaching may be entered in this tradition, because it shares with the previous models some didactical aspects.

Traditional models are linked by the following characteristics:

- The relationship between teacher and students is asymmetric.
- The teacher transmits information and the students receive it.
- The effectiveness of teaching is evaluated by the amount of information transmitted.

Traditional models, however, differ from one another in this way:

- Behaviorist teaching is born at the beginning of the twentieth century through behaviorist studies and it grew until the middle of the last century. Learning consists in associating stimuli and responses. Notions are captured and repeated. The role of the teacher and of the learning environment is emphasized.
- Cognitivist teaching is developed since the Second World War, at the middle of the twentieth century, with the birth of cognitive science. Learning means individual information processing and is intended with the purpose of carrying out cognitive tasks. Information is acquired through specific strategies and is rearranged in a personal way. The role of the student in the learning process is highlighted.
- Metareflective teaching has been identified between the 1970s and 1980s in the twentieth century. Learning is about reflecting on processes of knowledge and on acquisition and management of concepts and strategies. Students learn to recognize strategies they use to learn. Metareflective teaching can be considered a point of junction with current models of education. On the one hand it does not discuss

the asymmetric nature of the teaching and learning relationship, and it considers teaching a process of transmission. On the other hand, it does not evaluate the amount of information transmitted as an expression of the effectiveness of teaching. Metareflective teaching instead evaluates the quality of the organization of learning, cognitivist teaching does this partially, as well. This last aspect, with the accompanying idea that learning is not only individual but also collective, makes metareflective teaching close to postcognitivism and then linkable to present models of education.

#### Behaviorist Model

In the behaviorist model, learning is a response to a stimulus, an association between a stimulus and a conditioned habit. Learning is thus conditioning [49.48, 49].

At the beginning of the twentieth century, studies on behavior (*behaviorism*) challenged all knowledge of mind based on intuition and introspection. The mind was considered an unknowable black box: the cognitive behavior of a student is the product of her/his manifest and directly observable actions.

Teaching stimulates students and determines the learning process. The educational environment defines conditions and opportunities for learning. Any behavior can be acquired from the environment, except for the innate reflexes and the primary emotions. The motivation to study develops itself in relation to the external stimuli. The teacher is responsible for student motivation. The model is in fact teacher centered.

The teacher transmits information in a notionistic way. Students acquire information passively without critical reworking. The teacher controls the class by keywords and conventional gestures, such as clapping hands or opening the register. Students change their cognitive behavior under the teacher's control. The result is the disciplined behavioral response and the modeling behavior, through the recognition of the merits and the punishment of errors. Self-control and auto shaping are taught.

Students imitate the teacher through apprenticeships. There is not a significant difference between *know how* and *know that*. Each student must achieve a standard of mastery performance common to all. In this model individual diversity and personal learning paths are undervalued.

Emotional and cognitive processing is linked in learning and learning, which occurs through the same processes. It is believed that emotional states, although anxious, can play in favor of learning. The emotional

tension can stimulate cognitive enhancement. The manipulation of the emotional anxious states is useful for classroom management.

Learning is a sequential process, in which the start and end points have the same value. The path of instruction is divided into short learning units, as a series of steps. Teaching is programmed through explicit objectives predefined from the outset.

The evaluation of the student occurs through the analysis of what the student shows of knowing. Learning is strengthened through exercise and repetition. To avoid a consolidation of misunderstandings or mistakes, students are often interrogated; for example, after the explanation of a topic. It is thought that it is not necessary to leave to students the individual time that could be needed for a personal revision of contents. The time to learn must be reduced and optimized. The average of the results obtained by the class are considered to calculate the amount of time required to perform a task.

The evaluation of the teacher is heterodirect, that is, it depends on external factors, such as colleagues or superiors, who may suggest criteria for the revision of teaching.

### Cognitive Model

The cognitive model considers learning information processing of the mind [49.50]. The classic behaviorist formula becomes stimulus – organism – response.

The mind is compared to a computer and is simulated through it. The input stimulates the information processing mechanisms of the mind that, at the end of the processing, produces the output, a behavioral response produced by learning. Learning, however, is significant and not transmissive: to store information it is needed to manage units of meaning.

The *information processing* implies that the cognitive system works with different hierarchical functions, respecting specific activation sequences. The subject interprets the information and translates it into its own codes selecting the perceptual stimulation. The information selected, translated and encoded, are shaped as mental representations, i. e., linguistic symbols and numbers.

The processed data are stored in the short and in the long-term memory, for the retrieval of information involved in response planning. The cognitive system manages archives of memories and is intended to be as a computer, a system with a limited capacity that may contain a predefined number of information.

The cognitive system processes information sequentially and hierarchically. Learning is therefore a linear process from percepts to concepts, from simple to complex. The ascending vision of knowledge is

widespread in the West together with the idea of the mind governed by reason. Indeed, in the computational cognitive model the mind is considered as rational, guided by rules, abstract and complex.

Postcognitivist models – for which the mind is also influenced by the emotional, bodily and organismic components – have discussed this model; learning is not subjective but distributed and situated.

In the computational cognitive model, the mind is instead considered as a container, an operating system with limited capacity as the hard disk of a computer. Even if attention is given to cognitive processing, the teacher reflects on how much information can be taught in a lesson and therefore how much knowledge can be learned by each student and how this aim may be achieved to let information be understood and stored at best.

Sequences of instruction are organized from simple to complex. The learning contents are simplified and compacted in significant teaching units to facilitate understanding. Only understanding produces a significant long-term storage in memory. Among the objectives of the teaching is in fact the stabilization during time of the information in the long-term memory. Understanding means to interpret the meanings and to rework them, in an autonomous and individual way, through the use of learning strategies.

Another objective of the teaching is the organization of linguistic concepts. The processes of understanding, processing and storage in memory take place through language. The concept of mental representation implies the management of linguistic symbols and of symbolic translation of languages (*scripts, frames*).

The relationship with students tends to be predefined. For this reason, since the Second World War the educational offer has been often generalized as a standard one. However, around 1980s in the Anglo-Saxon contest, lines of research that encourage individually differentiated ways of teaching have been developed within this model [49.51, 52]. If in the previous model the evaluation of a student was limited by the *quantity* of her/his intelligence, for example through the ranges of IQ, now this model rather considers *how* an individual can be smart. The cognitive system is seen as differentiated inside and distinct in a plurality of aspects both at the perceptual, and the processing, level.

The individualization of teaching involves the rethinking of teaching strategies. Teaching should be individualized and personalized, that is, renewed according to a vision of the student as a unique, singular and variable, person in a dynamic relationship with the teacher and other students.

### Metareflective Model

This model is at the border between the traditional models – with which it can share the idea that teaching is asymmetric and transmissive – and the postcognitive models that have developed over the last twenty years of the past century, with which it can share a re-thinking of the mind as distributed and collaborative. The metareflective model represents a possible link between the traditional and current educational models.

If in traditional models the *amount* of the learned contents and the *quality* of the strategies used to process them are evaluated, this model is based instead on the evaluation of the awareness of each student about *how to manage* cognitive and emotional levels of learning through individual strategies [49.53–55]. Each student should in fact structure individual modalities of monitoring and control in order to regulate the flow of learning within its own cognitive system. Reflection on learning influences its self-regulating function of autonomous and self-conscious management. This reflection can be shared with other students in a collaborative way because each student may learn to assess her/his own quality of learning.

The teacher is an example of managerial organization of concepts because she/he achieves to regulate her/his own learning. The purpose of education is to stimulate students' self-reflective function. This function – that is, the awareness about the ways in which each cognitive system uses its resources – involves a second level work about learning that is defined precisely as metareflective, metacognitive, and meta-emotional as appropriate.

The role of the metareflective teacher is to make students aware of the ways in which they learn. The student that reflects on her/his own learning strategies can manage them and assess autonomously her/his preparation.

Among the processes for monitoring and control of cognitive functions are:

- The E.O.L. (ease of learning), that is, an estimation of the ease of learning of the information presented by the educational offer.
- The J.O.L. (judgment of learning), that is, the personal judgment of a student about the probability to recall a learned information.
- The F.O.K. (feeling of knowing), that is, the feeling of knowing a learned information that, however, the student can not remember at all (the phenomenon *on the tip of the tongue*).
- The P.T.R. (prediction of total recall), that is, the prediction of the final total amount of memory recall after a single learning session.

In this model the ways through which tacit knowledge – ideas, theories, and concepts of implicit nature that each individual develops dealing with reality – become aware, referable, and verbalized are also studied. Emerging theories about the surrounding world and the minds of other individuals are validated, reviewed or processed.

Each student has an explicit and implicit learning potential. Implicit learning, mainly present in the structuring of thought in the early stages of cognitive development, can absorb from the environment potentially disordered and disorganized information. One of the objectives of the metareflective model is therefore to make explicit the implicit acquisitions that may represent a potential source of discomfort for the functioning of the cognitive system. In this model implicit learning has a predominantly negative value and it is assessed its educational risk.

Learning opportunities also concern explicit and implicit contexts, defined as formal, nonformal, and informal educational contexts. It is namely possible to learn in a nonvoluntary indirect way by environmental experiences.

Even the teacher uses the metareflective method to review and possibly change her/his teaching strategies.

### 49.3.2 Actual Models

Current models of education have developed in the last decades of the twentieth century without a chronological linearity defining their onset. The recognizable types of teaching within these models have indeed emerged in a parallel and mutually interacting way; for this reason they are hardly distinguishable one from each other. However, it is possible to identify the teaching models of contextualism, culturalism, and constructivism, in the line of development of the patterns of thought of Vigotsky, Bruner, and Piaget.

These three models belong to the broader framework of interpretation called postcognitivism.

Compared to the traditional models of education, in the postcognitivist models:

- Cognitive interaction is considered not only in its abstract processing but also in its emotional, bodily, and organismic dimension.
- The study of the mind, therefore, is no longer in vitro but becomes in vivo.
- Cognitive and emotional aspects of the learning are linked.
- The mind is not separated from the body: knowledge thus includes perceptual and behavioral areas that are often expressed through implicit levels.

- The contexts of learning are intended as specific situations located in space and time.
- Learning is not a *task oriented* process but an embodied, situated, and distributed one.
- The educational relationship becomes almost symmetric, because knowledge is no longer transmitted but shared and co-constructed, negotiated within the learning community.
- The teacher acts as a facilitator of learning and a mediator in the processes of knowledge.

Knowledge is distributed, situated, and embodied [49.56–58]. Distributed knowledge has motivated contextualist models of teaching; situated knowledge has justified culturalist patterns, and both these interpretations have concurred to define constructivist and socio-constructivist didactics.

Didactics is no longer individually oriented (toward the teacher or the student) but is based on the concept of the *relationship* between the teacher and the student and among students.

#### Contextualist Model

In the contextualist model, knowledge is a distributed process, and it is no more the subjective patrimony of each individual. The mind is seen beyond the boundaries of individuality and is distributed among several individuals who perform a work of sharing, socializing, and negotiating learning [49.59, 60].

There is a shift from learning processes to knowledge structures. The student leaves the world of singular learning and enters that of shared learning, in which the knowledge itself is a collective heritage to which everyone can contribute. The educational relationship becomes almost symmetrical, with no-guided processes that are activated in different contexts – formal but also semiformal, nonformal and informal.

The class group becomes a learning community [49.61, 62]. The learning community is a real and/or virtual meeting place in which the educational exchange takes place. Knowledge becomes increasingly linked to the different contexts of belonging and is rooted in them.

Learning is a collective process. Knowledge is shared in the intersubjectivity: every task, that is the knowledge object to study, becomes a problem to be dealt with in the learning community, through dynamic exchange and discussion. Among the aims of the teaching there is not only the education of the individual student but also the education of the learning community. Therefore, the ability of students to learn to express their own views and to know how to relate to each other in a mediating way, continuously revising their own opinions, is enhanced.

Particular emphasis is given to the language as a tool of social communication that allows the educational exchange of ideas, theories and concepts in the processes of social co-construction and in the communitarian negotiation of meanings.

#### Culturalist Model

Even in the culturalist model, knowledge is distributed among multiple parties. The distribution of knowledge, however, includes the cognitive artifacts, i. e., the possible expressions that make up the various cultural frameworks. Attention is given to the different cultures – and to their evolution – in which the mind develops [49.63–65]. Cultures constitute learning environments where knowledge is acquired and is replayed also through the peripheral devices, i. e., the technology tools. The cognitive artifacts and the peripheral devices are contingent and relative to situations defined in space and time; therefore they are located in specific cognitive contexts, belonging to each culture. The mind is situated and embedded in the environment.

Situated knowledge loses its character of generality that it had previously: it is no longer a static and predefined patrimony of information, the *general culture*. The various areas of knowledge become dynamic, constantly changing, different in form and in content, and representative of specific ways to make culture. They are considered *domains* of knowledge, contextualized and interactive areas in which cognitive relations are activated. Knowledge is therefore related to times, places, cultures, relationships, and cognitive domains.

The teacher is proposed as a model of identification for her/his students. Learning means to enter into a cognitive relationship with others, within a learning community in which knowledge is shared, mediated and negotiated. The learning community represent the belonging group, with its own way of making culture, of producing knowledge and of teaching it.

Learning in a learning community means taking the cultural responsibility of personal cognitive heritage. At the same time, it can mean the possibility to detach from it in an autonomous way, even if always in relation to educational figures which have been configured as a model and as an example. What occurs is a process of identification that may lead to the recognition of the individual *cognitive identity*, i. e., the knowledge of the personal cognitive heritage. The acquisition of cognitive identity may involve both integrative and detachment functions.

The student can consider the experience and the personal knowledge as a resource of which she/he becomes responsible: she/he thus acquires the cognitive responsibility for her/his own choices and for the meaning

that these choices may acquire within the learning community. Through processes of initiation, the role of the student becomes that of a member of the community; an apprentice who learns to internalize the educational acts of the belonging adult system through processes of scaffolding. The apprenticeship is done under the guidance of an experienced adult who is also a mediator and a facilitator in the learning community. The student is educated in relation to the experiential knowledge of this educational figure that nevertheless plays a role of reference: the student may indeed choose to follow the example of her/his own adult model. Otherwise, the student may choose to detach herself/himself from the given model and to propose alternative models, after having however had a relationship of comparison with the adult model.

Knowledge thus is developed according to the community sharing of the belief systems, the discursive practices, namely the use of languages for the negotiation of meanings, then through the linguistic exchange but also through the sharing of cognitive artifacts, and of peripheral devices, so generating the productions of different cultures.

#### Constructivist Model

The constructivist model emphasizes the role of the subject in the process of construction of knowledge, even when students learn together. This model promotes the critical and interpretive development of autonomous learning. The experiential relationship with the environment is a process of guided discovery. The teacher collaborates in the development of individual knowledge structures.

In the course of the ontogenetic development, each individual elaborates implicit theories – defined as naive and of common sense – relative to the surrounding environment or to the minds of others [49.66, 67]. The teacher can make these implicit theories explicit through education. The intervention of teaching occurs on demand, when the teacher considers it necessary to clarify a concept or when specifically requested by a student. The teacher keeps a more asymmetric position toward the student than in other current models of education; in fact, the teacher's role is that of a guide. The educational guide takes place in semiformal contexts.

Learning is an adaptive process in which knowledge is constructed to be acquired and produced. In learning environments, educational interactions occur for adaptation and participation, as in sociocultural constructivism.

The process of change that accompanies the construction of knowledge should be autonomous and,

at the same time, guided by the teacher only when necessary. In this way their *visit* in the world of knowledge may enable students to interpret reality in a personal way. According to neo-Piagetian constructivism [49.68], the subjective theories about reality have to be shared within the community of learning to be validated, transformed, or abandoned.

The potential of the individual to know in a learning environment is then developed according to the individual knowledge structures and to their sharing in situations of collective co-construction.

#### 49.3.3 Experimental Models

Experimental models analyze the influence of neuroscience and biological sciences in education. The fields of study addressing the relationship between mind and brain, particularly bioeducational sciences, express the research perspectives of experimental models [49.69].

Experimental models share these views:

- Embodied cognition
- Holistic understanding of the human system as a complex phenomenon
- Relationship between the mental, organismic, and environmental dimension
- Study of the evolutionary processes in ontogenesis and in phylogenesis
- Interpretation of learning as an adaptive process
- Attention to the development of individual knowledge structures
- Designing implicit learning environments for educability
- Nonreductionist, interactionist, and integrative research approaches.

#### Enriched Model

The enriched model is a classical model; perhaps it has always been used in the teaching and learning relationship. The basic idea is that for an environment to be effective, it has to stimulate students as much as possible: therefore it has to be designed in a rich and stimulating way; it should use a multimodal methodology [49.70].

Learning is a process that is based on brain plasticity and on the neural network's modifiability. The teacher works to get from students openness to change, and to educational stimuli. The teacher tries to fully express the potential of each student; a poor and deprived learning environment may not activate students' readiness to learn. This model is widely used in the early school levels.

The enriched model sometimes uncritically reflects the ascensional and linear vision of knowledge, according to which concepts are developed by percepts, and abstract ideas are developed from sensations.

Furthermore, this model can be influenced by a consideration of the development as a continuous consequent progress. This idea involves an interpretation of the development itself as a process that may only occur according to certain conditions that may be present in a given learning environment.

Development in general should not be considered as a process that takes place starting on the basis of its potential genetic and epigenetic bases; it is instead a dynamic and interactive process, discontinuous and variable, which conditions cannot be predefined.

### Organismic Model

In the organismic model, mind is embodied [49.71], and not separated from body and brain as in a part of the traditional Western thought. The interaction between the affective/emotional and bodily/organismic level is studied in the processes of knowledge management. In this model, therefore, bodily and emotional functions are linked to cognitive functions in influencing the explicit and implicit processing of knowledge.

The organismic model studies implicit learning on the perceptual, motor, but also processing side [49.72]. Implicit learning can be automated, automatized, and contribute to the structuring of learning as an implicit form of knowledge. In some of them, it is expected that the implicit may interact with the explicit through specific dynamics of relationship.

Implicit learning is studied in its evolutionary and adaptive significance, as a possible form of knowledge that is based on the conservation and on the selective repetition of the strategies that prove to be the most effective in the ontogenetic and phylogenetic development. This model also explores the role played by implicit learning in the prototypical knowledge processing and as a default support for explicit learning, e.g., in the Elementary Logic Theory [49.73].

The organismic model attributes importance to the proxemics of communication in educational practices, to the influence of physiological states on learning, and to the diversity of learning times that cannot be predefined in relation to cognitive tasks.

### Adaptive Model

The adaptive model highlights the individual peculiarity of the learner and the unpredictability of situations in which learning occurs. In a general sense, the cognitive diversity of individuals interacts with the domain specificity of the various knowledge fields and with the relativity of each context. Consequently, knowledge appears as constantly modifiable and continuously changing [49.74].

The design of the educational offer becomes dynamic, ever predefined. Programming a learning environment foresees both its positive and negative development: evolutionary forces and resistances to change, according to the perception of the efficacy of learning by students.

Educational planning becomes adaptive. To be educational, interactions that eventually occur within it have to be reciprocal: if a student accepts the changes required by the environment as a condition of adaptation, at the same time the environment has to embrace the heterodirect change and to accept to modify itself consequently.

In the adaptive model, the teacher evaluates the possibilities and the constraints of the educational action, that is, he/she evaluates the educability of learners. Each student has a personal cognitive potential that has developed over time through continuous adaptation processes.

The explicit or implicit personal history of learners may be both open and close to change. The levels of modifiability of a cognitive system depend on the modularity of the learning within the system itself, in different ways for each individual.

Cognitive modifiability is related to the explicit and implicit choices that each student takes on in its path of experience. The individual strategic procedures of processing are intertwined with the external influences. The result may be the adaptive efficacy, but also the cognitive discomfort.

The levels of cognitive modifiability therefore also depend on the compatibility and on the adaptive interaction between the ways of learning of a student and the ways of teaching of a teacher.

Educability then concerns how aspects of the cognitive experience can be integrated with each other in the complex mechanism of any adaptive system, along the personal history of learning.

## 49.4 Conclusions

The *mechanism* of the pedagogical discourse is expressed in the complexity of the relationship between ideology, science, and utopia [49.1]. This last aspect, in particular, may represent the *trait d'union* between the scientific and the philosophical component. The utopian nature of pedagogy tends toward the model of an ideal educating society [49.75]. Utopia underlies the design of the pedagogical domain.

The vector of utopia reflects the deep complexity of the issue and its rejection of universality, as-

sertiveness, and uniqueness. This does not preclude, however, the research for models and methods as part of a scientific status of interpretive nature, sensitive to cultures, in dialogue with societies, open to the ideas of project and possibility; therefore, to utopia.

Pedagogy, in conclusion, is a very dynamic and open field of research whose developmental directions are horizontal, multidisciplinary pervasive and continuously in progress.

## 50. Model-Based Reasoning in Crime Prevention

Charlotte Gerritsen, Tibor Bosse

Model-based reasoning approaches can be used to formalize and analyze (informal) theories from the field of criminology, to help gain more insight in criminological phenomena that were not clear based on just the informal theory. The analysis of the *displacement of crime* is an important research interest in criminological research. In this chapter, an agent-based simulation model of crime displacement is presented, which can be used not only to *simulate* the spatiotemporal dynamics of crime, but also to *analyze* and *control* those dynamics. Methods are used that are aimed at developing intelligent systems that monitor human-related processes and provide appropriate support. More specifically, an explicit domain model of crime displacement has been developed, and model-based reasoning techniques are applied to the domain model, in order to analyze which environmental circumstances result in which crime rates, and to determine which support

measures are most appropriate. The model can be used as an analytical tool for researchers and policy makers to perform thought experiments, that is, to shed more light on the process under investigation, and possibly improve existing policies (e.g., for surveillance).

Criminology is the study of crime, criminals, and the punishment of criminals [50.1]. To study criminal behavior a number of standard research methods exist, for example, victim surveys, offender surveys, social experiments, and the analysis of police data. Based on these methods, multiple theories have been developed that provide insight into delinquent behavior. However, these theories are usually informal, meaning that they are written in natural language or described graphically and, thus, in principle ambiguous. Approaches based on computational modeling can prove to be very useful to address this void. Criminological theories can be translated into a formal, unambiguous, machine-readable notation so that they can be used for model-based reasoning and simulation, for example, [50.2–4] and help gain more insights in criminological phenomena that were not clear based on just the informal theory.

Within the field of criminology, one of the main research interests is the analysis of the *displacement of crime* [50.5–7]. Typically, certain locations in a city seem to attract many criminal activities, but only for

a short period. These locations where many crimes occur are called *hot spots* [50.7]. Questions that are important in understanding the displacement of crime are:

- When do hot spots of high crime rates emerge?
- Where do they emerge?
- And, perhaps most importantly, how can they be prevented.

In recent years, computational modeling and simulation have proved to be a useful instrument to answer such questions. Most of these approaches take the routine activity theory as a point of departure, that is, the assumption that crime is likely to occur when a motivated offender finds a suitable target, while capable guardians are lacking [50.5]. By creating an *artificial world* in a computational environment, populating it with computational entities representing the *agents* addressed by the theory (i.e., offenders, targets, and guardians), and establishing mathematical rules that govern the agents' behavior, the spatiotemporal implications of

the theory can be studied with the help of the computer.

Nevertheless, when investigating the literature on computational modeling of displacement of crime, a wide variety of different computational modeling approaches can be distinguished. Among the approaches that are applied, one can find agent-based modeling [50.8–11], population-based modeling [50.9], cellular automata [50.12, 13], different spatial analysis techniques [50.14], and evolutionary computing techniques [50.11]. The underlying principle behind *agent-based modeling* approaches is the *agent* metaphor, that is, the idea to compose a model of autonomous pieces of software that make their own decisions, based on information they observe in their direct environment. For instance, the agent-based approach presented in [50.8] simulates the spatiotemporal dynamics of crime as a result of individual decisions of offenders, targets, and guardians (e.g., to move around, or to perform assaults or arrests). In contrast, *population-based modeling* approaches, for example, [50.9] do not distinguish individual agents, but instead describe the dynamics of crime in terms of mathematical formulae (mostly differential equations) over variables that represent the densities of certain subgroups in the population. Furthermore, *cellular automata* (CA) are discrete models that consist of grids of cells that are in particular states (e.g., on or off), of which the dynamics are determined by rules that take the states of adjacent cells into account. Liu et al. [50.13] have used CAs to simulate individual crime events, in order to generate plausible crime patterns. In their approach, the main elements are offenders, targets, and crime places, of which different attributes can be manipulated, such as motivation of offenders, capability of guardians, and accessibility of places. Additionally, a number of *spatial analysis techniques* are used in [50.2]; these techniques include, among others, geographical information systems (GIS) and analytical methods. Finally, *evolutionary computing* is a subarea of artificial intelligence (AI) that attempts to find optimal solutions to mathematical problems by exploiting a computational variant of biological evolution. More specifically, by representing candidate solutions to an optimization problem in terms of individuals in a population, and having the population evolve using operations such as recombination and mutation (where the better performing individuals have a higher probability to reproduce), good solutions can be found to problems in a variety of domains, including criminology. For example, in [50.11] some results are presented that were achieved with GAPatrol, an evolutionary multi agent-based simulation tool devised to assist police

managers in the design of effective police patrol route strategies.

Although these approaches all share the aim of investigating crime displacement, the perspectives taken differ. For example, some authors try to develop simulation models of crime displacement in existing cities, which can be directly related to real-world data, for example, [50.13], whereas others deliberately abstract from empirical information, for example, [50.9]. The idea behind the latter perspective is that the simulation environment is used as an analytical tool, mainly used by researchers and policy makers, for thought experiments, to shed more light on the process under investigation, and perhaps improve existing policies (e.g., for surveillance) [50.15]. Also, some authors take an intermediate point of view, for example, [50.4, 8]. They initially build their simulation model to study the phenomenon per se, but define its basic concepts in such a way that it can be directly connected to empirical information, if this becomes available.

This intermediate perspective is also taken in the current chapter. Its main goal is to develop an agent-based simulation model of crime displacement, which can be used not only to *simulate* the spatiotemporal dynamics of crime, but also to *analyze* and *control* those dynamics. This second aim distinguishes it from most existing approaches, which are mainly descriptive (instead of prescriptive).

To achieve this goal, we make use of techniques from AI, and in particular from ambient intelligence (AmI). Ambient intelligence [50.16–18] represents a vision of the future where humans will be surrounded by pervasive and unobtrusive electronic environments, which are sensitive and responsive to their needs. In order to develop such intelligent environments, Bosse et al. [50.19] introduced a methodology to endow intelligent systems with the possibility to reason explicitly about the mental and physical states of humans. In this chapter, this methodology is reused in order to develop an intelligent system that reasons about crime displacement.

More specifically, this chapter will first describe the development of an explicit *domain model* of crime displacement (which describes displacement in terms of states of the world over time, and transitions between these states). On top of that, model-based reasoning techniques [50.20] will be applied to the domain model, in order to analyze which environmental circumstances result in which crime rates, and to determine which support measures are most appropriate [50.21]. Hence, both an *analysis model* and a *support model* will be developed.

In the remainder of this chapter, first some background information about the area of AmI will be provided, followed by an introduction to the basic methodology for the development of intelligent human-aware model-based systems that will be used. Based

on this methodology, the next sections will introduce, respectively, the domain model, analysis model, and support model for crime displacement. After that some preliminary simulation results will be presented, followed by a discussion.

## 50.1 Ambient Intelligence

AmI [50.16–18] represents a vision of the future where human beings will be surrounded by pervasive and unobtrusive electronic environments, which are sensitive and responsive to their needs. Such an environment has a certain degree of awareness of the presence and states of living creatures in it, and supports their activities. It analyzes their behavior, and may anticipate on it. AmI integrates concepts from ubiquitous computing and AI with the vision that technology will become invisible, embedded in our natural surroundings, present whenever we need it, attuned to the humans' senses, and adaptive to them. In an AmI environment, people are surrounded by networks of embedded intelligent devices that can sense their state, anticipate, and when relevant adapt to their needs. Therefore, the environment should be able to determine which actions have to be undertaken in order to keep this state optimal.

For this purpose, acquisition of sensor information about humans and their functioning is an important factor. However, without adequate additional *knowledge* for analysis of this information, the scope of such applications is limited. As argued by *Bosse et al.* [50.19], AmI applications can show a more human-like understanding and base personal care on this understanding when they are equipped with knowledge about the relevant physiological, psychological, and/or social aspects of human functioning. For example, this may concern elderly people, patients depending on regular medicine usage, surveillance, penitentiary care, psychotherapeutical/self-help communities, but also, for example, humans in highly demanding tasks such as warfare officers, air traffic controllers, crisis and disaster managers, and humans in space missions; for example, [50.22].

Within human-directed scientific areas, such as cognitive science, psychology, neuroscience, and biomedical sciences, models have been and are being developed for a variety of aspects of human functioning. If such models of human processes are represented in a formal and computational format, and incorporated in the human environment in devices that monitor the physical and mental state of the human, then such devices are able to perform a more in-depth analysis of the human's functioning. This can result in an environment

that may more effectively affect the state of humans by undertaking actions in a knowledgeable manner that improve their wellbeing and performance. For example, the workspaces of naval officers may include systems that, among others, track their eye movements and characteristics of incoming stimuli (e.g., airplanes on a radar screen), and use this information in a computational model that is able to estimate where their attention is focused at. When it turns out that an officer neglects parts of a radar screen, such a system can either indicate this to the person, or arrange on the background that another person or computer system takes care of this neglected part. Note that for a radar screen it would also be possible to make static design changes, for example, those that improve situation awareness, for example, picture of the environment [50.23]. However, as different circumstances might need a different design, the advantage of a dynamic system is that the environment can be adapted taking both the circumstances and the real-time behavior of the human into account.

In applications of this type, an ambience is created that has a better understanding of humans, based on computationally formalized knowledge from the human-directed disciplines. The use of knowledge from these disciplines in AmI applications is beneficial, because it allows taking care in a more sophisticated manner of humans in their daily living in medical, psychological, and social respects. In more detail, content from the domain of human-directed sciences, among others, can be taken from areas such as medical physiology, health sciences, neuroscience, cognitive psychology, clinical psychology, psychopathology, sociology, criminology, and exercise and sport sciences.

Although it does not directly fit in the description of AmI, the system envisioned by the current paper has a number of similarities with the types of systems sketched above. That is, it will also take information about humans and their dynamics as input (namely the spatial distribution of individuals over the city, and information about crime rates), it will also be equipped with (formalized) knowledge from human-directed disciplines (in this case criminological knowledge about crime displacement), and it will also generate sup-

port measures as output (i. e., advice to reduce crime). Thus, in order to develop the intelligent system for reasoning about crime displacement, it makes sense to

reuse approaches from the AmI area. In particular, the methodology from [50.19] is used, which is introduced below.

## 50.2 Methodology

In this section, the adopted approach to develop intelligent human-aware systems is presented in detail [50.19]. Here, human-aware is defined as being able to analyze and estimate what is going on in the human's mind (a form of mindreading) and in his or her body (a form of bodyreading). Input for these processes are observed information about the human's state over time, and dynamic models for the human's physical and mental processes. For the mental side, such a dynamic model is sometimes called a theory of mind [50.24] and may cover, for example, emotion, attention, intention, and belief. Similarly for the human's physical processes, such a model relates, for example, to skin conditions, heart rates, and levels of blood sugar, insulin, adrenalin, testosterone, serotonin, and specific medicines taken. Note that different types of models are needed: physiological, neurological, cognitive, emotional, social, as well as models of the physical and artificial environment (In this chapter, the main focus is on social/environmental states and models, that is, locations of persons, and decisions to move to other location. Nevertheless, the model is sufficiently generic to be extended with the other types of states as well).

A framework can be used as a template for the specific class of AmI applications as described. The structure of such an ambient software and hardware design can be described in an agent-based manner at a conceptual design level and can be given generic facilities built in to represent knowledge, models, and analysis methods about humans, for example (Fig. 50.1):

- Human state and history models
- Environment state and history models

- Profiles and characteristics models of humans
- Ontologies and knowledge from biomedical, neurological, psychological, and/or social disciplines
- Dynamic process models about human functioning
- Dynamic environment process models
- Methods for analysis on the basis of such models.

Examples of useful analysis methods are voice and skin analysis with respect to emotional states, gesture analysis, and heart rate analysis. The template can include slots where the application-specific content can be filled to get an executable design for a working system. The analysis method used in this chapter mainly addresses displacement of crime, that is, it calculates how a certain distribution of persons over space would lead to movement of criminal activities.

A general approach for embedding knowledge about the interaction between the environment and the human(s) in AmI applications is to integrate dynamic models of this interaction (i. e., a model of the *domain*) into the application. This integration takes place by embedding domain models in certain ways within agent models of the intelligent application. By incorporating domain models within an agent model, the intelligent agent gets an understanding of the processes of its surrounding environment, which is a solid basis for knowledgeable intelligent behavior. Three different ways to integrate domain models within agent models can be distinguished. A most simple way is to use a domain model that specifically models human behavior in the following manner:

*Domain model directly used as agent model.* In this case a domain model that describes human processes and behavior is used directly as an agent model, in order to simulate human behavior. Note that here the domain model and agent model refer to the same agent.

Such an agent model can be used in interaction with other agent models, in particular with *ambient agent models* to obtain a test environment for simulations. For this last type of (artificial) agents, domain models can be integrated within their agent models in two different ways, in order to obtain one or more (sub)models; see Fig. 50.2. Here the solid arrows indicate information exchange between processes (data flow) and the dot-

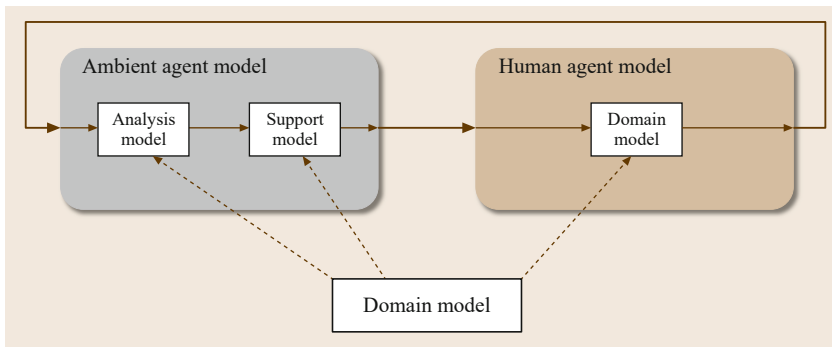

Fig. 50.1 Framework to develop intelligent human-aware systems (after [50.19])

**Fig. 50.2** Overview of the multiagent system architecture (after [50.19])

ted arrows the integration process of the domain models within the agent models.

As shown in Fig. 50.2, the following submodels can be obtained based on a domain model:

- **Analysis model:** To perform analysis of the human's states and processes by reasoning based on observations (possibly using specific sensors) and the domain model.
- **Support model:** To generate support for the human by reasoning based on the domain model.

Note that here the domain model that is integrated refers to one or more human agents, whereas the agent model in which it is integrated refers to an artificial

agent (the intelligent system). In the following sections, this methodology will be applied to the domain of crime displacement. First a domain model is presented which represents the spatiotemporal dynamics of crime. Next, an analysis model is presented, which is able to reason about the domain model in order to predict crime rates for particular situations. And finally, a support model is presented, which is able to suggest to the user the most appropriate measures to reduce crime rates. For example, in case the analysis model predicts that the crime rates at the railway station will increase with 20% in the next year, and that these rates can be kept stable by increasing the amount of police by 5%, then it may propose to invest in 5% more police forces.

## 50.3 Domain Model

This section presents the domain model for crime displacement. The important concepts used are introduced in Sect. 50.3.1, and their formalization is described in Sect. 50.3.2.

### 50.3.1 Crime Displacement

As explained in the introduction, most large cities in the world contain a number of *hot spots*, that is, locations where the majority of the crimes occur [50.7, 25]. Such locations may vary from railway stations to shopping malls. These hot spots usually have several things in common, among which the presence of many passers-by (which makes the location attractive for criminals) and the lack of adequate surveillance. However, after a while the situation often changes: the criminal activities shift to another location. This may be caused by improved surveillance systems (such as cameras) at that location, by an increased number of police officers, or because the police changed their policy.

Another important factor in explaining crime displacement is the *reputation* of specific locations in

a city [50.6]. This reputation may be a cause of crime displacement, as well as an effect. For example, a location that is known for its high crime rates usually attracts police officers [50.25], whereas most citizens will be more likely to avoid it [50.26]. As a result, the amount of criminal activity at such a location will decrease, which affects its reputation again.

To summarize, in order to model the process of crime displacement, several aspects are important. First, one should have information about the *total number* of agents in the different groups involved, that is, the number of *criminals*, number of *guardians*, and number of *passers-by*. Next, it is assumed that the world (or city) that is addressed can be represented in terms of a number of different *locations*. It is important to know how many agents of each type are present at each location: the *density* of criminals, guardians, and passers-by. Furthermore, to describe the movement of the different agents from one location to another, information about the *reputation* (or *attractiveness*) of the locations is needed. This attractiveness is different for each type of agent. For example, passers-by like lo-

cations where it is safe, for example, locations where some guardians are present and no criminals. On the other hand, guardians are attracted by places where a lot of criminals are present, and criminals like locations where there are many passers-by and no guardians. Finally, to be able to represent the idea of hot spots, the *number of assaults* per location is modeled. The idea is that more assaults take place at locations where there are many criminals and passers-by, and few guardians, cf. the routine activity theory by [50.5].

The interaction between the concepts introduced above is visualized in Fig. 50.3. This figure depicts the influences between the different groups at one location. Here, the circles denote the concepts that were mentioned above in italics, and the arrows indicate influences between concepts (influences on attractiveness have been drawn using dotted arrows to enhance readability). (Note that Fig. 50.3 does not depict the influence of some *basic attractiveness* of a location for certain groups (i.e., an attractiveness that is independent of the distribution of agents at the location). For the sake of readability, this notion has been left out of the picture, but it often plays a role in reality. For instance, locations like a railway station will be visited more often by passers-by than other locations, simply because people need to go there to reach their desired destination. Therefore, the notion of basic attractiveness will also be considered in this chapter).

### 50.3.2 Formalization

In order to build the domain model for crime displacement, the concepts that were introduced above (in italics) are formalized in terms of mathematical vari-

ables. The variable names that are used are summarised in Table 50.1.

Next, a number of mathematical equations are introduced to represent the causal relations between these variables. Most of these ideas are taken over from [50.9, 27, 28]. First, the calculation of the number of agents at a location is done by determining the movement of agents that takes place based on the attractiveness of the location. For example, for criminals, the following formula is used

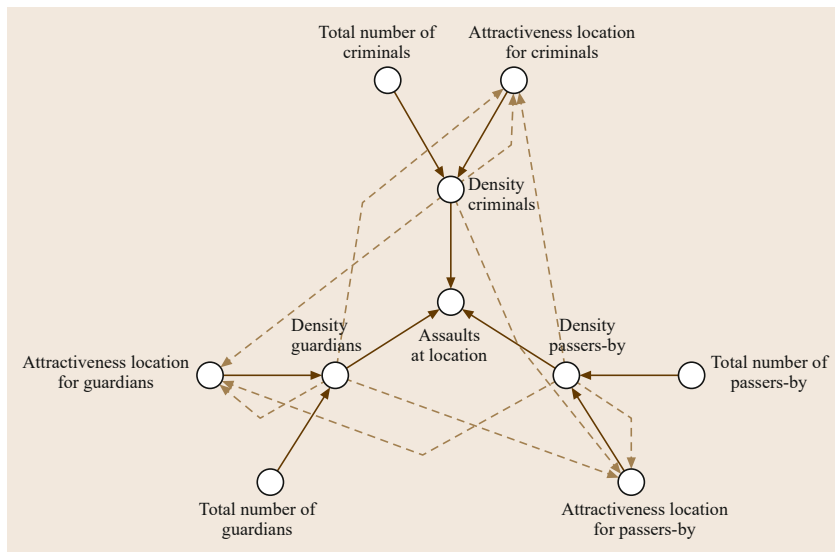

$$c(L, t + \Delta t) = c(L, t) + \eta(\beta(L, c, t)c - c(L, t))\Delta t.$$

This expresses that the density  $c(L, t + \Delta t)$  of criminals at location  $L$  on time  $t + \Delta t$  is equal to the density of criminals at the location at time  $t$  plus a constant  $\eta$  (expressing the rate at which criminals move per time unit) times the movement of criminals from  $t$  to  $t + \Delta t$  from and to location  $L$ , multiplied by  $\Delta t$ . Here, the movement of criminals is calculated by multiplying the relative attractiveness  $\beta(L, c, t)$  of the location (compared to the other locations) for criminals with the total number  $c$  of criminals (which is constant). From this, the density of criminals at the location at  $t$  is subtracted, resulting in the change of the number of criminals for this location. For passers-by, a similar formula is used

$$p(L, t + \Delta t) = p(L, t) + \eta(\beta(L, p, t)p - p(L, t))\Delta t.$$

However, as opposed to [50.9], the movement of the guardians is not (necessarily) modelled using this formula. Instead, to represent guardian movement, different strategies can be filled in.

Next, the attractiveness of a location can be expressed based on some form of reputation of the loca-

**Fig. 50.3** Interaction between criminals, guardians, and passers-by

**Table 50.1** Variables used in the domain model

Name	Explanation
$c$	Total number of criminals
$g$	Total number of guardians
$p$	Total number of passers-by
$c(L, t)$	Density of criminals at location $L$ at time $t$ .
$g(L, t)$	Density of guardians at location $L$ at time $t$ .
$p(L, t)$	Density of passers-by at location $L$ at time $t$ .
$\beta(L, a, t)$	Attractiveness of location $L$ at time $t$ for type $a$ agents: $c$ (criminals), $p$ (passers-by), or $g$ (guardians)
$ba(L, a, t)$	Basic attractiveness of location $L$ at time $t$ for type $a$ agents: $c$ (criminals), $p$ (passers-by), or $g$ (guardians)
Assault_rate( $L, t$ )	Number of assaults taking place at location $L$ per time unit.

tion for the respective type of agents. Several variants of a reputation concept can be used. The only constraint is that it is assumed to be normalized such that the total over the locations equals 1. An example of a simple reputation concept is based on the densities of agents, as expressed below.

$$\beta(L, c, t) = \frac{p(L, t)}{p} \text{ for criminals ,}$$

$$\beta(L, p, t) = \frac{g(L, t)}{g} \text{ for passers-by .}$$

This expresses that criminals are more attracted to locations with higher densities of passers-by, whereas passers-by are attracted more to locations with higher densities of guardians. This definition of reputation is used in [50.9]. Although this definition is simple, which makes the model well suited for mathematical analysis, it is not very realistic. To solve this problem, in this chapter, the following linear combinations of densities are used.

$$\beta(L, c, t) = \beta_{c1} \left( 1 - \frac{g(L, t)}{g} \right) + \beta_{c2} \frac{p(L, t)}{p} + \beta_{c3} ba(L, c, t) ,$$

$$\beta(L, p, t) = \beta_{p1} \left( 1 - \frac{c(L, t)}{c} \right) + \beta_{p2} \frac{g(L, t)}{g} + \beta_{p3} ba(L, p, t) .$$

(Note that these attractiveness formulae are not normalized yet. To ensure that the values stay between 0

and 1, each attractiveness value is divided by the sum of the values over all locations. Moreover, the influence by agents from the same group is not considered.)

This expresses that criminals are repelled by guardians, but attracted by passers-by. Similarly, passers-by are repelled by criminals, but may be attracted by guardians. In addition, for each type of agent some basic attractiveness can be defined. The weight factors ( $\beta_{xy}$ , which may also be 0) indicate the relative importance of each aspect. Again, for the guardians no formula is specified, since this depends on the guardian movement strategy that is selected.

Finally, to measure the assaults that take place per time unit, also different variants of formulae can be used [50.9]. In this chapter, the following is used

$$\text{assault\_rate}(L, t) = \max(c(L, t)p(L, t) - \gamma g(L, t), 0) .$$

Here, the assault rate at a location at time  $t$  is calculated as the product of the densities of criminals and passers-by, minus the product of the guardian density and a constant  $\gamma$ , which represents the capacity of guardians to avoid an assault. The motivation behind this is that the maximum amount of assaults that can take place at a location is  $c(L, t)p(L, t)$ , but that this number can be reduced by the effectiveness of the guardians (which corresponds exactly to the routine activity theory). In principle, this assault rate can become less than 0 (the guardians can have a higher capacity to stop assaults than the criminals have to commit them); therefore the maximum can be taken of 0 and the outcome described above. Based on this assault rate, the total (cumulative) amount of assaults that take place at a location is calculated as

$$\text{total\_assaults}(L, t + \Delta t) = \text{total\_assaults}(L, t) + \text{assault\_rate}(L, t)\Delta t .$$

Although the domain model is presented here in a purely mathematical notation, its actual implementation has been done in the agent-based modeling environment LEADSTO [50.29]. This environment is well suited for the current purposes, since it integrates both qualitative, logical aspects and quantitative, numerical aspects. The basic building blocks of LEADSTO are executable rules of the format  $\alpha \rightarrow \beta$ , which indicates that state property  $\alpha$  leads to state property  $\beta$ . Here,  $\alpha$  and  $\beta$  can be (conjunctions of) logical and numerical predicates.

## 50.4 Analysis Model

This section extends the domain model introduced in the previous section to an analysis model. The analysis model (and the support model, see next section) is created by taking the domain model as a basis, and applying model-based reasoning to it. In particular, two types of reasoning are applied taken from [50.20]: forward and backward reasoning. In short, these types of reasoning make use of the following kinds of (simplified) rules (where  $X$  and  $Y$  are variables in a model, for example, as in Fig. 50.3):

- If you believe  $X$  and believe that  $Y$  depends on  $X$ , then you also believe  $Y$ .

$$\text{belief}(X) \wedge \text{belief}(\text{depends\_on}(Y, X)) \rightarrow \text{belief}(Y) .$$

- If you desire  $Y$  and believe that  $Y$  depends on  $X$ , then you also desire  $X$ .

$$\text{desire}(Y) \wedge \text{belief}(\text{depends\_on}(Y, X)) \rightarrow \text{desire}(X) .$$

To illustrate the idea, assume that we focus on an existing city, of which the average number of criminals, guardians, and passers-by at the different locations is known (to a certain extent). Thus, specific numbers can be assigned to the variables  $\text{density\_criminals}$ ,  $\text{density\_guardians}$ , and  $\text{density\_passers\_by}$  in Fig. 50.3 (which correspond to  $c(L, t)$ ,  $g(L, t)$ , and  $p(L, t)$  in Table 50.1). Then, via forward reasoning (the first rule shown above), the model can predict how the number of assaults will change over time.

One step further, instead of taking the actual densities of guardians at the different locations, the analysis model can also be used to investigate how the crime rates would change in case the densities of guardians were different. To this end, the analysis model is extended with the possibility to specify particular crime

prevention *strategies*. The idea is that, in addition to the rules that govern the behavior of criminals and passers-by, the behavior of the guardians can be specified by selecting one out of multiple strategies.

In current practice, the crime prevention policies that are applied by law enforcement agencies are – mostly – reactive [50.25, 30]. That is, these agencies often only increase the level of guardianship at locations where crimes have been committed in the past. As a consequence, this often means that such a decision is made too late, because the damage has already been done. Instead, we hypothesize that a more anticipatory strategy (e.g., a strategy to invest in more guardians at locations where one predicts that a hot spot *will emerge*) may be more efficient.

To be able to investigate this, the analysis model is equipped with multiple strategies for movement of guardians (varying from reactive to anticipatory, and combinations of the two). The selected strategies are based on [50.27, 28], in which they were already tested against some initial scenarios. In total, the analysis model contains 10 different strategies (see also Table 50.2):

- The first strategy is a *baseline* strategy. In this case guardians do not move at all. Their density at the different locations remains stable over time.
- The second strategy (called *reactive 1*) states that the amount of guardians that move to a new location is proportional to the density of criminals at that location.
- The third strategy (*reactive 2*) states that the amount of guardians that move to a new location is proportional to the percentage of the assaults that have recently taken place at that location.
- The fourth strategy (*reactive 3*) states that the amount of guardians that move to a new location is proportional to the percentage of all assaults that have taken place so far at that location.

**Table 50.2** Guardian movement strategies considered by the analysis model

Strategy	Formalization of $\sigma(L, t)$
Baseline	0
Reactive 1	$(c(L, t)/c)g - g(L, t)$
Reactive 2	$\text{aar}(L, t)g - g(L, t)$
Reactive 3	$\text{taar}(L, t)g - g(L, t)$
Reactive 4	$(p(L, t)/p)g - g(L, t)$
Anticipate 1	$(c(L, t) + \eta_2(\beta(L, c, t)c - c(L, t))\Delta t)/cg - g(L, t)$
Anticipate 2	$p(L, t) + \eta_2(\beta(L, p, t)p - p(L, t))\Delta t/pg - g(L, t)$
Anticipate 3	$((c(L, t) + \eta_2(\beta(L, c, t)c - c(L, t))\Delta t)/c + (p(L, t) + \eta_2(\beta(L, p, t)p - p(L, t))\Delta t)/p)/2g - g(L, t)$
Hybrid 1	$((\text{aar}(L, t)g - g(L, t)) + (p(L, t) + \eta_2(\beta(L, p, t)p - p(L, t))\Delta t)/pg - g(L, t))/2$
Hybrid 2	$((\text{taar}(L, t)g - g(L, t)) + (p(L, t) + \eta_2(\beta(L, p, t)p - p(L, t))\Delta t)/pg - g(L, t))/2$

- The fifth strategy (*reactive 4*) states that the amount of guardians that move to a new location is proportional to the density of passers-by at that location.
- In the sixth strategy (*anticipate 1*), the amount of guardians that move to a new location is proportional to the density of criminals they expect that location to have in the future.
- In the seventh strategy (*anticipate 2*), the amount of guardians that move to a new location is proportional to the density of passers-by they expect that location to have in the future.
- In the eighth strategy (*anticipate 3*), the amount of guardians that move to a new location is proportional to the amount of assaults they expect that will take place at that location in the future. This predicted amount of assaults is approximated by taking the average of the expected densities of criminals and passers-by.
- The ninth strategy (*hybrid 1*) is a combination of *reactive 2* and *anticipate 2*. Here, the amount of guardians that move to a new location is the average of the amounts of guardians determined by those two strategies.
- The tenth strategy (*hybrid 2*) is a combination of *reactive 3* and *anticipate 2*. Here, the amount of guardians that move to a new location is the average of the amounts of guardians determined by those two strategies.

To formalize these strategies, the following formula is used

$$g(L, t + \Delta t) = g(L, t) + \eta\sigma(L, t)\Delta t.$$

This formula is similar to the formulae used for criminals and passers-by, but the amount of guardians that move per time unit is indicated by the factor  $\sigma(L, t)$ , which depends on the chosen strategy. The different definitions of  $\sigma$  are shown in Table 50.2. For example, for the baseline strategy,  $\sigma(L, t) = 0$ , which means that the amount of guardians at time point  $t + \Delta t$  is equal to the amount at  $t$ .

In the strategies *reactive 2* and *3*, the average assault rate  $aar(L, t)$  and the total average assault rate  $taar(L, t)$  are calculated by

$$aar(L, t) = \frac{\text{assault\_rate}(L, t)}{\sum_{X:\text{loc}} \text{assault\_rate}(X, t)},$$

$$taar(L, t) = \frac{\text{total\_assaults}(L, t)}{\sum_{X:\text{loc}} \text{total\_assaults}(X, t)}.$$

As can be seen from Table 50.2, the idea of the anticipation strategies is that the guardians use formulae that are similar to the formulae for movement of criminals and passers-by to predict how they will move in the near future. Obviously, these predictions will not be 100% correct, since they do not consider interaction between the different types of agents, but our assumption is that they may be useful means to develop an efficient strategy.

Furthermore, different values can be taken for the parameter  $\eta_2$  in the anticipation strategies. This parameter represents the speed by which the criminals and/or passers-by move in the predicted scenario (or, in other words, the distance in the future for which the prediction is made). For example, by taking a very high value for  $\eta_2$  in the *anticipate 1* strategy, guardians get the tendency to move to locations that are predicted to have a high density of criminals in the very far future.

As mentioned earlier, the idea of having different strategies is that the analysis model can test which one performs best. A question is however how to define the notion of a *good* strategy. One possibility is to look at effectiveness, for example, by considering the strategy that results in the lowest crime rates (total\_assaults) as the best. However, in reality also the *costs* of crime prevention play an important role. Various mechanisms to improve guardianship exist (e.g., adding and moving security guards, burglar alarms, fencing, lighting), but they all involve costs [50.30]. Thus, instead of only measuring the amount of assaults that result from each strategy, in the calculation of the *best* strategy one should compensate for the costs involved. For this reason, the following formula (which was not included in [50.20]) has been added

$$\begin{aligned} \text{total\_costs}(t + \Delta t) \\ = \text{total\_costs}(t) + \sum_{X:\text{loc}} \sigma(X, t)\varepsilon\Delta t. \end{aligned}$$

This formula counts the total costs that are spent on crime prevention (for all locations involved) during the simulation. Parameter  $\varepsilon$  represents the guardian movement costs per time step.

## 50.5 Support Model

On top of the analysis model presented above, also a support model for crime prevention has been developed. This model takes as input certain information about the future scenario for which the user desires support. Based on this information, it generates advices about which strategies are recommended to prevent crime in this scenario.

More specifically, the model first needs to have some information about the state of the world. In particular, the user needs to specify the geography of the city (i. e., which locations are relevant?), and the initial densities of the different types of agents for each location. In addition to this, the user needs to define a scenario, that is, (s)he needs to indicate the total time span for which the system is to provide support, and to specify for each location how its basic attractiveness will change during this time span. For instance, in case a circus will temporarily come to town, the basic attractiveness of the location of the circus is likely to increase. Finally, the user has to specify the maximum amount of money (s)he desires to spend.

To summarize, the support model takes the following information as input (which needs to be entered by the user of the system):

- Geography of the city (i. e., which locations are relevant?)
- Initial densities of the different types of agents ( $c(L, t)$ ,  $g(L, t)$ ,  $p(L, t)$ ) for each location
- Total time span of the scenario
- Basic attractiveness for the different types of agents ( $ba(L, c, t)$ ,  $ba(L, g, t)$ ,  $ba(L, p, t)$ ) for each location over time
- Maximum budget.

On the basis of these settings, the support model requests the analysis model to perform simulations for all possible strategies, to determine for each of these strategies to which crime rates it would lead, and what its costs would be. After that, the support model selects the *best* strategies, and presents information about those strategies to the user. The strategies that are assessed as best are those strategies of which the costs are lower than the maximum budget. Moreover, concerning the remaining strategies, in case some strategy  $s_1$  turns out both more expensive and less effective than some strategy  $s_2$ , then this strategy  $s_1$  is removed from the selection. Upon request, the model can also provide the user more detailed information about the dynamics of the effect of a particular strategy in the scenario.

## 50.6 Results

A prototype implementation of the model has been developed. To illustrate the behavior of the prototype, below (part of) the dynamics of an example execution are shown in detail.

This example addresses a scenario where there are three locations, and 3900 agents. The population considered consists of 600 (potential) criminals, 300 guardians, and 3000 passers-by. Initially, these agents are distributed equally over the three location (i. e., at each location, there are 200 criminals, 100 guardians and 1000 passers/by). Moreover, all locations start with the same basic attractiveness (= 0.33 on a [0, 1] scale). After 50 time steps the attractiveness of the locations changes: location 1 becomes very attractive (= 0.6), location 2 becomes slightly less attractive (= 0.3), and location 3 becomes much less attractive (= 0.1). The scenario lasts 100 time steps and the maximum budget the user can spend is 100.

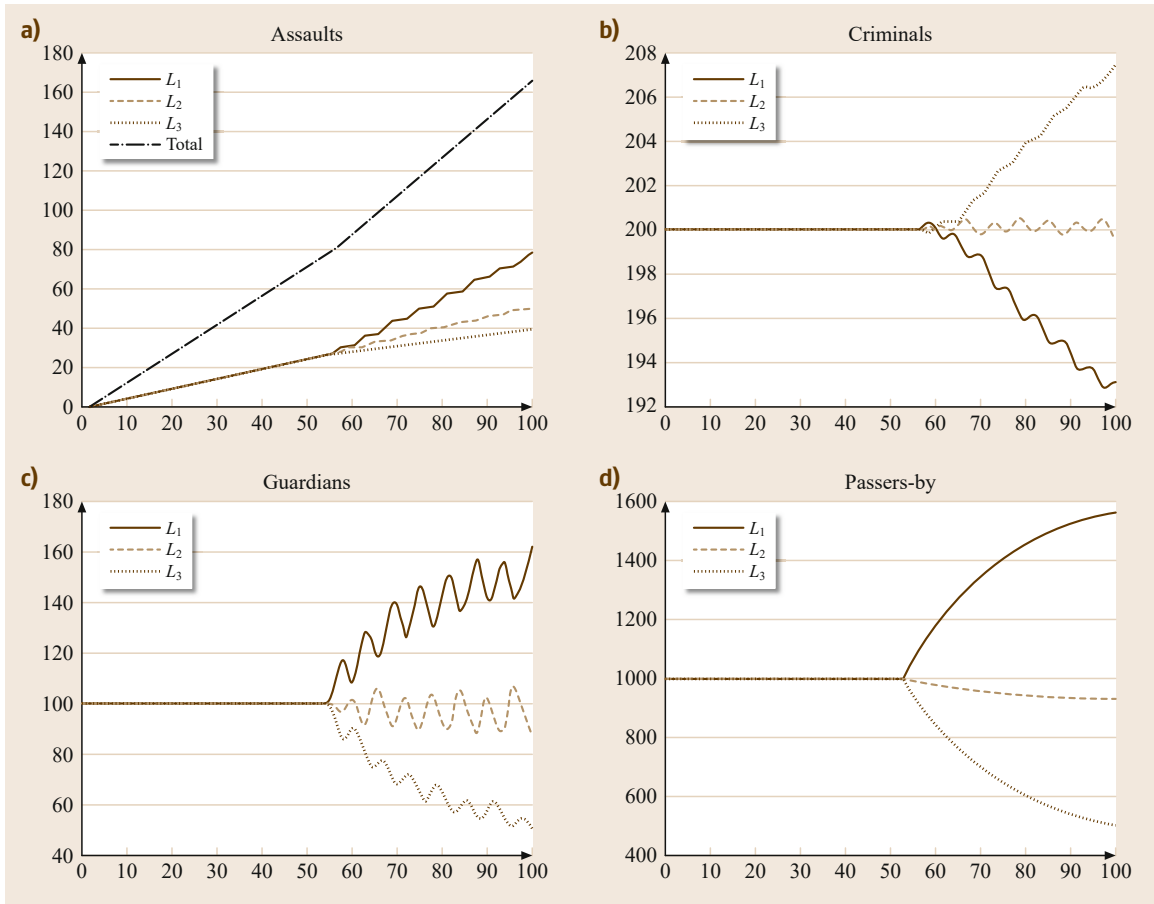

When executing the system based on these settings, for the analysis model would predict the dynamics of the scenario for each of the different strategies, as mentioned above. As an illustration, such a prediction

is visualized for one particular strategy (in this case, the *reactive 2* strategy, Table 50.2) in Fig. 50.4. Figure 50.4a–d shows the assault rate, and the amount of criminals, guardians, and passers-by at the different locations. In all graphs, the red line indicates location  $L_1$ , the green line indicates location  $L_2$ , and the blue line indicates location  $L_3$ . The black line in Fig. 50.4a shows the total amount of assaults, that is, the sum of the assaults at the three locations.

As can be seen in Fig. 50.4, over the first 50 time points, the number of the different types of agents at the locations stays equal. After time point 50, the amounts change. The guardians move away from location 3 to location 1, which is the most attractive location. The criminals move away from location 1 because they want

**Table 50.3** Recommendation by the support model

Recommended strategies	Predicted costs	Predicted % assaults prevented
Anticipate 1	30.38	7.7
Anticipate 2	93.16	70.9
Anticipate 3	45.10	40.6

**Fig. 50.4a-d** Results of an example simulation run by the analysis model

to move away from the guardians. The passers-by move toward location 1 since they want to be at the safest location (i. e., the location with the highest amount of guardians and the lowest amount of criminals). In this case, the strategy used by the guardians seems to work well, because the total number of assaults (i. e., the black line in Fig. 50.4a) grows not much faster than it did during the first 50 time points. When comparing this, for instance, with a baseline strategy in which the guardians are static (which is also tested by the analysis model but not shown in Fig. 50.4), this turns out to be a significant improvement.

All in all, the analysis model tries out all possible strategies and provides the results to the support model. Based on this, the support model selects the most promising strategies (in the context of the user's

preferences), and presents them as a recommendation to the user. Table 50.3 shows what this recommendation looks like for the current scenario.

As can be seen from Table 50.3, the system predicts that the three *anticipate* strategies are *best*, that is, they have costs that are below the budget of the user and are nevertheless effective. Moreover, the system predicts that strategy *anticipate 1* will be cheapest, but that strategy *anticipate 2* will be most effective.

Although this is only a single example scenario, it clearly illustrates that the model is able to generate an appropriate advice on police investment, which may actually be used by policy makers in order to reduce crime rates. For a more detailed comparison between the different strategies in various scenarios, see [50.27, 28].

## 50.7 Discussion

In this chapter, model-based reasoning techniques were applied to the domain of criminology. We presented an approach to analyze crime displacement. The approach was inspired by an existing methodology from AmI [50.16–18], which proposes that intelligent human-aware systems are composed of three separate components, namely a *domain model*, an *analysis model*, and a *support model* [50.19]. In the context of crime displacement, the role of the domain model was to simulate the dynamics of crime displacement, but on top of that, the analysis model proved useful to reason about such simulations for different settings, and the support model was able to generate advice on the basis of the results of this reasoning. The advice consists of a selection of guardian movement strategies that are recommended for a particular scenario, augmented with additional information about the costs and effectiveness

of these strategies. A prototype version of the model has been implemented, and some initial tests have pointed out that the model provides realistic advices.

Despite these encouraging results, one should be careful not to overgeneralize them. Currently, they were achieved in simulations that used several specific parameters and simplifying assumptions. Nevertheless, after further testing, the model may provide useful input for policy makers, in order to elaborate their thoughts about efficient strategies, and possibly improve existing surveillance policies.

# 51. Modeling in the Macroeconomics of Financial Markets

Giovanna Magnani

Since the stock price bubble of 1920 and the following 1929–1933 Great Depression, financial crises have become increasingly frequent and globalized. When in the late 2007 the Global Financial Crisis began to show the flawed characteristics of the US capitalist system while spreading throughout all other economies of the world, the ideas of the post–Keynesian School of Economics – a school of economic thought having its origins in *The General Theory* – and in particular, those of Hyman Minsky, became prominent. Minsky's conception of “crisis-prone markets” has become fundamental not only to interpret the 2007 credit crunch – as well as a sort of “ignored prediction” – but also to elucidate the features of the post-modern capitalistic system and its evolution. This chapter begins with a review of Minsky's thought on the *inherently unstable* nature of capitalism. It then examines Irving Fisher's debt deflation model and its application to interpret financial crises and recessions. A reflection on the issues of *finance-led capitalism* in the neo-liberal era completes the first part of the chapter where it is argued that the Minskyian model, if integrated with the social structure of accumulation theory, is very relevant for interpreting the causes and the evolution of the 2007 crisis. The second part of the chapter progresses with the investigation around the constructs of *risk and uncertainty*, and their modeling in Economics and Business Studies.

## 51.1 The Intrinsic Instability of Financial Markets

In the following sections, we review Hyman Minsky's financial instability hypothesis, starting from his interpretation of John Maynard Keynes' *General Theory*. Subsequently, we examine Minsky's financial theory of investment and the investment theory of the business cycle.

The central idea of Minsky's theory is that *stability is destabilizing* meaning that even a stable economic (capitalistic) environment will endogenously move toward unstable conditions. Capitalism is seen as prone to crisis, with the origins for economic collapse rooted inside the growth process itself. More specifically, a capitalist economy with sophisticated financial institutions is inherently flawed because of its cyclical nature, where short- and long-term expectations are unstable because of the presence of uncertainty.

During an economic downturn, banks and other financial institutions act more conservatively in their lending, as such practices produce efficient outputs to firms which are in turn taking on less risk (as they have a sustainable level of indebtedness). But during times of growth, firms start to engage in riskier activities borrowing money to accelerate growth to even higher rates as their optimistic forecasts are validated. Economic units become riskier – starting from a situation where they are simply hedge units to evolve into speculative or *ultra-speculative* ones – as financial institutions become laxer in their lending practices. Euphoria spreads over and low interest rates make leveraging affordable.

An economic system increasingly based on speculative units is going to be *intrinsically* much exposed to financial crises because it becomes more fragile; thus, any small fluctuation in financial markets (in particular an increase in interest rates) can have great rebounds on real variables.

Indeed, the ability to repay debt and to refinance business is a function of expected future profits. These latter are a function of investment and in turn, the ability to finance future investments is strictly correlated to the expectations that those investments will be able both to repay debts and to refinance business.

As the vicious spiral of increased speculative and ultra-speculative lending positions carries on, units which face liquidity problems caused by their over-indebtedness are forced to refinance or to sell their activities at declining prices (debt-deflation). This leads to falling investment, demand, and profits. Whenever over-indebted investors are forced to sell even their less-speculative positions to make good on their loans; at this point, a major sell-off begins and markets create a severe demand for cash: an event that has come to be known as a *Minsky moment*. The crisis of 2007

has been classified by many commentators as a *Minsky moment*. Paul McCulley, a bond fund director at the Pacific Investment Company, has been the first who coined the term following Hyman Minsky's financial instability hypothesis. The term has been subsequently clarified by George Magnus, a senior economic advisor at the global investment bank UBS. According to Magnus, a *Minsky moment* in financial markets is the point at which “credit supply starts to dry up [...] systemic risk emerges and the central bank is obliged to intervene” [51.1]. This stage is first characterized by “a prolonged period of rapid acceleration of debt” in which the most traditional debt is replaced by new debt borrowed to repay the already existing one. Then “the moment’ occurs when lenders became more and more cautious or restrictive” and at this point “the risks of systemic economic contraction and asset depreciation become all too vivid” [51.2].

According to Minsky, two sets of solutions emerge as necessary in order to reverse the income decline caused by a financial shock. First, central banks should act as lenders-of-last-resort (the so-called *big bank*) and second, the governments should run high deficits that can sustain firms' profits, employment, and final demand even if income has declined (the so-called *big government*). Countercyclical government spending, which constitutes a significant share of aggregate demand, can reverse the tendency toward debt-deflation that emerges during the crisis. Summing up, the bigger the government, the greater the stability of the economy.

### 51.1.1 The Interpretation of the General Theory

During the 1980s, when mainstream macroeconomic research started to study the role of finance within the economic system, Hyman P. Minsky's theories became of foremost importance. Minsky argued that the structure of the contemporary capitalism is made of exceedingly complex financial arrangements. He indeed preferred to call himself a *financial Keynesian* rather than a post-Keynesian because of his aim to clarify and extend Keynes' theories including the complex financial relations, markets, and institutions which characterize the contemporary capitalist structure. Indeed, Minsky's *financial instability hypothesis* – as it is generally called in the Academia – derives from his studies of Keynes, based in particular on *The General Theory of Employment, Interest and Money* [51.3].

His *financial Keynesian* perspective contrasts sharply with that in the mainstream macroeconomic de-

bates of the 1960s and 1970s where the role of financial relations was considered to be limited. The financial instability hypothesis arose out of an attempt by Minsky to understand Keynes in light of the extreme financial disturbance of the 1920–1930 decade which led to the Great Depression of 1929–1933. Such an interpretation is alternative to the one which led to the birth of the so-called *neoclassical synthesis* mainly developed by John Hicks and popularized by the mathematical economist Paul Samuelson, in that it stresses Keynes' explanation of complex capitalist economy's behavior made of sophisticated financial institutions. As mentioned already, Minsky believed that such a kind of economic system tends to be *inherently flawed*. This flawed feature is related to its cyclical nature, meaning that it is made of a succession of transitory phases where economic behaviors change and where, according to this definition, the system cannot by its own processes continuously sustain full employment [51.4].

With respect to the financial structure within a capitalist economy, we can identify the presence of (i) *private portfolios*, made of real-capital assets or speculative financial assets – and (ii) *banks*, generally defined as institutions specialized in finance. Monetary and financial institutions determine the way in which funds required for gathering stocks of capital assets and those needed for the production of new ones are obtained. Following Keynes, Minsky agrees with the assumption that the proximate cause of the transitory nature of each cyclical phase is the instability of investment, but the deeper cause is the *instability* related to *portfolios decisions* and *compositions*, and to *financial interrelations*. In order to better frame such an argument, we need to illustrate its foundation on a specific modeling of the construct of *uncertainty*. Uncertainty in this context means that future is not predictable, and therefore changing views about what will happen affect people's choices about portfolios compositions, financial decisions, and relations in general. The presence of uncertainty makes the formation of short- and long-term expectations precarious. Since short-term expectations are for instance – from firms' point of view – the basis for current production decisions whereas long-term ones affect investment decisions, a variation in one or both can change the equilibrium conditions between production and investment, as well as agents' portfolio choices.

While *classical economics* (i. e., the school of economic thought born in the eighteenth century with Adam Smith, David Ricardo, and John Stuart Mill) and the *neoclassical synthesis* (i. e., the consensus view of macroeconomics which emerged in the mid-1950s in the United States) are based upon a *barter paradigm*, the Keynesian theory of investment rests upon a *speculative-financial paradigm* [51.5, p. 21]:

“[...] in the General Theory Keynes adopts a City or Wall Street paradigm: the economy is viewed from the board room of a Wall Street investment bank.”

By adopting the City paradigm, Keynes assumes that the economy is a sophisticated monetary system where *money* has not only simple trade functions, but it also acts as a *financial veil* between “the real asset and the wealth owner.” As pointed out by *Davidson* [51.6], Keynes specifically argued that money has also another important function: since people know that they cannot predict future, society has attempted to create institutions that will provide people with some control over their uncertain economic destiny; the use of money permits individual to have some kind of control over their cash inflows (CIFs) and outflows and so, of their monetary economic future. Keynes' conception of money is clearly stated by his sentence [51.7, p. 169]:

“There is a multitude of real assets in the world which constitutes our capital wealth- buildings, stocks of commodities, goods in the course of manufacture and of transport, and so forth. The nominal owners of these assets, however, have not infrequently borrowed *money* in order to become possessed of them. To a corresponding extent the actual owners of wealth have claims, not on real assets, but on money. A considerable part of this *financing* takes place through the banking system, which interposes its guarantee between its depositors who lend money and its borrowing customers to whom it loans money wherewith to finance the purchase of real assets. The interposition of this veil of money between the real asset and the wealth owner is a specially marked characteristic of the modern world.”

Looking at the economy from a “Wall Street board room”, Minsky sees a world made of commitments to pay cash in the future in exchange for cash today, where the most crucial type of commitment is *business debt*, assuming that it is the very peculiar component of a modern capitalist economy. The ability of firms to repay debt and to refinance businesses in order to make new investments is a function of the expected future profits (gross profits), where gross profits themselves are, in turn, largely determined by investments. This means that the ability to finance future investments is strictly correlated with the expectation that future investment will be higher enough so that future cash flows will be able both to repay debt and to refinance the business. Minsky argues that an economic system with private debts is deeply influenced by agents' (firms and bankers) views about the future course of investment and thus the determination of units' liability structures

and in the end, future production, income, and employment. It is uncertainty – the Keynesian type of – for which “there is no scientific basis on which to form any calculable profitability whatever. We simply do not know” [51.8, p. 214]. In the next sections, we will progressively illustrate Minsky’s financial theory of investment and his investment theory of the business cycle, in light of the assumptions he made upon Keynes’ vision of behavior in an uncertain capitalistic economy. But first we need to portray Minsky’s model of the capitalist system itself.

### 51.1.2 The Nature of the Capitalist System

#### The Financial Nature of Capitalism and Money Supply Endogeneity

Minsky recognizes different distinct forms of capitalist systems, but at the same time he argues that they share similar characteristics. According to his analysis [51.9], our capitalist economy is first of all a monetary production system where money is at the center of economic decisions, and where the aim of any economic activity is to get a monetary gain. Following Keynes, money is understood as a *veil* that *camouflages* ultimate ownership of wealth [51.10] and that any economic theory (i. e., the neoclassical synthesis which considers money only as a *bartering veil*) which ignores this major aspect of money cannot be considered a useful tool to design appropriate policies. This kind of veil is different from the one in *quantity theory of money*. The veil of quantity theory basically says that the price level in an economy depends on how much money is in the economy: when money supply changes, the real economy does not because when money supply changes by a certain amount, everything else does as well. If it doubles, then prices double: money supply is the force that changes the price level

$$MV = PY, \quad (51.1)$$

$$M \rightarrow P, \quad (51.2)$$

where  $M$  is the money supply,  $V$  is money’s velocity of circulation,  $P$  is the general price level, and  $Y$  is the real value of national output (i. e., GDP).

The idea that money supply has to be treated as endogenous is largely accepted by post-Keynesian theories: accordingly, credit volume is generated endogenously inside the private sector because of banks introducing money into the economy directly by financing current productive activities. Credit is brought into existence by banks (without preventive savings acts), through the creation of deposits. The financing of production is therefore linked to banks’ availability and capacity of injecting money into the economic system through investment acts [51.11]. Hence, money is not

only a medium of exchange or a store of value, but also the financial mean through which banks allow credit to units. In such a prospective, banks’ credit potential is not fixed by the *monetary base* (i. e., a measure of the money supply that is the sum of all the money in circulation plus deposits, and commercial banks’ reserves with the Central Bank). Money supply is a function of the interaction between firms, banks, workers, and financial markets.

Within the Minskyan framework, money has an *endogenous* nature: it is a type of *obligation* appearing on the market as investment or current production activities are in the process of being financed. It has to be noted that according to Minsky, money supply endogeneity is compatible with the *liquidity preference* hypothesis [51.12] since he extends his financial instability hypothesis to banks and credit markets, analyzing creditor and debtor risk throughout all the business cycles phases [51.11], thus taking into consideration the liquidity preference functions of each actor. Liquidity preference means that the less liquid (i. e., easily tradable) the investment is, the greater the premium demanded by investors in the face of greater risk.

One of the most innovative arguments in Minsky’s theory is that when demand for money stimulates supply, it not only increases money velocity of circulation, but also causes the introduction of *financial innovations*. The release of less liquid and more onerous financial instruments (called *quasi-money*) is the reason why during boom periods the amount of money in circulation rises. Thus, money supply is not *given* once and for all: the amount changes during the economic cycle (during a boom period money demand will stimulate for an increasing supply). Although the effective quantity of money in circulation is demand driven, it is *not* unbounded. Money supply is positively related to the rate of interest with a given financial structure, but it increases when banks and financial intermediaries *squeeze* inactive money and issue new substitutes for money, reacting to monetary policy or just exploiting profit opportunities during the cycle [51.13].

#### The Role of Banks and of Financial Innovations

Banks are an essential component of the system at all stages of the economic process. In addition, bankers are both a source of dynamism and destabilization and, therefore, need to be managed [51.10]. Banks can be thought as all kind of institutions that contribute, directly or indirectly, to the financing and funding of economic activities. At the same time the aim of the banking activity is that of maximizing expected profits. Banks are considered by *Minsky* truly speculative enterprises since the maturity of their debts is far shorter than

the maturity of their assets, so that there is a refinancing cost upon which they have to speculate [51.5]. By allowing loans, banks are subject to credit risk; therefore, they first of all assess firms' expected profitability. Banks will profit from their lending activity only if firms are able to meet their debt payment commitments. Hence, bankers' expectations on entrepreneurship are pivotal in determining the economic course of events (even if also bankers' expectations are formed in a world made of uncertainty), since they are the prerequisite to obtain funds.

In order to maximize profits, banks attempt to make an increasingly efficient use of their lending potential, and push for an increase in loans. At the same time, similar to commercial banks, financial intermediaries that are profit-seeking agents, also constantly try to extend credit, by financing new positions. Financial intermediaries issue new kinds of financial instruments which serve as *effective* money without increasing required reserves [51.14]. A given amount of bank loans and demand deposits supports a higher volume of finance to the whole economy.

### The Centrality of Profits

In arguing about the financial nature of modern capitalism, and in particular of investment, Minsky recognizes three ways in which the former affects the latter. First, in financing of positions in the existing stock of capital assets; second, in financing investment and production/distribution activities; third, in meeting payment commitments as stated on financial contracts. He argues that the techniques employed to finance positions in capital assets affect asset prices and that prices reflect expected profits that can be earned by using capital assets into production and the payment commitments that have to be agreed to finance ownership. Since a debt involves an exchange of money today for promises to pay money tomorrow, the smaller the amount that has to be promised to obtain current money to finance capital assets, the greater the demand for such capital assets. Supply of capital assets is fixed and therefore an increase in their demand will cause an increase in their price.

It is necessary for *quasi-rents* – that is, the difference between the total revenue from selling output produced with the aid of capital assets and costs associated with that production – to be greater than future payment commitments (at least on a relevant time horizon), so that it is suitable to proceed to the production and acquisition of capital activities. The maintenance over time of a positive gap between cash-inflows and cash-outflows depends on the realization of expectations on future profits, but also on the debt-structure inherited from the past and on the course of financial costs in the current period [51.14]. Since we can say that

profits are inflows used by firms in order to meet debt commitments, and expected profits are the stimulus for making investments and determine the possibility to renew existing debts or to generate new ones – expectations on future profits are the determinants of current investment and financing decisions. The centrality of profits, seen as the engine for growth and financial dynamics (debt structures), is confirmed by the use of *Kalecki's equations of profit* by Minsky (Sect. 51.2.1).

### 51.1.3 Cash Flows Analysis and Classification of Financial Postures

All economic activities (real and financial assets) are acquired by firms through a combination of equity and short/medium long-term debt. Since debt implies a commitment in order to repay principal and interests, periodical cash outflows (COFs) are generated. On the other hand, investments and productive activities are expected to give birth to CIF. Note that current profits are a sign of the generation and of the amount of future profits and thanks to this, firms decide or not for greater indebtedness.

An economic unit – or the economy itself – needs to generate enough CIF or to have enough idle cash balance (ICB), in order to meet its COF [51.15]. If the net cash inflow (NCF) is negative and no ICB is available, an economic unit will be considered illiquid or even insolvent [51.9]. We can identify different sources and uses of funds for each economic activity, also depending on the level of analysis (business unit, sector, and whole economy): possible sources and main NCF are different. Our economy is one in which borrowing and lending on the margins of safety are commonplace. Each financing transaction involves an exchange of money today for money later on; the future cash receipts which will enable the borrower to fulfill the money-tomorrow parts of the contract are conditional upon the performance of the economy over a longer or shorter period. All economic activities involve income transactions, balance-sheet transactions, and portfolio transactions; we can classify sources of CIF into three categories [51.4, 16]. Cash flows from income operations are those deriving from productive activity or from investment: they are wages, salaries, and profits. Cash flows from balance sheet operations are those deriving from financial contracts (interest and principal). Cash flows from portfolio activities are those related to transactions involving real assets or financial ones (assets acquisitions or the issue of liabilities). It is the relative weight of these cash flows that determines the exposure grade of a system to a financial crisis. In particular, financial instability derives from the propagation of the practice through which a unit finances

long-term activities by underwriting new debt (position refinancing). The model in which Minsky investment theory is developed is a closed economy with a very small State (that is to say, public intervention has no relevant dimension), where capital accumulations implies debt, which in turn is constituted first of all by banking finance. There are two types of financing: the short term, which is to finance productive activities and the long-term, needed to finance capital assets (in general all those illiquid postures in capital assets such as plants and equipment, buildings, etc.). Usually these financings are made partly with own funds and partly with external ones; we can assume that banks finance current production and that the present stock of capital assets can be financed also through other financial intermediaries or directly by private savers, with instruments whose liquidity is directly linked to their convertibility in bank money [51.14]. As we mentioned, Minsky defines money as a particular type of obligation, created as production process activities, investments and postures on capital assets are getting financed.

It is important to remark that, according to Minsky, agents' ultimate purpose is not material production itself, but accumulation of money (production of money with money) through speculation, by holding portfolios of activities that are not quickly convertible into money which means, by engaging in *financial postures* (i. e., any capital value from which to expect future profits for instance machines, but also securities). There are three kinds of financial postures for the acquisition and ownership of activities not quickly convertible into money, including investment goods: hedge, speculative and *Ponzi*. Minsky argues that the stability of the economic system is deeply dependent on the mix of these financial postures: the greater the presence of hedge financing, the greater the stability of the structure, while on the other hand, the presence of excessive speculative and *Ponzi financing* will increase the tendency of an economy to become more and more unstable.

A necessary though not sufficient condition for their financial profitability is that the expected gross capital income exceeds the total payment commitments over time. In particular [51.9]

$$\begin{aligned} \text{Gross Capital Income} &= \\ &\text{Total Receipts From Operations} \\ &\quad - \text{Current Labor and Material Costs} \\ &\text{and} \\ \text{Gross Capital Income} &= \\ &\text{Principal and Interest Due on Debts} \\ &\quad + \text{Income Taxes} + \text{Owners Income} . \end{aligned}$$

This means that the total receipts of a business firm can be divided into the payments for current labor and pur-

chased inputs and a residual, gross capital income that is available to pay income taxes, the principal and interests on debts, and to be used by the owners.

Back to our sorting, a hedge financing unit implies that CIF (quasi-rents) from participation in income production exceeds debt payment commitments (principal plus interests) in every period and for each interest rate. Hence, a sharp rise in interest rates cannot reverse the condition where the actual value of capital assets exceeds the book value of debts. The actual value of activities is always non-negative even in the presence of very large changes in interest rates. A hedge unit is expected to be very liquid; there is no expectation that cash flows from operations will be lower than balance-sheet commitments at any time; therefore, there is no expectation that one will have to refinance. However, some idle cash and superfluous assets are kept aside to cover possible disappointments in expectations [51.17]. As time passes debt decreases, while equity and idle cash (retained for precautionary purposes) increase.

A speculative financing unit implies that cash flows from participation in income production, when totaled over the foreseeable future, exceed outstanding debt, but in the near term it is expected that cash flows from operations will not cover the capital component induced by debt (even if they are always sufficient to cover interests); therefore at least in the short term negative cash flows are expected. A refinancing is thus necessary, but only for the capital component of debt, thereby exposing the unit to interest rates fluctuations. A speculative unit may get more easily into troubles than a hedge unit because for a certain set of interest rates the activity actual value is positive, but a sudden increase can convert profits into losses.

A Ponzi finance unit is a speculative financing unit for which the net income portion from short-term cash flows is less than near term interest payments on debt. A Ponzi finance unit implies that cash flows from operations do not even cover cash disbursements due to interest payments. The unit bet on a favorable variation under market conditions and/or on gaining an exceptional profit that allows compensation of initially accumulated losses (e.g., who speculates at bullish trend). Both speculative and Ponzi units can fulfill their payment commitments only by borrowing again (or by disposing assets). The amount of refinancing of Ponzi units is greater than that of the speculative units, since the former must refinance in order to cover both principal and interest. In this case, the refinancing process is needed both to cover not only the capital components of balance sheet cash commitments but also their income components [51.16]. Debt increases over time till the (expected) realization of a final profit (that reverses the sign of the investment expected actual value). It has to be

noted that Ponzi financing can be hard to detect because it can be hidden by (creative) accounting practices.

We can identify two kinds of risk: *economic risk* and *financial risk*. Economic risk is linked to the possibility not to come up to firm's expectations about future profits, because of a sudden unforeseen worsening of commodities' markets conditions. Economic risk can arise because of lower incomes or higher expenditures than expected. Causes may be several, for instance a hike in the price for raw materials, lapsing of deadlines for construction of a new operating facility, disruptions in a production process, emergence of a serious competitor on the market, the loss of key personnel, the change of a political regime, natural disasters, etc. Financial risk (which is an umbrella term for any risk associated with any form of financing) is related to the possibility of unexpected worsening of financial markets conditions. Risk may be taken as *downside risk*, the difference between the actual return and the expected return (when the actual return is lower), or the uncertainty of that return. Risk related to

an investment is often called *investment risk*. Risk related to a company's cash flow is called *business risk*. The science that has evolved around managing market and financial risk under the general title of modern portfolio theory was initiated by Harry Markowitz in 1952 with his article, *Portfolio Selection*. We can therefore argue that hedge financing units are exposed only to economic risk, while speculative and Ponzi financing units are exposed both to economic and financial risks, thus making these two positions unstable and fragile.

As we have mentioned, the stability of an economy depends upon the mixture of hedge, speculative, and Ponzi financing, and in turn, the weight of Ponzi and *near-Ponzi* speculative finance is conducive to instability. During a tranquil period of economic growth, the weight of speculative and Ponzi financing can increase a lot because of euphoric expectations about the future. Thus, for these kinds of positions a rise in interest rates can transform a positive net worth into a negative net worth; and these together can intrinsically produce the conditions for interest rates to swing.

## 51.2 The Financial Theory of Investment

### 51.2.1 Aggregate Profit Determination

"A capitalist economy works well as an investing economy, for investment generates profits" [51.18, p. 104]. Profit expectations make debt financing possible: investment takes place because positive future profits are expected, but these profits will be forthcoming only if future investment takes places. This means that investments are the key variable in order to determine whether or not debt payment commitments will be met.

In order to determinate aggregate income, *Min-sky* [51.10, pp. 515–516] builds on Kalecki's equation of aggregate profit [51.19], which assumes a world where investment takes place, workers spend all their wages in consumption, and capitalists' profits are all saved.

$$C = W_c N_c + W_I N_I, \quad (51.3)$$

with  $C$  = consumption,  $W_c$  = money wage rate in the production of consumption goods,  $W_I$  = money wage rate in the production of investment goods,  $N_c$  = employment in consumption goods,  $N_I$  = employment in investment goods,  $W_c N_c$  = wage bill in the production of consumption goods, and  $W_I N_I$  = wage bill in the production of investment goods.

Assuming that  $P_c Q_c$  is consumption ( $C$ ) summed over all goods, then

$$P_c Q_c = W_c N_c + W_I N_I, \quad \text{so that} \quad (51.4)$$

$$\pi_c = P_c Q_c - W_c N_c = W_I N_I, \quad (51.5)$$

where  $\pi_c$  are profits in consumption goods. Thus, profits in consumption goods equal wages in investment goods.

Profits in investment goods  $\pi_I$  are instead

$$\pi_I = P_I Q_I - W_I N_I = \pi_I. \quad (51.6)$$

Since  $\pi_I + \pi_c = \pi$ , and  $P_I Q_I = I$ , we have

$$\pi = W_I N_I + \pi_I = I. \quad (51.7)$$

Kalecki's result can be expanded to

$$\pi = I + Df \quad (51.8)$$

if government is introduced ( $Df$  = government deficit), if consumption out of profits ( $C$ ) and savings out of wages ( $s$ ) are allowed, then we have

$$\pi = I + Df + C\pi - sW \quad (51.9)$$

and

$$\pi = I + Df + C\pi - sW + BPS \quad (51.10)$$

if the economy is open ( $BPS$  = balance of payments).

Total profits are the sum of capitalist consumption, investment, public deficit, net external surplus (exports minus imports) minus workers' savings. Today's profits depend on today's investment; they equal investment in a world in which we imagine work-

ers consuming all their wage and capitalists saving all profit. The curve that represents financing with internal funds is a function of realized investments, from which gross profits and so internal resources for further investments depend. At a *micro* level, firms' investments depend on *expected* profits (and on the level of interest rates as well), while at a macro level *realized* profits depend on the overall level of business firms' investments.

Since both investment and positions in capital assets must be financed, as a result financing terms influence prices of capital assets, the effective demand for investment and the supply price of investment outputs [51.16]. Once the determinants of investment are understood, a complete theory of financial instability can be constructed.

### 51.2.2 The Two-Price Model and the Determination of Investment

The two-price model is the analytical tool by which Minsky integrates his theory of money and finance into his theory of investment. From a microeconomic perspective, it is necessary to consider the price of *capital assets* as a key variable for investment. Such price embodies firms' changeable profit expectations, making investment an unsteady component of demand. According to Keynesian theory, the investment is governed by the marginal efficiency of capital, which is the marginal rate of profit expected from investment. The calculation of investment opportunity cost is carried out by comparing the marginal efficiency of capital with the interest rate. The limit of investment corresponds to the point at which, for increasing interest rates, marginal efficiency decreases. The Keynesian approach to investment theory was criticized by Kalecki who pointed out that it only allows us to determine the ex-post level of investment, but says nothing about ex-ante investment choices. In fact, entrepreneurs make their calculations of investment opportunity cost, by taking into account the present prices of capital goods and not the future ones. Investment and ownership of capital assets are indeed undertaken in the expectation that they will produce money. Financial assets (which are commitments to pay cash over some period) have current prices, which are the capitalization of the future cash flows as laid down in contracts [51.16].

The first set of prices is *prices of current output* and includes the price of consumption goods and the price of investment goods. With respect to consumption goods, producers have given short-term expectations about costs and demand. They fix prices to recover direct costs (the main component being, in the aggregate

closed economy, money wages) and to earn a residual: deducting costs, they obtain gross profits. With respect to investment goods, we have the supply price of capital assets ( $p_i$ ) that is determined by adding a mark-up to direct costs of production (a price sufficient to induce a supplier to provide new capital assets). If external (borrowed) funds are involved, then the supply price of capital also includes finance costs (interest rate, fees, etc.), such increase is due to the presence of *lender's risk*. The second set of prices is *prices of capital assets*, which in particular affects the determination of the demand price ( $p_k$ ) of investment goods. Demand price of capital assets (securities)  $p_k$  is the maximum price that the investor is willing to pay. Minsky argued that it is strictly dependent on the amount of borrowings of external funds required: the higher is the weight of external finance, the greater the risk of insolvency for the buyer. That is why a *borrower's risk* has to be incorporated in the demand price for capital assets. The amount of an investment depends on the ratio between the demand price of investment goods and the supply price of new capital goods.

The demand curve of a capital good is positively correlated with the long-term expected profits obtained from it and with the money supply, while is negatively correlated with the debtor's risk (more on debtor and creditor risk later on in this section). The supply curve of a capital good is positively correlated with production costs, with the producer's short-term profits expectations and with the creditor's risk. As we can see in Fig. 51.1, investments increase until  $p_k \geq p_i$ , where  $I = I_1$ .

For each investing unit, and for investment in general, a mix of gross retained earnings and external finance is needed [51.16]. The amount of investment

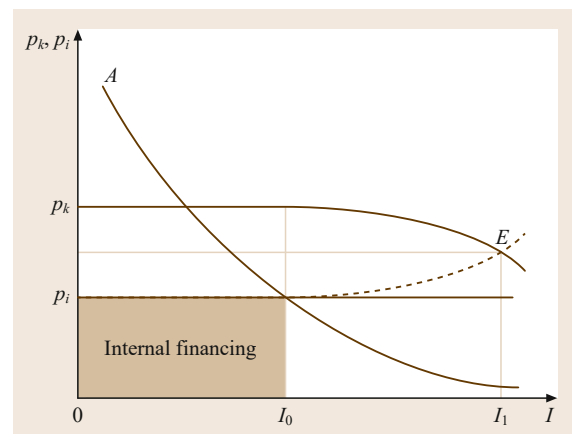

Fig. 51.1 The determination of the (real) investment level in the presence of risks (after [51.20])

**Fig. 51.2** Investment during the boom phase (after [51.20])

(at a micro level) is determined in the way shown in Fig. 51.1, where  $p_k$  and  $p_i$  represent, respectively, the demand price the investor is ready to pay for a certain type of investment good, and the supply price that is the price at which the producer of the investment good offers the latter. The equilateral hyperbola  $A$  represents all possible levels of investments that can be financed given the amount of *internal* funds, for each level of capital goods prices. Self-financing  $= p_i I_0$ . Given the supply unit price of capital goods  $p_i$  and the amount of internal resources for self-financing, beyond  $I = I_0$ , it is necessary to resort to external financing. It follows that, beyond such level  $I_0$  the demand and supply curves shapes modify, because of the rising of the borrower and lender risk (both increasing in  $I$ ).

The *borrower's risk* is the *subjective* risk linked to the possibility that an increase in the amount of financing made by using external funds reduces the safety margin (due to increased illiquidity), thus reducing the investor's portfolio diversification. Therefore, beyond the internal financing threshold, the demand price  $p_k$ , will reduce as investment grows. The *lender's risk*, which is subjective as well, objectifies in the form of interest expenses and increasing burdens. Hence, in the effective capital asset supply price must also include the (increasing) cost of external financing. Kalecki's principle of increasing risk is therefore intrinsically stated in Minsky's analysis. The principle states that, as expected external funds increase, there is an expected increase in the debt–equity ratio, which affects the perceived risk of engaging in an economic activity with external funds. The profit equation and the principle of increasing risk highlight the importance of financial factors in the determination of investment.

The determinants of investment at a micro level are then dependent on:

**Fig. 51.3** Investment during the recession phase (after [51.20])

- The investor's (buyer of capital goods) profit expectations; hence, on quasi-rents, which in turn influence the demand curve for capital goods position.
- The capital goods producer's production costs and mark up, which influence the capital goods supply curve position.
- The borrower and lender's perceived risks, which act respectively on both the demand and supply curves (for  $I > I_0$ ). The greater the borrower's and lender's risks are, the lower is the investment level (*ceteris paribus*).
- The inherited leverage (debt/equity ratio) level from past operations, which influences the availability of self-financing resources.

We can show how both demand and supply curves behave during the economic cycle. During the growth phase, we can observe (Fig. 51.2) an investment boom:

- Optimistic profit expectations and reduced perceived risks cause an increase in the amount of demand for new capital goods, causing the supply curve to shift downward.
- A multiplication of financing activity, a reduction in interest rates and thus an increase in indebtedness.
- A general increase of investments, the beginning of an economic boom.

During the recession phase (Fig. 51.3):

- Profit expectations are pessimist, and perceived risks increase.
- The amount of financing activities reduces and/or interest rates increase.
- Investment level reduces triggering an economic recession.

### 51.3 The Financial Instability Hypothesis Versus the Efficient Markets Hypothesis

The two fundamental propositions of the financial instability hypothesis are the following [51.16]:

1. Capitalist market mechanisms cannot lead to sustained, stable-price, full-employment equilibrium.
2. Serious business cycles are due to the financial attributes that are fundamental to capitalism.

These two propositions are in sharp contrast with the neoclassical theory which holds that unless exogenous forces disturb economy, the system will remain self-sustaining, with stable-prices and full-employment. Minsky criticizes standard economic theory because of its bad performance in explaining reality. According to him, the *crisis* – in economic theory – has two facets: *logical holes* appeared in conventional theory and the impossibility for conventional theory to explain financial crises. The first failure lies in its complete non adherence to empirical evidence. Classical economic theory, which has many variants such as *theory of efficient markets, classical or neoclassical theory, general equilibrium theory, mainstream economic theory* (including old and new Keynesian theory) lies on the mantra that free markets can cure any economic disequilibria that may arise, while government interference has to be considered as a problem. With respect to the second failure, Minsky criticizes the classical efficient market theory that assumes all agents to be able to *know* their future *intertemporal* budget constraints and act accordingly thus avoiding loan defaults, insolvency, and bankruptcy events. According to such a theory, future can be predicted efficiently thanks to the collection and analysis of reliable information on both

the probability of events that have already occurred and the probability of events that will occur in the future. In such a context perfect information is considered to be available to all decision makers. Rational agents are therefore not involved in insolvency problems thus, according to such theories, financial crises are impossible to happen.

In *Minsky's* theoretical framework, agents make arbitrages between the assets (productive and financial) they own on the basis of their future expected rate of return from income and capital gains [51.16]. Their fundamental speculative *decision* is which assets to keep and which to sell, and how to fund their investments [51.12, 16]. Following Keynes, Minsky explains the mechanism through which human beings use *practical equivalents* as a convention which is retained until it confirms reality, but abandoned when evidence becomes different and in contrast with it. Practical equivalents are the process through which (in a situation of uncertainty) a decision is taken making uncertain propositions equivalent to certain ones. These conventions are used ad hoc for practical purposes. Conventions play a central role in Minsky's analysis. In normal times, there is always a *consensus* that exists and stabilizes the decision-making process [51.21]. Hence, in order to make decisions, agents construct mental models of how they think the economic system works and will work in the future. They know that these are representations of reality that do not replicate the *true* model; economic agents thus know that they can be *systematically* wrong. Errors are possible since the future is uncertain.

### 51.4 Irving Fisher's Debt-Deflation Model

This section deals with Irving Fisher's debt-deflation model, its explanation, and application to interpret financial crises and recessions. After the 2007 crash and financial ruin, Fisher's theories have shown to be fundamental in determining the underlying mechanisms of the crisis.

Fisher's theory of *great depressions* is based on the interaction of an initial situation of over-indebtedness which, in conjunction with a dynamic process of deflation, produces a contracting economy. Fisher explicitly ties loose money to over-indebtedness, triggering speculation and asset bubbles. If over-indebted units hit by an exogenous shock start facing problems with debt

commitments, they begin to liquidate debt through distress selling of their assets at decreasing prices.

Fisher outlines the nine factors which interact with each other to create the process of boom to bust for a Great Depression:

1. Debt liquidation leads to distress selling and to
2. Contraction of deposit currency; this contraction of deposits and of their velocity, caused by distress selling, leads to
3. A fall in the level of prices (a swelling of the dollar)
4. A still greater fall in the net worth of business
5. A fall in profits

6. A reduction in output, trade, and employment. These losses, bankruptcies, and unemployment, lead to
7. Hoarding and
8. A further reduction in the velocity of circulation.

The above eight changes cause (9) a fall in the nominal rate of interest and a rise in the real rates of interest. The way out, according to Fisher, is deflation; the lender-of-last-resort function of central banks and government have to support the financial system through stimulating it with fiscal measures.

### 51.4.1 Debt Deflation as a Cycle Theory

During the peak of the Great Depression of 1929, Irving Fisher wrote *The Debt Deflation Theory of Great Depressions* [51.22], following his previous work *Booms and Depressions* [51.23] with the aim of finding an explanation for those years' dramatic events. As depression worsened, in 1932, Fisher became convinced that the crisis could not be simply interpreted as a downturn in the business cycle, however severe, but that was something radically different which needed a new theoretical explanation. In January 1932, therefore, he began to devise a new theory of great depressions, based on the interaction of two most important factors: (i) an initial situation of over-indebtedness; (ii) a dynamic process of deflation. The main point of the theory is that over-indebtedness acts in conjunction with deflation to produce a contracting economy causing bankruptcies, rising unemployment, and falling profits. Irving Fisher was the first economist to emphasize the potential connections between violent financial crises, which lead to *fire sales* of assets and falling asset prices, with general declines in aggregate demand and the price level.

The author starts with investigating the 1929–1932 debt-deflationary situation by listing (in logical order) the nine factors he recognized to be the cause of such trend, describing each one of them. The first main factor, as we just mentioned, is *over-indebtedness*. According to Fisher, debts are an intrinsic feature of a monetary economy and they are essential both for production and distribution processes; over-indebtedness is that degree of indebtedness that “multiplies *unduly* the chances of becoming insolvent” [51.23, p. 9]. It is a matter that affects both singular individuals and whole communities and it means that debts are too high relatively to other economic factors. As lenders and borrowers have become too incautious and, at a point, over-indebtedness is discovered, *distress selling* is likely to arise. The debtor begins to liquidate some of its assets (both tangible and intangible ones optionally) to run after its debt commitments, and/or debtor's

bank or broker cash-in its collateral; hence, the debtor becomes victim of distress selling either on its own initiative and on initiative of its creditors. The process of distress selling perverts the demand and supply equilibrium because in this particular event sales are not made – as Fisher [51.23] points out – in order to attract the highest possible price. Since distress sellers are being forced to sell, they usually do not receive a price as favorable as if they were able to wait for ideal selling conditions; the effect of a whole community involved in distress selling is a reduction in the general price level.

Linked to distress selling and *stampede liquidation* (as he defines the anxious selling of assets to repay debts), Fisher argues that such a situation has a major effect on the volume of currency (deposit currency) in circulation, shrinking it. The author is referring to debts to commercial banks which are paid by checks out of a deposit account, implying the disappearance of that amount of deposit currency. Thus, the reduction of circulating money is tied to debt-volume, especially debts to commercial banks. Such a disturbance passes to prices, with a consequent reduction in the price level (deflation) in other words, a swelling of the currency. This situation can be simply explained as Fisher did in the *The Purchasing Power of Money* [51.24, p. 25]:

“From the mere fact, therefore, that the money spent for goods must equal the quantities of those goods multiplied by their prices, it follows that the level of prices must rise or fall according to changes in the quantity of money, *unless* there are changes in its velocity of circulation or in the quantities of goods exchanged.”

Fisher uses the *equation of exchange* to assume that an increase in the quantity of circulating money has some tendency to raise the price level, and vice versa. In any given year,  $PT = MV$ : the price level multiplied by the yearly volume of trade is equal to the money in circulation multiplied by the number of times it circulates in a year.

Though, if we consider debts in *real* terms, we can realize how each unit of money that has to be paid by the debtor becomes bigger: he receives less money for its liquidating assets while at the same time owning the same amount of money as before on its debts. The acts of liquidation actually enlarge the real value of debts instead of reducing them. Fisher refers to this effect by introducing the third factor, *the price level* (deflation) and by pointing out that both creditors and debtors do suffer from what in literature is called *Money Illusion*, meaning that a few people are able to recognize the real significance of a unit of money by measuring how many goods that a unit can buy – and therefore, understanding

the real value of money and not the mere nominal one. Because of this *misunderstanding* [51.23, p. 18]:

“The creditor is unaware of receiving more than he is properly entitled to, and the debtor is unaware of paying more than he properly owes. One gains and the other suffers [...]”

Fisher argues that the point of the economic cycle at which stampede liquidation starts and a mass payment by the weaker debtors – which in turns produces the swelling of the currency damaging stronger debtors as well as weaker ones – takes place, a vicious spiral begins and a depression is on its way. Once the mass payment begins, each individual is forced to do so: if he stays out, the mass liquidation will swell its whole debt instead of only part of it. The two most important processes of debt-deflation theory are those Fisher calls *The Debt Disease* (over-indebtedness) and *The Dollar Disease* (a swelling currency), while decreased currency volume is just a link between the two [51.22, p. 341]:

“Disturbances in these two factors – debt and the purchasing power of the monetary unit – will set up serious disturbances in all, or nearly all, other economic variables.”

The fourth main factor is *Net Worth*: the fall of prices reduces the value of business assets while liabilities remain fixed, hence net worth value shrinks. The fifth factor is linked to deflation as well, and it is *Profits*. Because of the decreased value of receipts relative to that of expenditures (which we can assume as almost fixed) profits are reduced, and sometimes turned into losses. A depression might be defined as the contraction of net worth and profits. Variation in profits (and/or in profits' expectations) causes the variation in the general strategy of the firm, in particular with respect to current production and investment decisions. The sixth main factor therefore contains the three variables that are consequently affected by a fall in profits, which are *Production, Trade, and Employment* that come out of worsened. All this factors taken together produce a lack of confidence and pessimism (the seventh factor, *Optimism and Pessimism*) that translates into a general rush toward money: phenomena of hoarding thus multiply. The velocity of circulation of money reduces since people are scared and begin to spend less and slowly; thus deflation worsens again and consumption contracts even further (If, e.g., the currency is halved and it now also moves at half velocity than in the past, it will do only a quarter of its former work. Prices and/or trade must contract in the same degree) The effort by each agent to improve his own position leads to a worsening of the overall situation: “Every man who hoards does it

for his own protection; yet by hoarding he aggravates the very condition that started his fear” [51.23, p. 36]. The ninth and last factor is the *Rate of Interest*: since every debt bears interest, we can expect that a *cycle-tendency* in the former will produce a *cycle-tendency* in the latter. The disturbance consists in the fact that during depression nominal interest rates remains relatively low, while real interest rates are actually rising. We know that from the Fisher equation, we have  $i = r + \pi$ , where  $i$  is the nominal interest rate,  $r$  is the real interest rate, and  $\pi$  the inflation level. Since during a depression currency is swelling (deflation), the debt that for instance was contracted last year worthing 100\$, with a nominal interest rate of 5%, today will worth 106 of last year's \$; thus, if  $\pi = -1$ , the real interest rate is not 5, but 6%.

The Debt-Deflation Theory of Great Depressions is the explanation Fisher gives to describe the apparent prevailing boom-bust pattern of the economic cycle. With his *Cycle Theory*, Fisher defines different types of economic cycles and their possible causes. He dismisses the idea of the business cycle as being a single, self-generating one as a myth. In its place he introduces the notion that there are many interacting cycles within the economy, also interacting with noncyclical forces such as growth and chaotic tendencies. He divides cyclical tendencies into two types, forced cycles and free cycles. Forced cycles are imposed onto the economy by outside forces, such as the yearly season cycle, day–night cycle, and monthly and weekly cycles imposed by religion and custom. The free cycle is self-generating and is commonly thought of when referring to the business cycle.

According to Fisher, each case of over-indebtedness has its own *set of starters* that, thanks to their investment decisions, initially triggers a boom economy. Over-indebtedness causes can be various; according to Fisher, the most common one appears to be the presence of new opportunities and/or big profits perspectives, as compared with ordinary actual profits and interest. Investment opportunities can be represented by new inventions, new industries, and development of new resources, opening of new lands or new markets. Easy money is the biggest cause of over-borrowing [51.22, p. 349]:

“The public psychology of going into debt for gain passes through several more or less distinct phases: (a) the lure of big prospective dividends or gains in income in the remote future; (b) the hope of selling at a profit, and realizing a capital gain in the immediate future; (c) the vogue of reckless promotions, taking advantage of the habituation of the public to great expectations; (d) the development of down-

right fraud, imposing on a public which had grown credulous and gullible.”

The psychological factor is a critical one: agents have the perception that a *new era* has begun, and they start to be less cautious and risk-averse. They overlook profits perspectives and over-indebt themselves, thus giving start to the vicious cycle that sooner will trigger a depression.

### 51.4.2 How Debt Deflation Model Fits the Great Depression

According to Fisher, the debt deflation model well suit what happened in the United States and in Europe between 1929 and 1932. The World War propelled a series of inventions – not only destructive ones – and a number of technological improvements (especially in the manufacturing sector) begun to spread up and the American economy faced an investment boom. This situation encouraged many firms to borrow heavily in the expectation of higher profits, including those in the farming sector, stimulated by the sharply rising demand for food. The process that led to over-indebtedness found its *starters* in those investors incentivized by innovations on the expectation of high future profits.

In corporations, the practice of preferring investment in equities rather than bonds became the rule. The Wall Street crash was the detonator, triggering the downward spiral predicted by the debt deflation theory.

With regard to the first factor, over-indebtedness, Fisher was deeply convinced that on the eve of the stock market crash many firms and households were heavily indebted, as well as the government itself. One of the factors behind such enormous amount of debt was certainly the war.

Between 1929 and 1932, mass debt-liquidation took place, decreasing all American debts by 23% – except public debt, which increased. Deposit banks lost 21% of its volume and 61% of its velocity. The commodity price index decreased, losing 38%; industrial stocks lost 77%. In regard to net worth performances, they are best indicated by the number of firms' bankruptcies, around 29 000 in 1931; net profits of 163 industrial and noncorporations became losses. Production, employment, and trade all kept falling. However, with reference to the United States, it is also necessary to consider other aspects. *Booms and Depression* accurately reconstructed the dramatic events of 1929–1932 that had thrown the world into depression: in particular, the link between bank failures in Austria and Germany (United States was the main lender of both countries), the ensuing crisis of pound (motivated by the huge amount of short-term credit granted to these countries

by the British monetary authorities) and the simultaneous speculative attack on American gold reserves. This in particular, as Fisher wrote, demoralized the US banking community, spread hoarding and prompted bank runs.

### 51.4.3 How Debt-Deflation Model Fits Current Economic Conditions

Although inflation has been the norm during the latter half of the twentieth century, there were long periods in the history of the United States during which prices actually fell. In 1836, the money supply contracted by at least 30% pushing prices down. Between 1875 and 1896, prices fell in the United States by 1.7% per year. Between 1930 and 1933, prices fell almost 10% per year. In 2008–2009, the United States experienced the first deflation since the 1950s. In 2009, the Fed has *doubled* the money supply in less than a year and lowered interest rates to almost zero in order to fight deflation. Deflation's threats are several, in particular the possibility for nominal interest rates to reach very low levels thus increasing real interest rates. Moreover, if nominal rates reach the zero level, central bank monetary policies will be ineffective and economy could be stuck into the so-called *liquidity trap*. The liquidity trap is defined as a situation in which the short-term nominal interest rate is zero. In this case, many argue, increasing money in circulation has no effect on either output or prices. The liquidity trap was originally a Keynesian idea and contrasts with the *quantity theory of money*, that expects prices and output to be, roughly speaking, proportional to money supply. According to Keynesian theory, money supply has its effects on prices and output through the nominal interest rate. Increasing money supply reduces the interest rate through a money demand equation, while lower interest rates stimulate output and spending. The short-term nominal interest rate, however, cannot be less than zero, based on a basic arbitrage argument: no one will lend 100 dollars unless he/she gets at least 100 dollars back. This is often referred to as the *zero bound* on the short-term nominal interest rate. Hence, the Keynesian argument goes, once the money supply has been increased to a level where the short-term interest rate is zero, there will be no further effect on either output or prices, no matter by how much the money supply has been increased. The ideas which underlie the liquidity trap were conceived during the Great Depression, when the short-term nominal interest rate were close to zero. At the beginning of 1933, for example, the short-term nominal interest rate in the United States – as measured by three-month Treasuries – was only 0.05%. Sixty decades later another example is that of Japan where

**Fig. 51.4** US 12-month percent change in CPI for All Urban Consumers (CPI-U), not seasonally adjusted, Jan 2013–Jan 2014. Source: Bureau of Labor Statistics. **Fig. 51.5** Inflation (%) – EU and Advanced Economies. Source: International Monetary Fund, April 2011 World Economic Outlook

the short-term nominal interest rate collapsed to zero in the second half of the 1990s: the Bank of Japan more than doubled the monetary base through traditional and nontraditional measures to increase prices and stimulate demand.

Once the economy moves toward a deflationary situation, it shifts from a relatively short-lived recession to a much more serious and persistent depression. The perspective of future lower prices damages investment by decreasing them, lowers demand, and raises unemployment immediately causing a mass transfer of wealth from debtors to creditors. Usually, such wealth redistribution has no first-order impact on the economy. However, in the face of large shocks, deflation in the prices of assets leads to a decline in the nominal value of assets on banks' balance sheets. For a given value of banks' liabilities, also denominated in nominal terms, this deterioration in banks' assets threatens insolvency. As banks reallocate assets away from loans to safer government securities, some borrowers, particularly small ones, are unable to obtain funds, often at any price. Furthermore, if bank portfolio reallocation is long-lived,

the shortage of credit for these borrowers helps explain the persistence of the downturn. As the disappearance of bank financing forces lower expenditure plans, aggregate demand declines and contributes again to the downward deflationary spiral.

In order to apply the debt deflation theory for an understanding of twentieth and twenty-first century's financial crises, we must first expand it to an *open economy setting*. The international contest characterizing our age is different from 1930s' one when capital movements were small; globalization patterns are the crucial feature of these era where financial deregulation (the so-called Washington consensus) had led to high levels of indebtedness, especially in the South East Asia. Risky-kind of debts, allowed throughout complex financial transactions related to securitized debt obligations as well as to derivatives financial contracts, and in general the boom of financial innovations (leading to decreases in capital goods prices) are typical causes propelling units to further indebted themselves. The financial system results in a complex structure bearing more and more risk: when over-indebtedness is reached, a pro-cyclical boom spiral begins. As a consequence of excessive *financialization* and *deregulation*, the Washington consensus as a matter of fact increased the possibility of a rising endogenous excessive indebtedness, thus causing (as in Fisher's theory) debt deflationary processes [51.25], asset devaluation, and recession.

It could seem that the current financial crisis, since 2007, is evidence against Fisher's theory since it did not imply a significant deflation in consumer prices. The US consumer price index fell 2.1% in the year ending in July 2009 (Fig. 51.4), but it was an isolated event, caused substantially by a sudden and catastrophic drop in commodity prices. Still, the rate of annual inflation measured by the consumer price index did fall from the 3.4% average for the four years between September 2004, until the Lehman crisis in September 2008

down to 0.7% for the two years from October 2008 to October 2010. If people expected the 2004–2008 rate of inflation to continue, then the decline of nearly three percentage points in inflation for last two years has already, as of this date, magnified the real value of debts by over 5%. Moreover, if the low inflation is widely expected to continue for a while, it will lower long-term bond yields, amplifying the real value of debts relative to precrisis expectations by even more. Declining long-term bond yields push up the real value of long-term debts immediately, even more than the immediate decline in prices affects the real value of money today. The effects on balance sheets are of course disruptive to business, to confidence, and thus to the aggregate economy.

From Figs. 51.5–51.7, we can observe the inflation trends in Japan, United States, and the European Union (this latter compared in the same figure with those of Advance Economies) starting from 1980 to 2016 (data contain projections). In all cases, the inflation rate calculated using the Current Consumer Price Index shows its declining performance, reaching the lowest level in 2008 corresponding to the financial crisis.

That is probably enough to give substantial support to Fisher’s debt-deflation theory in the current era. It is particularly notable that in the recent crisis there has been a mortgage refinancing boom. The otherwise large effect of inflation was, in a sense, reduced because many mortgage holders exercised the call option to move to a lower interest-rate mortgage. Anyway relying on call provisions clearly is not the key to solve instability of purchasing power. Because they are one-sided, that is, they protect borrowers against the risk of declining inflation, but do not protect lenders against

Fig. 51.6 Inflation (%) – US Source: International Monetary Fund, April 2011 World Economic Outlook

the risk of increasing inflation, they have the effect of increasing the cost of borrowing.

## 51.5 Policy Implications and the Shareholder Maximization Value Model

### 51.5.1 Stability is Destabilizing

The central idea in Minsky’s financial instability hypothesis is that a solid economic system can transform itself into a fragile and unstable one due to endogenous changes in cash flows [51.13, p. 12]:

“The financial instability hypothesis states that tranquil growth and prosperity in modern capitalist economies naturally bring about changes in cash-flow interconnections leading from solidity to fragility, and that the normal functioning of the economy may easily convert fragility into open financial crisis.”

Minsky’s financial instability hypothesis incorporates the concept that *stability is destabilizing*: it is during tranquil growth periods that conditions for an economic crisis are laid down. When the economy is basically constituted of hedge financing positions and there are good safety margins about future positive profits, a financial crisis can happen only because of an unexpected drop in incomes. At the contrary, an economic system increasingly based on speculative units is going to be *intrinsically* much exposed to financial crises since even small financial markets fluctuations will have great rebounds on real variables. In particular, an increase in interest rates can cause:

- The impossibility of refinancing for speculative units that must sell their assets
- A drop in prices, income, and expected and realized cash flows of each unit
- An overall increase in the level of indebtedness.

We can start by analyzing the process through which an economic system switches from stable to unstable by imagining a financially robust economy, where almost every agent is in a hedge-financing position. The economy experienced cycles (including recession phases) in the past, but is now in tranquil prosperity. Agents remember past crises: they maintain, therefore, ample margins of safety in their liability structures, and balance sheets are awash with cash and very liquid assets. As long as the economic development goes on without shocks, optimistic forecasts are validated. Banks and firms expect large positive future quasi-rents, and bet on an upward trend in the value of real and financial assets. As growth goes on, optimism propagates and firms have the opportunity to rise their debt–equity ratio associated both with higher short-term financing of fixed capital and long-term financial assets. Banks, that are profit seeking units, have interest in allowing firms’ requests for funds, thus they also start using innovative financial instruments to increase credit availability. The improvement of expectations, the reduction for liquidity preference and of safety margins, and the expansion of quasi-money (financial innovations) cause an increase in capital assets demand and prices. Such a context is the midst of an investment boom which, in turn, drives production and sustains profits (note that these latter are an important factor for lenders’ decision making). Optimism propagates and indebtedness increases again. The presence of low interest rates make financial leveraging affordable, and raises the conditions of fragility of the whole system. Nonetheless until euphoric expectations are realized, there is no way to stop financial fragility growth. With the emergence of a state of *euphoria*, speculation has two main aspects: (1) owners of capital assets speculate by financing with external funds ownership of investment goods and securities; (2) families and firms speculate on financial activities they own and on the way they can finance ownership of such activities [51.12]. In particular, speculative positions of families, firms, and banks are characterized by a high ratio between financial commitments and income. The intrinsic presence of a temporal shift in the financing process becomes crucial when units understand that they overvalued their expectations and that they now have to face a liquidity problem linked to high debt payment commitments. Units are thus forced to refinance. This process sooner or later will make interest rates to grow (banks are

indebted as well), reducing the actual value of investments: it translates into a reduction of safety margins. We shall recall that banks have long-term activities, due to the financing of investments, while they have short-term liabilities. With an increasing number of loans during the boom phase, this temporal structure can determine a condition where cash COF are not covered by CIF in each period. Banks are forced to increase interest rates in order to face increased liabilities. This is the upper turning point of the cycle. In order to avoid bankruptcy, indebted units sell their activities at declining prices (triggering debt-deflation), with a debt revaluation in real terms, and a loss of liquidity. It follows a drop of investments, demand, and profits, that are dragged down by pessimistic expectations.

In the course of an economic crisis, speculative activities that were undertaken during the boom period are the first to collapse; moreover, these will also have rebounds on hedge activities because of the so-called *interconnections of budgets*, that is, our financial system is a stratified one, where one unit’s debts reflect into another’s credits. The number of bankruptcies – households’ insolvency included – increases, and assets price deflation prolongs as far as Ponzi and the most of speculative units exit the market. In this phase, liquidity preference reaches its maximum level, investments activity almost stops; income, profits, and assets value drop, while unemployment raises. The only positive aspect of a financial crisis is that, according to Minsky, it lowers the financial fragility of the system, which is a necessary endogenous condition for the following economic recovery.

To sum up, Minsky argues that our economy is unstable because of capitalist finance. In particular, if a mixture of hedge, speculative and Ponzi positions, and of internal and external financing can rule innocuously for a while, but, at some stage – encouraged by a period of economic boom and widespread euphoria – they will breed endogenous incentives for units to change the mix, shifting toward riskier financial positions and more external financing. It follows an investment boom phase where debt–equity ratios raise and margins of safety erode. The severity of the subsequent financial crisis (and recession scenario) will depend on the relative size of government intervention and on the breadth of the central bank’s *lender-of-last-resort* action.

### 51.5.2 From the Debt Deflation Model to Policy Proposals

*Fisher* argued that one of the causes of the collapse of US economy in 1929 (and subsequent depression that lasted until 1933) was the choice by the Federal Reserve to abandon the stabilization policy that had been

pursued during the twenties by Benjamin Strong, Governor of the Federal Reserve, who died in 1928. *Fisher* was convinced that it is always economically possible to stop or prevent long depressions simply through *reflation* [51.26], in other words, pursuing a monetary expansion to bring prices back up to their pre-29 levels at which debts were contracted. An essential point in Fisher's plan was the belief that pursuing an increase in demand, even if necessary, was inevitably only a first step. To get out of a depression, a substantial rise in prices was needed. A second point is the transmission mechanism which explains how an expansionary monetary policy can induce an increase in output and prices. An increase in the means of payment available to agents produces an increase in aggregate demand, which in turn boosts prices. As already mentioned, during a serious depression, agents tend to hoard their own liquid assets, thus it may be argued that a greater supply of liquidity could have no real effect. But Fisher was aware of this point. In the second half of 1932, the worst period of the Depression, he became a supporter of a plan for *stamped money*. Stamped money was a promise of payment issued by a public body or municipality, usually with the guarantee of a bank, which circulated as a banknote but that, within a given period of time, could be taken out of circulation and converted into legal tender. Its peculiarity was that it was subject to a periodic *tax* (for example two cents per dollar per week) in the form of a stamp that had to be affixed on the back of the note. This made the plan a self-liquidating operation at no cost to the finances of the authority that issued the notes. The notes were obviously characterized by an high velocity of circulation, as every agent had an evident interest in spending the scrip quickly so as to avoid the tax [51.22].

### 51.5.3 Financialization, Neoliberalization, and the 2008 Crisis

The so-called *subprime crisis* has been the peak of a decade of a housing boom in the US economy, stimulated by a number of regulatory changes of the financial system which gradually moved it toward conditions of fragility. The subprime crisis can be thus interpreted as a so-called *Minsky moment* which soon transformed into a so-called *Minsky meltdown*; excessive financialization and deregulation led to over-indebtedness, debt-deflation, asset devaluation, and recession. A *Minsky meltdown* is when financial instability becomes so acute that only an immediate, global, and massive government intervention can avoid a systemic banking failure. A *Minsky meltdown* thus starts when the *Minsky moment* is so intense to trigger a recession.

The world that emerged after the Great Depression was characterized by low private debts, high govern-

ment debt (war finance), and a lean financial system. Such features boosted rapid economic growth, corporations mostly used retained profits to finance expenditures, finance was kept small, regulated, and relatively irrelevant, risky financial practices were outside commercial banking. Over time a process of *neoliberalization* (see next section) changed all those regulations which were relaxed or defeated by financial institution through innovations. Private debt grew, and risky practices emerged. The weight of finance moved away from institutions toward markets – the so-called *originate to distribute* model. Weakened labor through part-time practices and lower remuneration was emerging (often under the label of labor *flexibilization*. *Money manager capitalism* and practices such as securitization were born and spread over.

#### Neoliberalization

In the 1980s, the President of the United States, Ronald Reagan and the Prime Minister of the United Kingdom Margaret Thatcher were pushing the free-market doctrine across the world to make privatization and deregulation policies politically viable out of their countries. Deregulation of the banking system spread from the United States to Europe to many developed countries and to the emerging economies of the Asian *tigers*, Russia, and Thailand.

Neoliberalism started as an intellectual movement in the 1980s and then transformed in the so-called *Washington Consensus* in the 1990s. The ideological roots of neoliberalism can be traced to the liberal theory of self-regulating markets developed during the belle époque and later, thanks to the contributions of Friedman and Hayek. The term *Washington Consensus* is used to describe the policy prescriptions given by the economist John Williamson as a baseline of directions for nations in need of assistance from international economic entities such as the World Bank and the International Monetary Fund. The *Washington Consensus* was originally laid out in 1989, and refers to all the most evident neoliberal policies: free trade, flexible labor, active individualism, anti-statism, and the cutting of institutional welfare policies, in particular after-war Keynesian ones. Neoliberalism is thus a set of political beliefs which firstly include the belief that the only legitimate intervention of the state in economic life is that of safeguarding individual, especially commercial, freedom as well as private property rights.

During the Thatcher and Reagan governments, the IMF was supporting worldwide liberalization of capital movements; in 1997 a global agreement on financial services was made with the supervision of the World Trade Organization [51.27].

Through a process of *neoliberalization* US banks were experiencing deregulation and were increasingly investing in foreign-exchange trading, expanding geographically as well as widening their range of services. With the concept of neoliberalization, we refer to the processes of regulatory restructuring under post-1970s and post-2008 capitalism. As argued by *Peck et al.* [51.28], such a process implies: commoditization, movement of huge amounts of capital and speculative (innovative) financial tools throughout the world in search of profit opportunities, privatization, deregulation, and trade liberalization.

Since the 1970s, a new kind of global economy has started to shape. Restrictions on capital have been progressively reduced, free currency exchange, free world trade, and free capital circulation were intensifying. At the same time, extensive privatization was taking place, while a process of weakening of the negotiation power of labor, and its flexibilization through part-time and lower remuneration was emerging. Such a set of policies, summed up with an aggressive dismantling of the welfare state, has produced a declining share in both real wages and investment, and thus slower growth of effective demand. In particular with respect to the US case, Reagan increased government military expenditures, which resulted the only demand component with a positive tendency and the public deficit was worsened by tax reductions.

In such a sociopolitical context, finance appeared to be increasingly valuable. It is however only during the 1990s that a complete picture of the new economy was clear; labor is progressively subdued to finance, consumers are increasingly over-indebted and class power is gradually restored. Federal Reserve's Chairman Greenspan was the promoter of a number of financial deregulatory measures. More importantly his monetary policy goals have shown to be significantly different from those of the post-WWII era, which were focused on full employment and rising real wages. Greenspan's policies gave prominence to fight inflation rather than unemployment, thus rising wages were brought down since considered inflationary; but as *Palley* [51.29] argues, the same logic was not applied to raising profits (in accordance with the Chicago School theories). Under Reagan the conjunction of restrictive monetary policies and expansive fiscal policies, the differential in the level of interest rates in favor of the United States led to capital inflows and to a revaluation of the US dollar.

### Money Manager Capitalism

*Minsky's* work on structural economic change [51.16] and on the financial instability hypothesis is not only useful for explaining the economic changes of the pe-

riod between 1945 and 1966, but it catches a broader historical analysis to help interpret the subsequent developments of the capitalistic system and the evolution of the financial structure. *Minsky* [51.30] argues that capitalist economies undergo various stages of development. During expansionary periods, financial innovations prosper, in turn relaxing financing constraints, and leading to increased investments. This implies an increasing reliance on outside sources of funding and debt leveraging that, in turn, boosts investment, aggregate demand, and profits. *Minsky* believes that capitalist economies which own such a structure – based on reinforcing expectations and on the possibility of increasing financial innovations – are intrinsically prone to boom and bust cycles. Indeed, when an endogenous shock causes a shift in entrepreneurial prospects, investment will drop bringing down aggregate demand and profit too. A wave of risk aversion and desire of liquidate debts leads to bankruptcies and debt-deflation progresses – unless the Big Government and the Big Bank intervene.

The evolution of the US financial industry in the post-WWII period shows the emergence of various innovative instruments and institutions. Especially during the inflationary period of the 1970s, the differential between securities and mutual funds yields and those of insured deposit institutions was increasing, thus leading to new profit opportunities and the birth of money market funds. *Minsky* [51.31, p. 12] defined the five stages of capitalistic development in the United States,

“(i) commercial capitalism, (ii) industrial capitalism and wild-cat financing, (iii) financial capitalism and state financing, (iv) paternalistic, managerial and welfare state capitalism, and (v) money manager capitalism.”

We focus on the transformation from what *Minsky* calls managerial capitalism – shaped by the experiences of the Great Depression and World War II – to the current system of managed-money capitalism (which he believed had emerged by the early 1980s).

During the period of managerial capitalism (the post-war period) the financial structure was conservative, with low debt levels and contained speculation; firms owned most of their net positions in governmental debt. Macroeconomic conditions were generally stable and the accumulation of wealth was possible, as well as distributed equally. But it is during such conditions that money manager capitalism is born, especially because of the shared confidence in profitable future. During the 1970s inflation, financial and technological innovation led funds to flow from bank deposit accounts to mutual funds and securities. Money manager capital-

ism is defined as one dominated by highly leveraged funds (in particular pension and mutual funds) searching for the maximum return within an environment made of little regulation or supervision of financial institutions and underestimation of risk. Money managers mix nontransparent and intricate instruments that have the quality to quickly spread throughout the world. Market stimulates managers to bear high risk by giving them greater remunerations.

Managed-money capitalism is part of the trend toward an increase in the proportion of financing that takes place through markets rather than intermediaries [51.30, p. 70].

Securitization of home mortgages began in the early 1980s. As Minsky saw it emerging, he understood the risks it would imply, and in 1987 he wrote a Policy Note telling that such an instrument was the result of the increased importance of money manager capitalism (the market) and the decline of banks (commercial banks).

#### Financialization: A Finance-Led Economy

From the mid-1980s, the growth of financial sector indebtedness has been huge: from one-fifth of GDP to 120% of GDP [51.32], especially because of the growing securitization process and the issue of increasingly volatile products into portfolios to fund positions in securities. As we mentioned in the previous paragraph, the relative stability of the post-war period led to the increase of financial innovations, easy credit availability, higher competition, and leverage ratios. Thanks to such easy credit, asset prices started rising, prompting other financial innovations and raising leverage ratios again. This in turn caused loans to expand, especially those for home buying, thus raising real estate values, expanding loans even further and increasing leverage ratios in an attempt to cover the raised value of real estate. This structure can be considered a Minskyan's Ponzi position.

The wave of financialization after the 1980s has been huge. With the term financialization [51.29], we refer to the process through which financial markets, financial institutions, and financial actors (élites) acquire importance and are able to seriously influence economic policies as well as economic outcomes. The relationship between financialization and neoliberalism is strong: neoliberalism and its counterpart in globalization are heavily sustained by an extraordinary expansion and promotion of financial activity. Those who support financial deregulation improvement have argued that financialization provides superior risk-management [51.33, p. 6]:

“for example, securitization was supposed to slice risk into different parts (by means of different se-

curities) and allocate it to those who were best equipped to hold it”

in a sense thus increasing the stability of the entire system. At the opposite, it could be argued that since the beginning of the financialization era, a series of major crises (such as the debt crisis in 1982, the Savings & Loans crisis in the USA in the 1980s, the Peso crisis in 1994, the 1998 Asian Crisis, the Dot.com bubble in 2000, and lastly the current global financial crisis, started in 2007) have showed this assumption to be unsustainable.

During the post-1980s era, financial markets greatly expanded and put increased pressure on nonfinancial corporations (NFCs) to generate increasing earnings and distribute them to financial markets. Firms that failed to meet financial markets' expectations faced fall in stock prices and threats of hostile takeovers. Such environment produced what Crotty calls the *neoliberal paradox* [51.34]. Unable to increase their profits due to adverse conditions in the product markets, firms were forced to pay an increasing share of their internal funds to financial markets.

Financialization gave birth to two new models of growth. The Anglosaxon growth model, based on consumption (consumption-led growth model), and the German, Japanese, and Chinese model, based on export (export-led growth model). The two models rely on each other. The Anglosaxon countries developed a credit-financed consumption as the most dynamic component of demand growth and a current account deficit and capital inflows, while in the other group of countries consumption remained low, but demand growth was fuelled by very high exports. The US, the UK, Ireland, and Greece ran large current account deficits, whereas Germany, Japan, and China had large surpluses. International imbalances have played a major role in the debate on the causes of the 2008/2009 crisis. As argued by *Stockhammer* [51.33], financial globalization and liberalization led to exchange rate crises. Exchange rates changes are determined by capital flows an amount of capital inflows can reverse because of a sudden shock and thus rapid withdrawal. This can lead to exchange rate crises which are furthermore made possible because of the widespread practice of the currency-carry trade in international markets. By implication, assets and liabilities will then be denominated in different currencies; thus abrupt exchange rate realignments may have disastrous effects on firms' or banks' balance sheets. Exchange rate crises have been a common feature of emerging economies, such as for Mexico in 1994, and in the case of South East Asian crisis of 1997–1998 and Argentina in 2001. Exchange rates crises all have led to long-lasting recessions.

Second, capital flows liberalization has allowed some countries to run current account deficits (much more than during the Bretton Woods agreement period). Because the balance of payment is composed of the current account and the capital account, a deficit in the current account can be balanced by net capital inflows allowing countries to run current account deficits and balancing them by attracting capital inflows.

Financialization has profound effects on income distribution. The dominance of capital against labor has been one of the results of the neoliberal break-up of labor stability. For instance, in the US, Europe, and Japan, wages are stagnating since the 1980s. Wages stagnation has been spurred by increasing income inequality, the rise of the so-called *rentiers income* and the growth in the financial sector especially in the form of bonuses.

With respect to the economic environment we have just described, the mainstream corporate governance doctrine spreading from the Anglo Saxon countries to Europe and to the Emerging Markets has been the *shareholders value maximization theory*. This conception argues that since the firm belongs to stockholders, managers should run it in order to maximize shareholders value. Such a process leads to increases in dividend disbursements and share buybacks. At the same time management remunerations are increasingly linked to profit and stock market value, which in turn increases managers' incentives to keep stock prices on a high level. It has been argued [51.35] that one of the main causes of US growing inequity is the stock-based compensation of the executives. The key management change has been from a *retain and invest* strategy to a *downsize and distribute* one (on organizational restructuring see [51.36]). Shareholder maximization value practices were born in the United States in the 1980s, then spread to UK and to continental Europe as well. In the 1990s, both Germany and Japan leading executives were calling for the adoption of more American-style corporate practices, in order to compete in increasingly globalized capital markets. Convergence hypothesis theories highlight the role of global capital flows in eliminating inefficient forms of governance, since the early 2000s OECD and World Bank were busting the adoption of common standards.

Neoclassical shareholder theory defines shareholders as the only *residual claimants* of a firm, they bear

the risk of business success/failure and the return/loss they get is what has left after other stakeholders have been paid. Furthermore, they are the only stakeholders which have an incentive in investing productive resources [51.37]. The problem with the concept just described is that it does not consider workers as residual claimants as well. *Freeman and Evan* [51.38] and *Blair* [51.39] argue that workers do own like shareholders the status of residual claimants because they invest in firm-specific human capital with the expectation of having returns from such investment during their future career. They do bear risk as well, because they would suffer in case of lack of inter-firm labor mobility. This vision is much more related to the *stakeholder theory* [51.40]: managers should take decisions so as to take account of all stakeholders of a firm (not only financial claimants, but also employees, customer, communities, etc.). *Evan and Freeman* [51.41, pp. 102–103], asserted that “management has a duty of safeguarding the welfare of the abstract entity that is the corporation” and of balancing the conflicting claims of multiple stakeholders to achieve this goal. They further argued [51.41, pp. 102–103]:

“A stakeholder theory of the firm must redefine the purpose of the firm. [...] The very purpose of the firm is, in our view, to serve as a vehicle for coordinating stakeholder interests.”

The shareholder value orientation leads to increases in dividend disbursements and share buybacks, since management remunerations are increasingly linked to profit and stock market value which increases managers' incentives to keep stock prices on a high level.

With respect to the role of the state in the economy, from the 1980s onward, it was a priority of neo-liberals to downsize its presence in the economy. *Stockhammer* [51.33] shows that the state share, as measured by the size of state employment and transfers, has not been reduced in most OECD countries (except for Ireland, United Kingdom, and Netherlands); at least there has not been a growth in the share of state intervention, but the level has remained as its 1970s level. Nonetheless privatizations and deregulations have in practice reduced the influence of the state into the economy.

## 51.6 Integrating the Minskyian Model with New Marxists and Social Structure of Accumulation (SSA) Theories

Since the summer of 2007 to the spring of 2008 the Global Financial Crisis has been spreading throughout the world. Furthermore, since late 2009 fears of sovereign debt crises in the euro zone including Greece, Ireland, Spain, and Portugal arose. In the European Union, especially in countries where sovereign debts have increased sharply due to bank bailouts, bond yield spreads widened and risk insurance on credit default swaps between these countries and other EU members, most importantly Germany, grew.

I hereby argue that Minsky's financial instability hypothesis needs to be combined with the sociopolitical scenario (i. e., a *neoliberalized* and *financialized* economy) described in the earlier sections. I indeed agree with the structural Keynesian synthesis [51.29, 42] of the new Marxists view [51.43] and of the social structure of accumulation SSA theory [51.44]. In interpreting the crisis, a common aspect stressed by these theories is the acknowledgment on the critical role played by the neoliberal model and its adoption by many advanced economies in the 1980s. These approaches indeed believe that the crisis has its roots in the real economy; this could seem at first in contrast with the pure Minskyan explanation of crises as endogenous financial system processes of excessive optimism and indebtedness. Nonetheless it will help us to generate a more extensive comprehension of the subject of our work.

Both New Marxists and SSA theorists adopt an *under-consumptionist* position according to which the economy cannot reach full employment because of the lack of demand caused by an excessive wage squeeze. The new Marxists use a monopoly capital mode of analysis to explain the crisis, arguing that it is the result of the three decades of wage stagnation and widening income inequality caused by the contradictions inherent in the neoliberal model of growth. In this perspective Karl Marx was the first to argue that capitalism produces recurring and increasingly dangerous crises because of its inherent feature to direct large amounts of wealth toward a few pockets of wealthy elites, leaving a growing number of people without the possibility of affording to buy goods and services produced by firms. It follows the emergence of an *industrial reserve army* of poor and unemployed, and a contracting economy. The new Marxist (e.g., [51.45]) theory – as well as that of Marx, Minsky, and Fisher – stresses the role of accumulation of private debt as a means of sustaining the cycle. However, the new Marxist framework does not incorporate the mechanisms of Minsky's financial in-

stability hypothesis, even if the role of debt as a means of sustaining the cycle is a common feature.

The SSA theory focuses on the problem of neoliberal wage-squeeze and exploitation, interpreting stagnation as a purely real phenomenon caused by a lack of aggregate demand caused by a worsened income distribution. Such an approach does not by the way incorporate the financial instability hypothesis as well.

On the other hand the third approach, the structural Keynesianism, developed by *Palley* [51.29, 42], offers a synthesis of the two points of view. First, it shares the Marxist perspective that there is a real economy problem regarding a wage squeeze and an unequal income distribution, which ultimately gives rise to a Keynesian lack of aggregate demand. Second, structural Keynesianism recognizes that finance plays a critical role in fuelling asset price bubbles and over-indebtedness which sustains the lack of demand caused by the wage squeeze. Then it adds two other remarks:

- By assuming that financial innovation and deregulation are the sources to fuel demand, it is possible to incorporate Minsky's financial instability hypothesis into the structural Keynesian approach.
- It takes into consideration the US model of global economic engagement in causing the crisis, that spreads throughout the world by means of three channels: leakage of spending on imports, off-shoring of jobs, and off-shoring of new investment.

As mentioned, the processes identified in Minsky's financial instability hypothesis play a critical role in the actual crisis, but we must consider a larger economic scenario involving the neoliberal growth model implemented around the 1980s. Thus integrating the structural Keynesian approach into the Minskyan one, financial markets have been the means through which the neoliberal model of growth could regenerate and sustain demand escaping its *stagnationist* tendency. This explains why the crisis took the form of a financial crisis; financial markets have been *the place where to sustain and generate demand* in order to counteract the wage squeeze. Economic policy deteriorated the workers position and neoliberalism used financial innovation to sustain increasing lacks of demand.

Minsky's financial instability hypothesis explains how the neoliberal *growth* model avoided stagnation for so long and could reproduce through over-indebtedness and leverage (produced in financial markets) instead of wage growth, leading to the crash identified by Minsky.

With respect to structural Keynesianism, new Marxists and SSA conclusions about the *cure* for the crisis, they show differences only in terms of degree of optimism. They all endorse the belief that monetary and fiscal policies are not sufficient to restore full employment: they identify the need to reverse neoliberalism and restore the link between wages and productivity

growth. Structural Keynesians believe it is possible to manage appropriate institutions that, combined with traditional Keynesian policies, can produce full employment and shared prosperity. New Marxists and SSA theorists are more pessimistic and they see an institutional design with a larger public sector and more nationalization, especially regarding the financial sector.

## 51.7 Risk and Uncertainty

In the previous section, we have been dealing with a few macroeconomics theories of investment and financial markets. In the theoretical frameworks described, the concepts of risk and uncertainty have from time to time emerged. We have for instance mentioned the issue of lender's and borrower's risks in the Minskyian model for investments, as well as the role of risk and uncertainty in investment decisions (e.g., the determination of the (real) investment level in the presence of risks). As mentioned, according to Keynes, investors' speculative decisions about what assets to retain and what to sell is based on a mechanism through which human beings use *practical equivalents* as a convention which is retained until it confirms reality, but abandoned when evidence becomes different and in contrast with it.

This example about agents modelling for investment in the presence of uncertainty, and the use of practical equivalents as a mechanism to make decisions, is one of the various models advanced in the economic theory – as well as in business studies – to introduce uncertainty in economics agents decision-making processes.

### 51.7.1 Models of Risk and Uncertainty in Economics and Business Studies

The topic of uncertainty is prominent in the twentieth century's economic discourse, starting with the marginalist revolution of Carl Menger, the Austrian School, and then thanks to the seminal contributions by John Maynard Keynes and Frank Hyneman Knight. Standard neo-classical economics assumes that actors have complete knowledge of means-end relationships and they maximize their utility on the basis of a given set of knowledge, technology, and preference ordering. The notion of complete knowledge allows for the functioning of markets according to the neoclassical model and for the development of Pareto optimal equilibria. Much of twentieth-century economics, especially General Equilibrium Analysis, deals with the mathematical formulation of the functioning of the economic system under conditions of *perfect knowledge*, and *perfect rationality*. The notion of *incomplete knowledge* can

be traced back to the *marginalist revolution*, with Carl Menger, and the Austrian School of Economics.

The Austrian School looks at the human limits in cognitive capacity as the crucial source of uncertainty in the production process [51.46]. Furthermore, it sees uncertainty in terms of limited knowledge of future outcomes, and uses such an assumption to assert that rational state-planned production activities are not conceivable. Only recently, attention has been devoted to the analysis of imperfect markets, as a result of incomplete information [51.47].

One of the most important contributions to the conceptualization of uncertainty in Economics is the seminal work by Knight titled *Risk, Uncertainty, and Profit* [51.48]. The author argues that agents are not able to produce optimal forecasts of all future states; therefore, in a dynamic economy, they cannot make decisions leading to equilibria outcomes. According to Knight, disequilibria are caused by uncertainty because omniscience is not possible. Uncertainty undermines perfect information and therefore the ability to predict the *distribution probability of future instances* (i. e., it is difficult for the decision maker to predict the probability whereby future outcomes will arise). In the Knightian acceptance of uncertainty, not only it is difficult to estimate the frequency distribution of future possible outcomes, but often it is even hard to classify events themselves. Neither they can be grouped on the basis of features of similarity, nor it is helpful to make reference to the past (e.g., a series of historical data) because some events are, just, not knowable. In all these cases, decision makers face a situation pervaded by *uncertainty*. Instead, in those cases when (i) either the distribution of the outcomes can be drawn in advance or (ii) it can be induced by looking at historical data (using this criterion to group instances) – decision-makers face a situation of risk (Sect. 51.7.1).

*Risk, Uncertainty, and Profit* has been the object of several interpretations by the literature. For instance, LeRoy and Singell [51.49] have interpreted Knightian uncertainty in light of the *agency theory* [51.50], stating that in some situations insurance markets can operate

thanks to the possibility to calculate and reduce *risk*, while in other situations they would collapse because of moral hazard and adverse selection (i. e., because of conditions of uncertainty). Also, *Langlois* and *Cosgel* [51.51, p. 457] interpret Knight's characterization of the firm as

“the system under which the confident and venture-some ‘assume the risk’ or ‘insure’ the doubtful and timid by guaranteeing the latter a specified income in return for an assignment of the actual results”

stressing the different risk aversion faced by the entrepreneur and the worker.

The entrepreneurship literature has argued that business decisions often deal with unique situations where objective probabilities or chance are immeasurable, and that entrepreneurial action is affected by uncertainty and ultimately involves strategies to cope with it [51.52, 53]. According to classical theories of entrepreneurship (e.g., [51.48, 52, 54]), entrepreneurial behavior is the fundamental engine that influences the environment through innovation. Schumpeter argues that the willingness to bear uncertainty is intrinsic to entrepreneurial activity and is given by the innovative act of creating new combinations. According to the Schumpeterian view, the role of entrepreneurial action in coping with uncertainty determines the success of the firm.

A variety of definitions of the concept of uncertainty exist in business studies literature. Uncertainty in Organization Studies is seen as lack of information for, and knowledge in decision making [51.55, 56]. It is also postulated as resulting from the indistinct and convoluted causal configuration underlying the internal operations of the firm, its environment, and the complex relationship between the firm and the environment [51.57]. Uncertainty is viewed as a product of unpredictability [51.58], environmental turbulence [51.59], and the complexity of influential variables [51.60]. Further, uncertainty is also a tangible facet of the external environment, and at the same time a perceptual attribute internal to managerial decision making [51.61].

In the Organization Studies, literature uncertainty [51.55, 56, 62, 63] is often found under the label of *environmental uncertainty* or *perceived environmental uncertainty*, the former referring to variation of conditions in the organizational environment, the latter to the ability of management in predicting such variation. According to transaction cost economics (TCE) [51.64], *environmental uncertainty* is one of sources – together with behavioral uncertainty and asset specificity – determining the choice for a firm to perform the transaction using the market (i. e., outsourcing the transaction) or hierarchy (i. e., internalizing the

transaction). Moreover, TCE has modeled behavioral uncertainty as a situation where the greater the asset-specificity of an investment, the greater the threat of opportunistic behaviors. Asset-specificity is a feature of all those investments that have value only within a specific transacting relationship, and lose value outside such transaction. Asset-specificity give rise to what in the literature is known as the *hold-up* problem meaning that, in a bilateral transaction, after one party has made the asset-specific investment, the other may take advantage of such specificity to appropriate of some rents expected to be earned with the investment through opportunistic behavior.

In the Agency Theory framework “uncertainty is viewed in terms of risk/reward trade-offs, not just in terms of inability to preplan” [51.50], while according to the Resource-Based View approach [51.65] a distinction between risk and uncertainty exists [51.65, p. 56]:

“[...] the fact that the future can never be known with accuracy means that the planning of business firms is based on expectations about the future which are held with varying degrees of confidence [...] *Uncertainty* refers to the entrepreneur's confidence in his estimates or expectations; *risk*, on the other hand, refers to the possible outcomes of action, specifically to the loss that might incurred if a given action is taken.”

### Uncertainty and Knowledge

In Economics models of uncertainty are usually incorporated into economic actors' decision-making [51.66–70] and uncertainty is generally defined as a *lack of knowledge* about the state in the future. *Keynes* [51.3] investigated the role of the quantity and quality of information owned by agents in their decision-making process and the role of incomplete information as being the core of uncertainty. The Keynesian conceptualization of uncertainty is not distant from the Knightian one. Indeed, the former believed that some social processes cannot be classified as *ergodic* or deterministic. These are the outcome of decision-making processes and thus behaviors are guided by two factors: the creation of premises through the imagination and the making of choices on the basis of nondeterministic forces like *animal spirits*. Arrow describes uncertainty as follows [51.3, pp. 33–34]:

“Uncertainty means that we do not have a complete description of the world which we fully believe to be true. Instead, we consider the world to be in one or another of a range of states. Each state of the world is a description which is complete for all relevant purposes. Our uncertainty consists in not knowing which state is the true one.”

From a micro perspective, if we look at theories of the internationalization of the firm – especially at those labeled as Process Theories – the impact of knowledge and learning gained through international experience emerges as crucial to the pace and direction of firms’ internationalization activities, especially those taking place after the first stages of international growth. The most famous Process Theory is the Uppsala Model developed by *Johanson* and *Wiedersheim-Paul* [51.72] and *Johanson* and *Vahlne* [51.73]; it theorizes that firms internationalize following a (linear) *learning process*: they first approach closer markets and subsequently more distant ones (distance in this stream of literature not only refers to geographic distance, but also to differences for instance in terms of culture, institutions, etc.). The level of commitment in a market (i. e., the *mode* of investing in that country) changes according to the *learning path*: the first internationalization stages are carried out only by engaging in (unsolicited) export activities, while the last ones entail establishing wholly owned subsidiaries. The Swedish authors advanced two basic assumptions:

- The *lack of knowledge* about foreign markets and operations is an important obstacle to the development of international operations.
- The *necessary knowledge* can be acquired mainly and preferably through operations abroad.

These hypotheses hold for the two directions of internationalization that were distinguished, (a) the increasing involvement of the firm in the individual foreign country – vertical expansion – and (b) the successive establishment of operations in new countries – lateral expansion. The determinant of the time order of such expansions and their geographical disposition is determined by the *psychic* distance between the home and the import/host country. *Psychic distance* is one of the pillars on which the Uppsala model is built and

refers to the “sum of factors preventing the flow of information from and to the market, and is often correlated with geographical distance” [51.72, p. 308]. Given the previous considerations, *Johanson* and *Vahlne* derived that internationalization is the product of a series of incremental decisions in small steps, rather than large foreign production investments at single points in time. In other words, internationalization is intended as the consequence of a process of incremental adjustment to changing conditions of the firm and its environment. Subsequent models about the internationalization of the firm, that is, the Innovation-Related Internationalization Models can be rightly regarded as behaviorally oriented theories and the organization’s internationalization process can be considered as influenced by (i) the lack of knowledge by the firm, especially experiential knowledge; and (ii) uncertainty associated with the decision to internationalize.

Figure 51.8 illustrates *Khaneman* and *Tversky*’s *phenomenology* of uncertainty [51.71]. The primary distinction refers to two loci to which uncertainty can be attributed: the external world and our state of knowledge. The second level distinguishes four prototypical variants of uncertainty that arise depending on the nature of the data that “the judge might consider in evaluating probability” [51.71, p. 152]. External uncertainty can be assessed in two ways: (i) a distributional mode, where the instance in question is part of a class of similar cases, for which the frequency distribution is known, or it can be estimated; or (ii) a singular mode, where probabilities are estimated by the propensity of that particular case to happen. Internal uncertainty can be either (a) reasoned or (b) introspective, but in both cases it reflects (partial) subjective ignorance, rather than disposition of external objects. The statement “Copenhagen is much colder than Milan” reflects a process of “sifting and weighing” [51.71, p. 154], while the statement “I think her name is Anna, but I am not sure” expresses a certain level of *confidence* based on an introspective judgment.

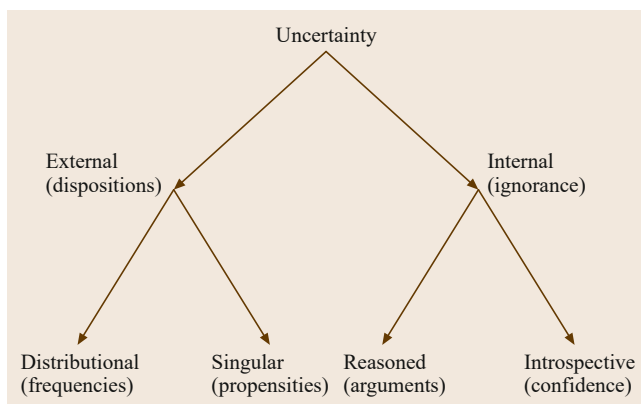

Fig. 51.8 Variants of uncertainty (after [51.71])

### Epistemic Issues About Probability Beyond Models of Risk and Uncertainty

The academic debate born during the 1920s and 1930s around probability and risk can be basically divided into two streams: *objectivists* and *subjectivists*. The formers are scholars arguing that probabilities are real, intrinsic in nature, hence discoverable through logic or statistical estimates. The latter are scholars asserting that probabilities are human beliefs [51.74]. Theories assuming that probability is merely a type (and not an object) of knowledge include the subjectivists, including *Savage* and *Friedman*, and some objectivists, including *Keynes*. Scholars that, on the opposite, suppose that probability exists as a part of external reality include, among

others, Knight and proponents of the rational expectations hypothesis [51.75]. In proposing a simple lexicon to discuss of probability, [51.76] argues that there are only two basic ideas of what probability is. One of these is the idea that the probability of an event is its long-run frequency of occurrence. Following Hacking's classification of probability types, a first conception is that probability is based on the proportion, percentage, or fraction of times that an event occurs in repeated trials: this is called *aleatory* probability (from the Latin word for a dice game, *alea*). The other conception of probability focuses on the uncertainty of the final outcome; hence, a probability is the degree of belief that one has in a hypothesis given some evidence. Because this conception depends on one's knowledge of the likelihood of an event, rather than solely on its relative frequency, it is called epistemic probability (from *episteme*, the Greek for knowledge). In addition to the aforementioned dichotomy, we can then distinguish between objective and subjective conceptions of probability. In the former, probabilities are unique and have the same value for all individuals, in the latter are individuals themselves assigning values to probabilities.

*Knight* distinguishes three types of probability situations [51.48, p. 225]:

1. *A priori probability*. Absolutely homogeneous classification of instances completely identical except for really indeterminate factors. This judgment of probability is on the same logical plane as the propositions of mathematics (which also may be viewed, and are viewed by the writer, as "ultimately" inductions from experience).
2. *Statistical probability*. Empirical evaluation of the frequency of association between predicates, not analysable into varying combinations of equally probable alternatives. It must be emphasized that any high degree of confidence that the proportions found in the past will hold in the future is still based on an a priori judgment of indeterminateness. Two complications are to be kept separate: first, the impossibility of eliminating all factors not really indeterminate; and, second, the impossibility of enumerating the equally probable alternatives involved and determining their mode of combination so as to evaluate the probability by a priori calculation. The main distinguishing characteristic of this type is that it rests on an empirical classification of instances.
3. *Estimates*. The distinction here is that there is no valid basis of any kind for classifying instances. This form of probability is involved in the greatest logical difficulties of all, and no very satisfactory discussion of it can be given, but its distinction from

the other types must be emphasized and some of its complicated relations indicated.

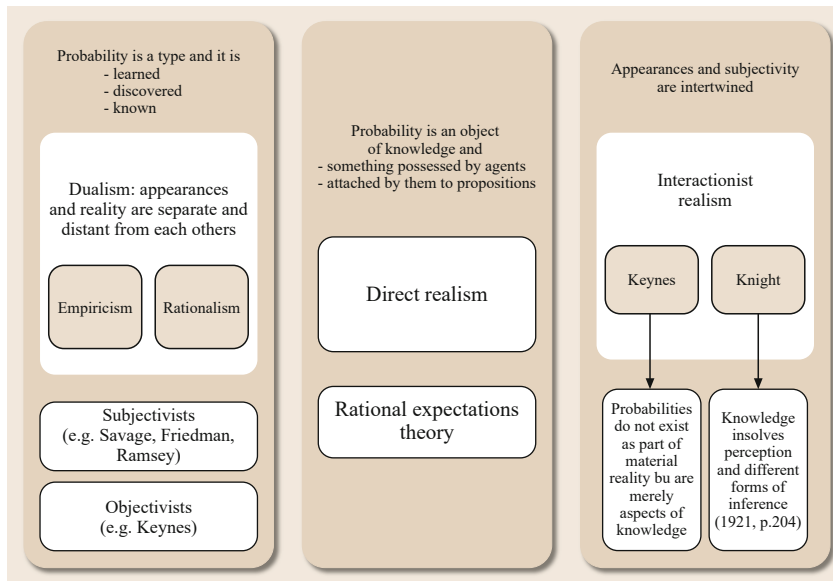

In (1) and (2), probability judgments are referred to as a priori probability and statistical probability, respectively. Concerning a priori probability, Knight stresses the "absolutely homogeneous classification of instances completely identical except for really indeterminate factors" [51.48, p. 224]; and in referring to statistical probability, *Knight* emphasizes that "any high degree of confidence that the proportions found in the past will hold in the future is still based on an a priori judgment of indeterminateness" [51.48, p. 225]. In the third type of probability situation the relevant judgment that is formed is referred to as an estimate. The first type of uncertainty is commonly referred to as risk, against which we can insure. Such a classification has been often translated by commentators into a differentiation between objective and subjective probabilities. For subjectivist theorists including, for example, Savage, Ramsey, and Friedman, probability cannot be known and it is the degree of belief in a given proposition or event, held by an actual individual at some specific point in time. On the contrary, scholars such as Lucas (in conversation with *Klamer* [51.77]) focus on the fact that what matters in terms of uncertainty is not that we do not know the probabilities but that we do not know the *classification* of outcomes.

With the aim of answering the question whether "are probabilities, as understood with economic analyses, a property of this external material reality, or are they only a property of knowledge?" *Lawson* [51.75, p. 40], works out different accounts in the notion of probability from the perspective of realism. The choice of such a stance is justified as useful for the need to state the presence of an [51.75, p. 39]

"objective material (physical and social) world which exists independently of consciousness (or of any individual consciousness in the case of the social) but which is knowable by consciousness."

Indeed, the author distinguishes amongst direct realism, dualism, and interactionist realism. Figure 51.9 and Table 51.1 illustrate Lawson's argument.

- Direct realism: According to such a perspective knowledge is reality.
- Dualism: Appearances and reality are separate and distant from each others. Inside dualism, we can distinguish among two streams of thought that are empiricism and rationalism. The former gives primary role to sensory experience in knowledge (e.g., Locke), while the latter gives central role to reason where first chaotic impressions are at a later mo-

**Fig. 51.9** Different notions of probability from the stance of realism (after [51.75])

**Table 51.1** Classification of prominent accounts of probability and uncertainty in economic analysis (after [51.75])

	Probability is a property of knowledge or belief	Probability is also an object of knowledge as a property of external material reality
Uncertainty corresponds to a situation of numerically measurable probability	Subjectivists (e.g., Savage, Friedman)	Proponents of the rational expectations view (e.g., Muth, Lucas)
Uncertainty corresponds to a situation of numerically immeasurable probability	Keynes	Knight

ment transformed and ordered by processes of the human reason (e.g., Kant).

- Interactionist realism: Appearances and reality are intertwined. Knowledge is an active process where thought, theory, and practice have equal weights in the process.

**Expected Utility Theory and Subjective Expected Utility Theory Models.** In the last 60 years, the leading theories of choice in economics and psychology have been the expected utility (EU) theory of [51.78] and the subjective expected utility (SEU) theory of *Savage Leonard* [51.79]. EU assumes that the probabilities of outcomes are known. Agents’ preferences are represented by real-valued utility functions where preferred choices correspond to higher utility, and the utility of a choice is the EU of expected possible outcomes weighted by the probability of their occurrence.

In SEU, probabilities are not necessarily objectively known, decision makers face uncertain states and are assumed to have subjective probabilities attached to these states. Under the SEU, axioms preferences can be represented by expected utilities that use subjective probabilities to weigh the probability of outcomes’ oc-

currence. The theory combines the von Neumann and Morgenstern EU approach with *De Finetti’s* [51.80] calculus of subjective probabilities. The key elements of EU theory are (1) a value function that is concave for gains, convex for losses, and steeper for losses than for gains, and (2) a nonlinear transformation of the probability scale, which overweight small probabilities and underweight moderate and high probabilities [51.81]. SEU theory was first developed by Savage (inspired by Ramsey and De Finetti), and then derived by Anscombe and Aumann in an approach that essentially combined EU and SEU. According to subjective probability theory – typically represented by the Bayesian approach – it is possible to assign numerical probabilities to virtually any proposition or event probability is the degree of belief in a given proposition or event held by an individual at a specific point in time. According to [51.75] for this group of scholars, probability is only epistemic, a property only of knowledge or belief, that does not necessarily has to correspond to external reality. As *Weatherford* [51.82, p. 226] asserted a “subjectivist [...] recognizes that his opinion is the final authority [...]. There is no correct reference class, since there is no correct probability.”

A person's subjective probability regarding the truth of a proposition (or the occurrence of an event) is revealed by the odds at which that person is exactly indifferent between betting for and against the proposition (or event) [51.83, p. 338]:

“For example, if a person is willing to accept to pay  $P^*$  for a gamble that pays  $S$  if proposition  $h$  is true and nothing if  $h$  is false, then for  $P^*/S$  to express the person's subjective probability it is necessary that the person be also willing to receive  $P^*$  for a gamble that involves a loss of  $S$  if  $A$  is true and nothing if  $A$  is false.”

This requires very precise beliefs, but presumably allows subjective probabilities to be assigned even to unique events [51.84]. According to Keynes, no proposition is subjectively probable, meaning that the likelihood for it to happen depends on our belief in it.

Radical Subjectivists, among which we can mention *Shackle* [51.85] and *Lachmann* [51.86], have a subjectivist view of expectations. The key point is that, for Shackle and his followers, imagination cannot be brought under the cover of reason: “expectation undermines the view of conduct as purely rational” [51.85, p. xvii]. According to such a view, agents vary not only in their tastes but also in their expectations, that is, in their visions of the future [51.87, p. 29]:

“In this view, the future is not so much unknown as it is nonexistent or indeterminate at the time of decision. The agent's task is not to estimate or discover, but to create. He must therefore exercise imagination.”

**The Concept of Ambiguity.** EU theory has been for several decades the dominant normative and descriptive model of decision-making under uncertainty, but at the same time a substantial body of evidence shows that decision makers systematically violate its basic assumptions [51.81].

The most famous challenge to SEU has been posed by the Ellsberg paradox. Nonetheless similar problems were argued earlier by *Knight* [51.48, pp. 218–219] as well as by *Keynes* [51.88]. Much empirical evidence *Camerer* and *Weber* [51.89], inspired by *Ellsberg* [51.90] and others, shows that people prefer to bet on events they know more about, even when their beliefs are held constant. In *Ellsberg's* [51.90, p. 657], ambiguity is the “quality depending on the amount, type, reliability, and *unanimity* of information,” or “Ambiguity is uncertainty about probability, created by missing information that is relevant and could be known” as defined by *Camerer* and *Weber* [51.89, p. 325]. According to these Authors it is misleading to suppose that ambi-

guity about outcomes and ambiguity about probabilities are parallel conditions or treatment variables [51.89, p. 331]:

“If people are averse to ambiguity about which outcome will occur, but outcome probabilities are known, then they are risk averse and consistent with EU. But if people are averse to ambiguity about the probability of an outcome, they are ambiguity averse and inconsistent with SEU. The two kinds of ambiguity are fundamentally different.”

**Ergodicity and Nonergodicity.** Ergodic theory has been explicitly developed in the theory of stochastic processes although the term derives from statistical mechanics [51.91]. Samuelson has argued that economics' claim to be scientific rests on the acceptance of the *ergodic hypothesis* [51.92]. To Keynes the source of uncertainty was in the nature of the real – nonergodic – world. It had to do, not only – or primarily – with the epistemological fact of us not knowing the things that today are unknown, but rather with the much deeper and far-reaching ontological fact that there often is no firm basis on which we can form quantifiable probabilities and expectations at all. Post-Keynesians economists typically distinguish between ergodic and non ergodic processes: the latter involving fundamental uncertainty and non ergodicity can be used to explain the existence of firm in the long run [51.93]. The fact that real social and economic processes are nonergodic is given by the pervasive presence of uncertainty.

*Davidson* [51.94] stresses the distinction between ergodic and nonergodic world and argues that uncertainty is associated with the latter situation. He concludes that the implication of this is that the inverse of knowledge, unknowledge, that is (fundamental) uncertainty, must be expounded in terms of the ergodic theory. The concept of ergodicity is described by *Davidson* [51.94, p. 6] as a situation in which

“the probability distribution of the relevant variable calculated from any past realization tends to converge to the probability function governing the current events and with the probability function that will govern future outcomes.”

The assumption of *bounded rationality* – conceived by *Herbert Simon* – refutes the assumption of rationality in the classical economic theory of the firm, arguing that its limits arise distinctly (i) when risk and uncertainty are introduced into the demand function, the cost function, or both; and (ii) when we assume that actors have incomplete information about all alternatives for their choices [51.95]. When uncertainty is introduced, a maximization behavior is replaced

by an approximation one, and actors do not optimize choices, but approximately optimize them: a satisfying behavior in decision-making is found to be more appropriate [51.95].

### 51.7.2 Models of Risk

There are numerous conceptions of risk both in the economics and business studies literature. According to most of the literature in economics, finance, and strategic management risk is associated to a variation in outcomes' performance.

*Luce* and *Raiffa* [51.96, p. 13] distinguish among three types of situations under which the decision-maker is in the realm of certainty, risk, or uncertainty:

1. Certainty is a situation where each action is known to lead invariably to a specific outcome.
2. Risk is linked to situations where each action leads to one of a set of possible specific outcomes, each outcome occurring with a known probability.
3. Uncertainty, where actions may lead to a set of consequences, but where the probabilities of these outcomes are completely unknown.

*Business risk* is defined to be the "risk inherent in the firm, independent of the way it is financed" [51.97, pp. 207–208] and it is related to the variability of net operating income or net cash flows.

*Financial risk* is defined as the added variability of the net cash flows of the owners of equity that results from the fixed financial obligation associated with debt financing and cash leasing [51.98]. Financial risk can be identified by the following equation [51.99, p. 561].

$$FR = \frac{\sigma_2}{cx - I} - \frac{\sigma_1}{cx}, \quad (51.11)$$

where  $\sigma_1$  is the net standard deviation of net cash flows without debt financing;  $\sigma_2$  is the standard deviation of cash flows with debt financing, but before the deduction of debt servicing payments,  $cx$  is the expected net cash flows without debt financing; and  $I$  are fixed debt servicing obligations.

The most important paradigm of risk emerged in the financial economics literature during the past quarter century is part of the set known in the literature as the *SBL model* (i. e., Sharpe–Lintner–Black model), known in the strategic management literature as the Capital Asset Pricing Model (CAPM). Such a model was developed by *Sharpe* [51.100], *Lintner* [51.101] and refined by *Black* [51.102] as an extension and simplification of earlier work by *Markowitz* [51.103]. The CAPM's main predictions and are summarized by *Fama* and *French* [51.104, p. 427]. Most of the studies using the CAPM [51.100, 101] framework employ measures of:

1. Systematic risk reflecting the sensitivity of the return on a firm's stock to general market movements.
2. Unsystematic risk refers to the extent to which general market movements cannot explain a firm's stock return.

Systematic and unsystematic risks are standard measures of risk for stock market return data. *Miller* and *Bromiley* [51.105] found that both types of risk, defined with accounting data, influenced performance. The definition of risk as unpredictable variation in business outcomes has to be found also in accounting literature in the form of return on assets, and return on equity. Hence, one measure of risk based on financial ratios is, for instance, the debt-to-equity ratio: a standard measure of corporate financial leverage reflecting a company's risk of bankruptcy [51.106, 107], and capital intensity, that is, the ratio of capital to sales.

Although the CAPM was developed explicitly for use in a finance context, it has been widely employed also in the field of strategic management, especially regarding issues related to corporate diversification strategy or in situations where maximization of stockholder wealth is taken as the primary objective of the firm. Variance is also a widely measure of risk used in the strategic management literature. Risk has been rarely addressed as a specific area of study in strategy formulation [51.108]. An analysis of the role of risk in strategic planning is given by *Gluck* et al. [51.109] with the identification of four phases in the development of strategic management within a firm.

In the acceptance that risk is variation from an expected probability distribution of outcomes, the relative magnitude of risk could be defined by the amount of dispersion in that distribution such as the standard deviation or variance:

1. *Variance* is a measure of the variability of a measured datum from the average value of the set of data;

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^n (xi - x) . \quad (51.12)$$

2. *Standard deviation* is a measure of the dispersion of a set of data from its mean. The more spread apart the data, the higher the deviation. Standard deviation is calculated as the square root of variance

$$\sqrt{\sigma^2 = \frac{1}{n} \sum_{i=1}^n (xi - x)} \quad (51.13)$$

Since distributions with different shapes and differing amounts of downside risk (the difference between

the actual return and the expected return) can have the same variance, measures such as *skewness* and *kurtosis* can be used to better quantify the risk that is not adequately described by variance alone. *Value at risk* (VaR) is a widely used risk measure of the risk of loss on a specific portfolio of financial assets. For a given portfolio, probability and time horizon, VaR is defined as a threshold value such that the probability that the mark-to-market loss on the portfolio over the given time horizon exceeds this value (assuming normal markets and no trading in the portfolio) is the given probability level. Given some confidence level  $\alpha \in (0, 1)$ , the VaR of the portfolio at the confidence level  $\alpha$  is given by the smallest number  $l$  such that the probability that the loss  $L$  exceeds  $l$  is not larger than  $(1 - \alpha)$

$$\begin{aligned} \text{VaR}_\alpha &= \inf \{l \in R: P(L > l) \leq 1 - \alpha\} \\ &= \inf \{l \in R: F_L(l) \geq \alpha\}. \end{aligned} \quad (51.14)$$

### 51.7.3 Models of Uncertainty

Several decades ago, Knight and Keynes, each in his own way, discussed uncertainty as a notion distinct from something else, which Knight called risk. The Keynesian approach to uncertainty comes straight from his studies on probability, we previously mentioned in the Treatise on Probability, and notion of logical probability.

#### Keynes on Uncertainty

The manner in which Keynes deals with uncertainty appears, on its face, quite similar to that of Knight. According to *Keynes* [51.88, p. 15]; the probability is the “degree of truth of a proposition contained in the evidence,” and the *weight of the argument* of a given proposition is the measure of the disbelief in the truth of such a proposition [51.88, p. 84]

“There appear to be four alternatives. Either in some cases there is no probability at all; or probabilities do not all belong to a single set of magnitudes measurable in terms of a common unit; or these measures always exist, but in many cases are, and must remain, unknown; or probabilities do belong to such a set and their measures are capable of being determined by us, although we are not always able so to determine them in practice.”

Uncertainty is linked to the concept of perfect knowledge and to the problem of investment decisions under uncertainty (the *weight of the arguments*).

In Keynes’s concept of uncertainty not only some premises may be unknown at the moment of decision but they may also actually be unknowable. Uncertainty

means the acknowledgement of the impossibility of dealing logically with this complexity

*Keynes* suggested that agents form their expectations based on how much *weight* they put on different possibilities of outcomes (i. e., they for subjective probabilities). In order to clarify his concept of uncertainty, we may quote a famous passage from *The General Theory of Employment, Interest, and Money* [51.3, p. 214]:

“The sense in which I am using the term is that in which the prospect of a European war is uncertain, or the price of copper and the rate of interest twenty years hence, or the obsolescence of a new invention, or the position of private wealth-owners in the social system in 1970. About these matters there is no scientific basis on which to form any calculable probability whatever. We simply do not know. Nevertheless, the necessity for action and for decision compels us as practical men to do our best to overlook this awkward fact and to behave exactly as we should if we had behind us a good Benthamite calculation of a series of prospective advantages and disadvantages, each multiplied by its appropriate probability, waiting to be summed.”

It seems that Keynes viewed the world as consisting of different degrees of uncertainty rather than in a dichotomy of uncertainty and probabilistic certainty. A related issue raised by *Coddington* [51.110] is whether or not certainty is obtainable. Moreover in Keynes’ account such certainty corresponds to knowledge. Keynes, however, does consider that knowledge and thus certainty are obtainable, he distinguishes between two types of knowledge: knowledge that is obtained directly and that which is obtained indirectly.

The distinction between risk and uncertainty in Keynes regards the distinction between short-term and long-term expectations. Unlike short-term expectations, long-term expectations (investments) do not entail continuous process of daily revision on the basis of actual market outcomes, rather involve long-term and largely irreversible commitments in advance of actual market outcomes. A risky situation is characterized by stable deterministic and stochastic components of which the decision maker has a very high degree of knowledge; all the range of future possible outcomes is known [51.111, p. 626],

“decision-makers are essentially backward looking, looking at past outcomes as a guide to future actions. Decision makers act on the assumption that the causal structure will remain fixed, at least in the short term, and form their expectations accordingly.”

An uncertain choice situation is that the probability distribution is partially, or totally unknown because only partial knowledge is possible for future outcomes and their likelihood. In such a situation, past offers little guidance to actual decision-making and firms have to form long-term expectations for investment decisions [51.111, p. 627]:

“Decision makers have to be forward-looking and *scientific*, in the sense of being willing to entertain alternative hypotheses about the causal structure and possible future outcomes, and able to interpret new information as confirming or disconfirming evidence that increases/decreases the degree of belief in any specific hypothesis.”

According to *Minsky* [51.31, p. 359] in its remarks upon receiving the Veblen-Commons award:

“The uncertainty that permeates the economics of Keynes and the economics of bounded rationality is due to the un-sureness about the validity of the model of the economy that enters in the decision process. Action involves a suspension of disbelief by both sides in the negotiations, and economic success fosters such a suspension. Government institution building can be interpreted as adding dimensions to the economy whose behaviors are not as uncertain as that of market-determined variables.”

According to *Minsky*, at a systemic level, money manager capitalism doubled with New Deal reforms have drastically increased the level of uncertainty.

#### Post-Keynesians on Uncertainty

*Dequech* [51.112] contends that uncertainty has proved to be a key concept in post-Keynesian economics. Important theoretical implications have stemmed from it:

1. It is the source for liquidity preference
2. Some post-Keynesians have derived a privilege of short-run analysis from uncertainty [51.113]
3. The possibility of structural breaks and sudden shifts in behavior [51.3, 114] and
4. The rejection for ergodicity [51.114].

The post-Keynesian Scholar argues that the rationale for the existence of the firm is not that it is efficient in the sense that it reduces transaction costs. Rather the institutional form of the firm is chosen to deal with uncertainty. Scholars of different schools of heterodox economic thought have identified situation of uncertainty of a more radical type, that is, characterized by the possibility of creativity and structural change, hence by “significant indeterminacy of the future” [51.112]. In a dynamic context, “the future cannot be anticipated

by a fully reliable probabilistic estimate because the future is yet to be created” [51.112, p. 41]. Such a kind of more radical uncertainty does not only refer to the lack of information needed to assess the probability distribution of future outcomes, rather to the impossibility of even imagining an event. This argument has clear antecedents in the work of *Shackle* [51.85], who is against the use of probability distributions, even subjective ones, in situations of fundamental uncertainty. A similar point has been raised against both the rational expectations hypothesis and SEU theory by *Bausor* [51.115], *Davidson* [51.116], and *Vickers* [51.113], among others.

According to *Dequech*, in his acceptance of uncertainty, Keynes refers both to situations of ambiguity and of fundamental uncertainty, without explicitly distinguishing between them. There is still disagreement around the interpretation of Keynesian uncertainty, based on the author’s treatise. Some commentators have argued that uncertainty refers to an absence of numerically determinate or even comparable probabilities, while, others contend that Keynesian uncertainty is measured by weight [51.112].

The concept of fundamental uncertainty claims that significant parts of economic decisions are made under conditions where the outcome of these decisions is not subject to a probabilistic calculus, but rather cannot be determined by scientific means. Thus, decisions under such circumstances are based on emotions or conventions. Typically, such conditions apply to decisions that involve a long time horizon and involve irreversible costs, what *Shackle* called *crucial experiments*. Fundamental uncertainty is a result of the fact that economic processes in the real world do not follow ergodic pattern. Under such circumstances no probability distribution for outcomes can be given. This inability to give probability does not merely reflect the limited knowledge or information processing abilities of humans, but is a reflection of the openness of the historical process in which human societies and economies evolve.

Scholars such as *Carabelli* [51.117], *Davis* [51.118], and *Arestis* [51.119] see the problem of agents’ uncertainty about each others’ expectations as being the fundamental source of general uncertainty [51.120]. Since we can never know for certain at what *degree* other people will be thinking about how average opinion will be forming its expectation of itself, we cannot ever know for certain what other peoples’ expectations of average opinion will actually be. This dependence of people for each other on the formation of their expectations, opens up the possibility of sudden mass changes of these expectations, and such an event goes under the name of *mob psychology*.

### Knight on Uncertainty

As already mentioned, one of the most important contributions to the conceptualization of uncertainty in economics is the seminal work of *Knight*, *Risk, Uncertainty, and Profit* [51.48]. Knight has both a conceptualization of what uncertainty is, and how individuals cope with it. Knight's theoretical framework begins by studying some with some very crucial points of the theory of thought. Among many other definitions [51.89] the economic understanding of risk, uncertainty, and ignorance has its origin in [51.48]. There has been a considerable discussion and disagreement about over the meaning of Frank Knight's risk and uncertainty [51.121], considering his two most famous contributions *Risk, Uncertainty and Profit*, and *Profit and Entrepreneurial Functions* [51.122]. A most common definition of risk is that it is related to outcomes that can be insured against, and uncertainty to outcomes that cannot be insured against [51.123]. Such an interpretation builds on the Knightian distinction of three possible future outcomes, and related probabilities: (i) a priori, (ii) statistic, and (iii) estimates which we have described in the previous section, hence on the measurability/immeasurability of probabilistic outcomes [51.48, p. 20, Emphasis author's own]:

“It will appear that a measurable uncertainty, or *risk* proper, as we shall use the term, is so far different from an unmeasurable that it is in effect not an uncertainty at all. We shall restrict the term *uncertainty* to cases of a nonquantitative type.”

Outcomes of the first (i) and second (ii) type can be grouped together as they are homogeneous instances, and hence, they can be insured against, while outcomes of the third type, of which we do not neither know the distribution (iii) nor we can draw it from historical data cannot be grouped, and insured against. Outcomes of the first and second type are risky, outcomes of the third type are uncertain. Outcomes subject to risk can be insured against, either through traditional insurance contracts or by holding a portfolio of stocks. *LeRoy* and *Singell* [51.49] offer a refinement on the insurance interpretation claiming that Knight anticipated the literature on the failure of markets as a result of adverse selection and moral hazard.

The second interpretation of Knight's distinction of risk and uncertainty relates to the difference between situations in which profit cannot exist (because of the presence of risk), and those in which profit can arise (thanks to the presence of uncertainty). *Knight's* aim in *Risk, Uncertainty, and Profit* [51.48] was to explain profit as the reward for bearing uncertainty [51.48, p. 232]:

“It is this true uncertainty which [...] gives the characteristic form of *enterprise* to economic organization as a whole and accounts for the peculiar income of the entrepreneur.”

A further interpretation is the one by *Langlois* and *Cosgel* [51.51], which claims that the Knightian distinction refers to states of the world that can be conceived and those that cannot. A risky decision is defined as a decision with a range of possible outcomes with a known probability for the occurrence of each state (e.g., a fair roulette game); or the probabilities are not precisely known and a decision has to be made under uncertainty (e.g., sport events and elections). In this sense, decisions under risk can be seen as a specific case of decisions under uncertainty with precisely known probabilities.

A practical example of the difference between Knightian risk and uncertainty is the one given by *Gueron-Quintana* [51.124, p. 10]. Suppose to throw a coin knowing that it is fair, and the unknown is whether the coin will land heads or tails. Since it is fair, we know that the odds for each flip to have either head or tail are 50-50. In such a case we know exactly the odds of each of the possible events: 50% heads and 50% tails, and we have this knowledge before starting the experiment. This is an example of Knightian risk. A second experiment involves flipping a coin that is no longer fair, furthermore the coin is replaced with a new (and unfair) coin after each flip. In this case we do not know the odds of obtaining heads, the only thing we know is that the coin will land either heads or tails. If we were thinking about flipping the coin 100 times, we could not (before we start the experiment) tell how many times the coin will land on heads. This is an example of Knightian uncertainty.

### Game Theory

Game theorists study uncertainty about the *strategic choices* of other players. They deal with uncertainty by reducing economy to a static equilibrium in which all economic activities take place at fixed one point in time. We can distinguish among three major stages in the development of game theory. The first one, classical game theory, is defined by John von Neumann and Oskar Morgenstern. The axioms for the concept of individual rational player making decisions in the face of certainty and uncertainty are developed. Such a player does not assume that the other players also act rationally. In contrast, modern game theory is defined by the Nash player who is not only rational but assumes that all players are rational to such a degree that they can coordinate their strategies so that a Nash equilibrium prevails. The more recent, third stage in the develop-

ment of game theory, new game theory, is defined by the so-called *Harsanyi player*. This player is rational but knows very little about the other players, e.g., their payoff functions or the way they form beliefs about other players' payoff functions or beliefs.

### Uncertainty in General Equilibrium Theory

The *General Equilibrium Theory*, as developed mainly by Arrow and Debreu in the 1950s, sets out to prove that the possibility of a competitive equilibrium in the economy does exist and that such an equilibrium is Pareto efficient. The analyses of Arrow and Debreu deal with uncertainty about the environment. The *world* is divided into two sets of variables: decision variables, which are control-led by economic agents, and environmental variables, which are not controlled by any economic agent. The *General Equilibrium Theory* was claimed by Arrow and Debreu both in a mathematically rigorous manner, but also rests on specific assumptions. Most importantly they assume the so-called dated, contingent commodities that allow for future markets for all goods, through which agents can determine their entire production and consumption plans, for they know the prices of all goods in all future periods, and they can insure them against all eventualities. Indeed, there exist markets for all actual and future goods because of the assumption that all economic actors share the same information.

Arrow himself sought the limitation of the General Equilibrium Analysis in light of informational asymmetries, leading to agency problems, moral hazard and adverse selection. Once asymmetric information is considered it leads to the arising of market failures hence Pareto-inefficient markets.

### New Institutional Economics

According to *Alchian* [51.125], uncertainty arises from at least two sources: imperfect foresight and human inability to solve complex problems containing a series of variables even when an optimum is definable. Under uncertainty each action is identified with a distribution of potential overlapping outcome. As Knight, Alchian sees uncertainty as the precondition for profits to arise. And coping responses are made by imitation of observed success; adaptive behavior via imitation provide opportunities for innovation. According to scholars of New Institutional Economics, such as Hodgson and Demsetz institutions have a *cognitive function* contribute reducing the mentioned complexity, and therefore ultimately to reduce perceived uncertainty.

### Transaction Costs Economics

TCE [51.64, 126, 127] theory assumes that firms' efficiency is maximized given a static set of knowledge,

technology and preference. Bounded rationality and opportunism are the two behavioral assumptions about human factors of transaction cost theory [51.128]. The former refers to the impossibility for individuals to retrieve information, and process it without error. The latter deals with the manifestation of opportunistic behaviors of two types: asymmetric information, and moral hazard. According to Williamson, the consequences of bounded rationality are less severe when transactions take place in a context with little environmental uncertainty. Williamson builds on Koopmans distinction among primary, secondary, and third type uncertainty. Primary uncertainty reflects a lack of knowledge about states of nature, such as the uncertainty regarding natural events, whereas secondary uncertainty refers to a lack of knowledge about the actions of other economic actors. Primary uncertainty also corresponds closely to state uncertainty as described by [51.61], in that both refer to the lack of knowledge about various states of nature. The third type of uncertainty might arise from opportunism, "self-interest seeking with guile" [51.129, p. 56].

Behavioral uncertainty relates to the informational problems that ensue from the coexistence of bounded rationality and opportunism [51.130]. "In circumstances where behavioral uncertainty is a pervasive and surrounds asset specific investments, then market based transaction costs are likely to be high" [51.130, p. 420]. Behavioral uncertainty in an international perspective arise from the inability of a company to predict the behavior of individuals in a foreign country. Hierarchical ownership conveys the right but not the means to control a foreign operation. Controlling foreign operations is a special skill that requires time to develop and refine. When a firm lacks such internal control mechanisms, it may reduce the chances of opportunistic behavior by shifting control to a foreign agent. Firms lacking international control related experience tend to prefer nonequity modes of entry.

*Behavioral Uncertainties*. They arise from the inability of a company to predict the behavior of individuals in a foreign country. According to transaction cost theory, behavioral uncertainty may lead to opportunistic behavior involving cheating, distortion of information, shirking of responsibility, and other forms of dishonest behavior. In order to minimize opportunisms, a company has to develop some type of control mechanisms, such as internal control, achievable through hierarchical ownership that gives the firm a legal right to control the actions of foreign-based employees. However, hierarchical ownership conveys the right but not the means to control a foreign operation. Controlling foreign operations is

a special skill that requires time to develop and refine. When a firm lacks such internal control mechanisms, it may reduce the chances of opportunistic behavior by shifting control to a foreign agent. Firms lacking international control related experience tend to prefer nonequity modes of entry. Behavioral uncertainties may be an especially important influencing factor for small and medium enterprises (SMEs), they tend to rely on the managerial abilities of one/two entrepreneurs. SMEs may not have the ability or willingness to establish a competent managerial control structure in another country and in most cases will not have the ability to send their own people to a foreign country for any extended period of time [51.131]. Therefore, behavioral uncertainties may discourage SMEs from organizing foreign operations in a hierarchical form.

**Environmental Uncertainties.** They are created by the target market environment, and refer to the risks associated with the host country, for example the ability to enforce contracts and control or other types of political and legal risks [51.64]. In other words if a company desires increased control, it has to commit additional resources. However, by committing additional resources, a firm increases its exposure to external environmental risks. In countries with high environmental uncertainty, companies may be better off selecting nonequity, low investment entry modes. By following a low-resource commitment strategy in an uncertain market, a company can retain flexibility and, if the need arises, switch partner organizations or exit the market entirely, if the situation so dictates.

### The Subjectivist School

As *Hey* [51.132] argues subjective expected utility theory, which is intrinsically bound up with subjective probability theory, is the very “foundation stone of the Economics of Uncertainty” [51.132, p. 130]. In addition, *Diamond* and *Rothschild* [51.133] provide a collection of thirty papers in a volume entitled *Uncertainty in Economics*, all of which associate uncertainty with the Ramsey/Savage subjectivist view of probability. And in their expository survey of the “analytics of uncertainty and information” this view of uncertainty is also adhered to by [51.68]. Agents are optimal forecasters, and, in the individual’s mind personal (as Savage calls them) probabilities regarding future prospects at the moment of choice govern future outcomes. These subjective probabilities need not coincide with objective distributions, even if well-defined objective distributions happen to exist.

### The Rational Expectations School

During the 1970s and 1980s, significant theoretical contributions have been made in the general area of uncertainty and expectations covering the modeling of individual decision-making under uncertainty to the implications of rational expectations in temporary general equilibrium and macro models.

Theory of Rational Expectations [51.134, 135] argued that Keynesian economics was fundamentally flawed in that it relied on the assumption of adaptive or exogenous expectations. In Sargent’s argument, *bounded rationality* means that the agents in the economy are unsure about the degree of rational belief that is warranted in the model that they use at any time to guide their action. Thus, in Sargent’s artificial world, intractable uncertainty is pervasive because the agents in the model need to learn the properties of the model from experience. The self-seeking agents are uncertain (or unsure) in their knowledge artificial world, intractable uncertainty is pervasive because the agents in the model need to learn the properties of the model from experience. The self-seeking agents are uncertain (or unsure) in their knowledge of the economy and they accept that others are also unsure. Sargent’s definition of uncertainty is similar to the Minskyan one.

The theory of rational expectations deals with the uncertainty of future events by assuming that agents can anticipate rationally the choices of other agents using the information they hold from the observation of past behavior of the agent. The models assume that economic actors behave as if they know the structure of the economy so they can deduce optimal forecasts despite the ongoing changes in the economy. If no objective probabilities can be calculated, the expectations of agents are modeled by using Bayesian decision theory, which operates with subjective probabilities.

Therefore, the model used to deal with situations of uncertainty does not change fundamentally for economists even if they assume the absence of objective probabilities because agents can attach subjective probabilities to outcomes, provided that actors share the same information and the same subjective probabilities. *Bayesian rationality* can be integrated into static economic analysis. This claim has been empirically challenged with the argument that the degree of foreknowledge and rationality attributed to agents in these advanced economic models becomes increasingly sophisticated and it becomes more and more unlikely that economic actors understand all relevant variables of the model properly. But this in itself does not yet constitute a theoretical challenge that would affect the theoretical validity of economic decision-making models that deal with uncertainty.

## 52. Application of Models from Social Science to Social Policy

Eleonora Montuschi

The use of models in social science is now widely acknowledged, and well beyond cosmetic or illustrative purposes. However, the details and the mechanics of their use still prove hard to pin down. Equally, the usefulness of social scientific models in social practice and intervention is often challenged by a number of contentious and recurrent issues. One of these issues is ontological: How do model descriptions and aspects of social reality relate to each other? Often the descriptions offered by models are thin and unrealistic. Can we (and how much) learn about what goes on in the real-social world by analyzing the way/s that world gets described or explained by a model? A second issue is methodological: why using models when we can design experiments in the social world that are able, with some rigor, to inform us on *what works*? Nowadays there is an established trend to prefer the results achieved, for example, by well-conducted randomized control trials, by many considered the golden rule to doing good and useful social science.

In this chapter, we will first show some of the limitations and costs of using models in representing real-life situations, and suggest some strate-

Ever since it was acknowledged that models do not only perform a cosmetic or a heuristic function but, more substantially, can capture parts or features of the real world and fulfil an explanatory function, a vast philosophical literature has been developed on the many ways model ontology and reality relate to each other [52.1–4] (This change in perspective originates in the shift from the syntactic to the semantic view of theories in the philosophy of science, between the 1960s and the 1970s.). Models can simplify, approximate, idealize, or abstract from target systems (e.g., the behavior of a gas, the trajectory of a planet, the decision of a board committee, long-term average inflation rates, the migration movements of a population in a suc-

gies by which we can still formulate informative inferences from model to target system. We will then point out some of the virtues and benefits of using models (particularly causal models) when what is at stake is not only answering the question *what works* in policy terms, but also *why it works* – or, even more interestingly, why it does not work in given circumstances.

cession of historical periods) that often appear complex and difficult to be described or comprehended as they stand. Despite differences in construction, one feature that all models – be it formal/quantitative, or qualitative, or a combination of the two – have in common is that of being representational devices [52.5]. Models' representational power is displayed by establishing appropriate relationships with the target system (this is a theory, or a phenomenon, depending on the models concerned). Appropriate in what sense? How are these relationships established?

*The World in the Model* – the allusive title of a recent book by Morgan [52.6] – points us in two equally suggestive directions of thought. It refers to the world

the model creates, out of its own premises, variables, operations and conditions. Or it questions what of the world as we know it (or don't know it) gets captured (portrayed, described, explained) by a model.

Undoubtedly some models create ontologies that take shape out of their own principles and goals. But when, for example, we try to represent the real functioning of, say, a magnetic field, or a chemical reaction, or a decision on whether to implement a certain educational policy, how far do these ontologies travel from model to target?

A problem that is consistently pointed out in the vast and heterogeneous literature on models is that a good number of them offer descriptions of imaginary situations (model ontologies) which, compared to the target situations (real-world ontologies), are both thin (they are built on very few details) and, more worryingly, unrealistic (the details they are built on are untrue). These are models that routinely use a mixture of formal and natural language and that are built in such a way as to provide their results by deductive inference. It is, however, pointed out that thin and unrealistic assumptions prove necessary to these models in order to obtain the degree of rigor they aspire to, namely the type of rigor achieved deductively by means of controlled variables and operationalized language [52.7]. Therefore, thin and unrealistic assumptions are not a problem for the models as such. They nonetheless become a problem when a “result that must occur given characteristics different from those in the target inform conclusions about what will happen in the target.” [52.7, p. 3]. The problem just described takes then the form of the following question: Can thin and unrealistic premises in the model give rise to realistic conclusions concerning the target? When the target is *the world* (real, occurring situations in the world we live in and that we try to explain, predict, etc.) then the problem becomes deep indeed. This does not imply that unrealistic assumptions prevent us from learning something valuable about targets, but how exactly does this happen requires clarification.

In the first half of this chapter, we will pay specific attention to this problem, by showing the virtues as well as the limits of using the imaginary to model the real. The domain of reality where this problem will be tested is that of social settings. Modeling decisions, individual behaviors, social conducts, and social causes inevitably confront us with the issue of how much and how well does a model construction guide us into de-

scribing, understanding, and predicting what goes on in the complex realms (and often the vagaries) of real decisions, behaviors, etc. – as the first example analyzed in the following section will prove. If models in social science are to be explanatory and not just illustrative, if what they describe is to be of real use and guide in intervening on problematic or contentious social situations, the nature of their assumptions and the quality of their inferences deserve careful analytic scrutiny.

Learning how to master the use of models in social analysis will also bring us to address another important issue. Nowadays there is a consistent movement toward the use of experiments in the social world, and particularly certain types of experiments (e.g., RCTs) are considered to be the best methodology to understand and intervene on social problems. We intend to show how social experiments on their own do not often secure the understanding and the effective answers they promise to offer, and how the appeal to adequately formulated models (and a good use of them) is able to explain why. In the second half of the chapter, we will deal with how a particular category of models – causal models – relates to some types of social experiments, and with what consequences. We will briefly describe what causal models are, and we will then detail what we can learn from using them that we cannot apprehend by following a strictly experimental methodology. A number of examples will assist us in this task. They will point out:

1. How causal models can identify what necessary factors are decisive in increasing the chances of success of a course of action or an intervention
2. How using these models makes us realize how the results of an experiment can work in different contexts, or identify the reasons why they do not/cannot work in some
3. What is entailed by the expression *why something happens the way it happens*, and why causal model are well equipped to achieve this goal.

The overall aim of this chapter is not to provide a comprehensive taxonomy of social models, nor to offer a literature review (a task well pursued in Chap. 42 in this handbook). Here we focus on a selected range of issues that make us reflect on the *use* and *usefulness* of models (or at least some types of models) in social practice.

## 52.1 Unrealistic Assumptions

Cartwright claims that at least some models function like *Galileian thought experiments*. With these models, arguably, unrealistic assumptions are a necessity, not a hindrance. What is a Galileian thought experiment? In *Cartwright's* own words [52.7, p.4]:

“A Galileian thought experiment isolates a single factor to observe its natural effect when it operates *on its own*, and *without impediment*. [...] In a Galileian thought experiment it is the principles built into the model that determine what the effect must be. [...] the thought experiment has only the factors in it that we put there. So we can be sure that confounders are absent but we cannot be sure the effect is right because that depends on the principles we provide in the model.”

Two bodies move inertially only in the absence of forces, only if they move in a Euclidean framework, only if they travel on geodesics (shortest distance between two points), etc. The loss of skills during periods of unemployment makes unemployment persist in the future if skills matter to productivity, if the creation of new jobs is motivated by firms' expected profit, if loss of skills is predominantly due to unemployment and not to other factors, etc. This model was studied by *Pissarides* in [52.8]; discussed in [52.7].

So, there is no guarantee that we learn the right lesson *vis a vis* the factors singled out by the model. Nonetheless, these models have a virtue, namely that of eliminating all sorts of intervening circumstances and interferences real situations are frothed with. And this somehow breaks it even *vis a vis* real experiments, where also we are not sure whether an effect is due to natural law or to intervening confounding factors.

However, the problem with this way models function is, if we follow Cartwright, that they find themselves by necessity introducing much more unrealistic assumptions than those required to isolate the factor from confounders. So, for example, in order to isolate a particular cause we need to produce a suitable background for that cause to operate appropriately (causes do not work in isolation). Or else, things are to be presented in rather particular ways within the model if calculations are to be made possible, and often this requires mathematically tractable descriptions which take into account almost exclusively the results that the model is equipped to handle. So these models end up being over-constrained. They are to include all the conditions and factors that the model requires in view of successfully isolating its factors. This indeed becomes a problem when we include all these conditions and factors in the deduction of the results in the model: learning

a lesson that goes outside the rather special framework set out by the model and meets its target proves difficult.

Part of the problem, Cartwright argues, is that we wrongly try to learn a lesson directly from the model, and from within its own boundaries and premises. We expect that a model behaves like a fable, from which a *moral* can be extracted. For example, in a fable like the one constructed by Lessing – “a marten eats the grouse; a fox throttles the marten; the tooth of the wolf, the fox” (Lessing 1759, Sect. I, p.73; quoted in [52.9, p. 39]) – the moral can be *read out* of the fable itself – *the weaker is always prey of the stronger*. With models we find ourselves in a different situation. The move from the model to the target is not written in the model, nor should be provided by it. And it is not obvious, nor automatic. We might need a good deal of interpretation, theory, empirical work, etc. to fill in the gap between what is stated in the model and what the model, in its own language, points out about its target (outside the model). *Filling the gap*, and in ways that cannot be straightforwardly inferred from stated premises, is the way models pursue the task of letting us learn a lesson that goes beyond their boundaries. That is why it has been suggested [52.9] that we should think of them as if they were parables – where morals are not written within them but where “the prescription for drawing the right lesson must be supplied from elsewhere” (from Greek *parabolein* → to set beside; *para* = besides; *ballein* = to throw).

Besides, when we refer to a *moral*, there are two aspects to consider: what the moral says literally (the weaker is prey of the stronger) and how we value what it says (it is wrong that the stronger takes advantage of the weaker). If the former aspect is difficult to infer directly from the model, the second is even more difficult – as we will point out by means of the example to follow.

### 52.1.1 Quality of Life

By means of this first example I will analyze a model of measurement of a social concept that is particularly relevant in terms of both research design and policy implications. I refer to the model of QALY (Quality Adjusted Life Year) that is meant to assess the worth of a treatment/intervention in the context of the *quality of life* of a patient, and by comparison with other patients' life expectancies. Models of this sort are certainly timely if we consider that, at least in modern Western society, there has been a considerable progress in cures, care, and medical technology, as well as improvements in early diagnosis of potentially terminal illnesses, or of those pathological conditions possibly leading to lethal

illnesses. As a consequence, there has been an increase in the occurrence of so-called chronic or degenerative diseases, which modern medicine is able to treat and, within limits, to control by postponing the moment of acute crisis and eventual terminal resolution.

Due to this emergent scenario, a new social attitude toward the process of illness and death has come forth. *Taking care* of the extension of time that modern medicine is able to secure to more or less severely diseased people has become a form of social duty for institutions and social organizations in modern Western society. Social investment on care leads to improved conditions of care, and better conditions of care mean increased opportunities for survival.

This new scenario, however, clashes with the well-known and established fact of the limited resources that can be allocated to care/cure in our societies. So the *quality* of life as extended by social and medical progress is to be assessed in the context of how limited resources can be best distributed in view of maximizing health and health improvements. Cost–utility analyses and econometric tools have been devised to create standard measurements that can account for both quantity and quality of life. Since the 1970s, measuring the quality of life has become a constant topic of interest for those social scientists involved in fields of research such as epidemiology, or health economics, with potential applications in practice and policy [52.10, 11]. Models of measurements have been since used widely in health-care policy making and by institutions such as the National Institute of Clinical Excellence (NICE) in the UK.

So, how can we calculate how much quality one’s life possesses which makes it, objectively and reliably, both worth living and investing resources on? QALYs are an interesting case for what we are discussing in this chapter, as the models on which these measures are based put forward a series of problems akin to those we have discussed in the preceding section.

### 52.1.2 QALY: What Are We Measuring?

QALY stands for *Quality Adjusted Life Year*. It is a formal tool that allows to quantify the health benefits consequent to some treatment/intervention, and to make comparisons with other treatments/interventions. How does it do that? By valuing health states in terms of utilities, and by valuing life-years in terms of preference weights. Health states are weighted by associating utility scores to them. *Alan Williams* summarises the QALY measurement rationale as follows [52.12]:

“The basic assumption is that it takes a year of healthy life expectancy to be worth 1, but a year

of unhealthy life expectancy is regarded as worth less than 1. Between 1 and  $-1$  there are a number of intermediate states of health (death = 0), each of which is given a value. Its precise value is lower the worse the quality of life of the unhealthy person (which is what the *quality adjusted* bit is all about).”

The efficacy of health-care interventions is quantified not only on the basis of life expectancy (how many extra years an intervention can predictably grant) but also on the quality of life that those very interventions possibly achieve. For example, an intervention that secures 10 years of extra life at full health would have a QALY value of 10. An intervention that improves quality of life from 0.5 to 0.8 for a person with a life expectancy of 30 years, would have a QALY value of 9. [0.3 (0.8–0.5) multiplied by 30] [52.13].

How is a *state of health* defined? Typically by parameters (or dimensions) and levels. For example, *Rosser* and *Kind* [52.14] define a *state of health* on the basis of two parameters: an objective invalidity and a subjective pain. Objective invalidity is subdivided into eight levels, and subjective pain into four. Both invalidity and pain are not referred to specific diseases (see Table 52.1).

How are states of health valued? As we saw above, utilities are attached to health states, based on prefer-

**Table 52.1** Classification of states of sickness (after [52.14, p. 349])

Disability	
1.	No disability
2.	Slight social disability
3.	Severe disability and/or slight impairment of performance at work. Able to do all housework except very heavy tasks
4.	Choice of work or performance at work very severely limited. Housewives and old people able to do light housework only but to go out shopping
5.	Unable to undertake any paid employment. Unable to continue any education. Old people confined to home except for escorted outings and unable to do shopping. Housewives able only to perform a few simple tasks
6.	Confined to chair or to wheelchair or able to move around in the home only with support from an assistant
7.	Confined to bed
8.	Unconscious
A.	No distress
B.	Mild distress (slight pain which is relieved by aspirin)
C.	Moderate distress (pain which is not relieved by aspirin)
D.	Severe distress (pain for which heroin is prescribed)

ences for different states, and in such a way that the most preferred (or most desirable) will receive greater weight (1 = full health; 0 = death; 0 to 1 = not full health; -1 = bad/worse/worst health). The QALYs are then calculated by multiplying the utility score by the time spent in each state.

Who attaches utility scores to health states? The values are normally established via interviews. The interviewees are either members of the public (who are asked to imagine being in a particular health state), or patients (who are experiencing, or who have actually experienced particular health states). There is a lively debate on who is in a better position to be interviewed for the purpose of calculation. In Rosser and Kind's model, the sample of interviewees is mixed – about 70 subjects including patients, doctors and nurses, and a number of healthy people. During interviews subjects were asked first to mark each state according to the severity of each state (including death), and to express numerically comparative judgements among states – for example, how many times a person in the state  $x$  is *more ill* than a person in the state  $y$ , etc. Then, they were asked to indicate (by being given appropriate statistical information concerning the prognosis of patients) the proportion of resources to allocate for the cure of the various states.

The scores and data emerging from these calculations are to be used first of all to establish the quality of life of a patient as the result of a cure – as in the intentions of its creators as well as of its supporters (e.g., Williams [52.15] as quoted in [52.10]). For example, a patient who without treatment would continue to live for a further 20 years in state 4A in Table 52.1 would enjoy 19.28 QALY. If it is assumed that treatment  $x$  will facilitate a complete cure and add a further 10 years to the patient's life, then a further 10.72 QALY would be yielded. If we assume that an alternative treatment  $y$  would give the patient 35 years of life but with slight disability the QALY can be used to assist deciding which treatment to use [52.10, pp.32–33].

Second, the outcomes of calculations are meant to assist in deciding in what way available resources for treatment could be equally and efficiently distributed. Once the QALY value of a health-care intervention is calculated and its cost is known, it is in fact possible to calculate the cost per QALY of each intervention and provide a direct comparison between interventions (generally high priority is given to health-care activity where the cost per QALY is as low as it can be). Overall, an evaluation on the basis of QALY takes into account the costs of a range of interventions relative to the changes in terms of quality of life and to the projections of life expectancy as a consequence of the interventions themselves.

On the basis of all these considerations, QALY measurements are taken to be as much objective a tool as possible to decide, in real-life situations, how limited resources can be distributed in the community of people in need of treatment and care. However, they also raise a number of controversial issues. Some have to do with the methods of calculations of quality adjustment factors, others with the assumptions made by the underlying model of quality these measurements entail. In what follows I will focus on the latter, as the problems raised by the model's assumptions reflect some of the concerns expressed in the previous section.

### 52.1.3 Unrealistic Utility Assumptions

The utility model informing QALY measurements assumes that there are *facts* about human life that can arguably be used as criteria to decide whether a life is more worth living than another (or worth living at all). *Good health* is one of them: It is a fact that good health is a highest ranked preference among people. What the model implicitly asks us to do, then, is first of all to assume a type of *ideal life*, on the assumption that there is one that is the most preferable, in the absence of any intervening circumstances. This is the *healthy life*. Secondly, on the basis of this type of life the model asks us to choose between types of real life, where health approximates by a multitude and variety of degrees to the parameter set up by the ideal life. This second assumption (types of lives are equally comparable) becomes, for example, explicit when, once confronted by the alternative between a brief but healthy life and a long but unhealthy one we are led by the model's calculations to prefer the former. (Of course the extent to which this is true will depend on the weights.)

Now, these assumptions work for the purpose of the model (they allow to calculate QALY), but at a cost. As I said, the model seems to advocate, as a term of comparison, a picture of *ideal life* construed on the basis of measurable and comparable *facts*. However, in order for such a picture to work in the way the model requires, a series of further assumptions must be put in place that seem to make the model *overconstrained*, in the sense explained in the first section. For example, it is assumed that what matters is not just life but a trade-off between life and quality; that the just distribution of resources maximizes the thing that matters (qualys); and that a combination of real people's preferences plus more *objective* facts such as invalidity and pain is the way to decide on the quality of life (at least for the purposes, set out by the model, of deciding on the distribution of resources).

Equally, the questionnaires the interviews are formulated on assume that: Individuals' bias toward

certain kinds of diseases or handicaps are excluded (weights are assigned by the people interviewed on degrees of invalidity and pain independently of types of illness); individuals' beliefs (religious, moral, or other) concerning, for example, the absolute value of human life do not interfere with assessment, or can be set aside for the sake of policy deliberation; individuals are, or can be forced to be (by means of policy) *altruistic*, in the sense that they should not expect an action to be performed in their own interest should it prove detrimental to others (e.g., they would not undertake some medical treatment which is not widely available because some other people rather than themselves might benefit from that very treatment, according to qaly criteria, or from other treatments at equal cost, etc.). One might indeed argue that there is a difference between interpreting the model from the side of the policy that it is meant to guide or from the side of the individuals that a policy is meant to protect; and that the reasonableness of a policy, or the practical issue of how we get everybody to agree on a course of action, should be treated separately from the model. Nonetheless, in order to calculate benefit in terms of QALYs the model needs to assume that individuals choose within the constraints described above.

All this means that an overconstrained model ensures that its results follow, but only under the rather specific and often unusual conditions the model requires for reaching those results. And "[...] unrealistic assumptions that overconstrained the results are a problem for learning lessons that apply elsewhere [...]]" [52.7, p. 4].

There is a further assumption that detrimentally forces yet more constraints on the model. QALYs, as we said above, measure benefits in terms of utilities, and the utilities in QALYs' terms are the extra years of life, adjusted for quality, granted to people by allowing certain treatments. Benefit (this is the model assumption) is what the model isolates in order to study its effects without confounding factors. Obviously, when it comes to health, benefits are important, and QALYs have an important role to play in guiding how to distribute limited resources. But if the model is to focus exclusively on benefit it must introduce extra assumptions to allow a correct analysis and delivery of outcomes; and this gets in the way when we then come to *read out a moral* from the model that has an impact on real target situations outside the model.

One of these extra assumptions is the neglect of fairness. Benefitting from treatment is not the same as deserving treatment. In real-life situations individuals (healthy or not) weigh quality not just on their desire for health but on their desire to live, admittedly as long and as well as possible, and to a larger or lesser extent

independently of intervening circumstances. A focus on QALYs seems to obscure fairness: Giving priority to those who better benefit from treatment is not necessarily the fairest choice. It might make us discriminate the old for the sake of the young, for example, or more generally those in a better position to benefit from treatment [52.16, p. 196].

When we use a model to guide us in real-life situations, the results we aim at should prove to be right both in the sense of being correct and in the sense of being just (of the type: the stronger abuses the weaker – and it is bad that it does so). Instead the *moral* we read out of an overconstrained model seems to confuse what is right in terms of the models' assumptions with what is right for reasons that might go well beyond the boundaries of the model.

Such confusion might also give the impression, or the illusion, that the model's scope is wider than it is. For example, could the model be used to assist in the thorny and controversial debates on euthanasia? Indeed, QALYs are meant to offer guidance in assessing what makes a life *bearable*. The state of death is very much part of the benefit calculus. In the original matrix of Rosser and Kind's model (Table 52.1), states such as *being confined to bed with moderate pain* or *being on a wheelchair with intense pain* were marked on average by the interviewees at the same level as the state of death. States like *permanent loss of consciousness* or *being confined to bed with intense pain* received a value even inferior to that given to death. In such cases, it would appear well justified to terminate somebody's life, both from the side of policy (distribution of resources) and from that of the interest of the individual in question (bearability of one's life). Allowing an individual in that kind of pain to terminate his or her own life (or helping him to achieve this) would be based on an objective assessment of that life's quality (or lack of it).

*Barrie* [52.17, p. 1]:

"In a climate where evidence-based decisions are valued so highly, numerical measures that provide a guide to quality may be more widely used and trusted than general ethical concerns about the elderly or very sick that cannot be expressed in the same quantifiable terms."

However, social debates surrounding euthanasia teach us that decisions about the right to die, when the desire to live has ceased, can hardly be made on the basis of a concept of quality as calculated in terms of a benefit for the people whose right to die is at stake. QALYs calculations seem to assume an equivalence between the fact that some health states make somebody's life so unbearable that he/she is better off dead than

alive and the idea that actively pursuing the termination of somebody's life is more beneficial than any of those states [52.17, p. 2]. 0 utility score or negative scores indicate that death is preferable, but do not indicate that death has to be procured or induced. The fallacy in the underlying reasoning consists of making us infer from a state of fact (supposedly backed up by empirical evidence: We know how to calculate how bearable a life is) a state of principle (it is acceptable to allow somebody to die, or to terminate his/her life). If the model is to inform a decision regarding the right to die, a whole series of factors and conditions, well beyond the boundaries of the model, must be put in place. Let us see what some of them are by means of a discussion of some real cases.

In 1973, George Zygmanski was involved in a motorcycle accident near his house in New Jersey [52.18, pp. 177–178]. As a consequence, he was confined to a hospital bed, paralyzed from the neck down, with no prospect of recovery and in severe pain. This is a typical case that in terms of QALYs would receive a utility score below 0 (e.g., in Table 1 and 2 in Rosser and Kind's model above). George Zygmanski told his doctor and his brother Lester that he did not want to prolong his life in such a state. In fact, he begged them both to kill him. One day Lester went to the hospital smuggling in a pistol. He asked George once again whether he wanted his pain to be ended. George, who could not speak any longer, because of an operation performed in order to ease his breathing, nodded. Lester shot him.

Several levels of questioning become relevant in this episode. First, a factual-empirical level: Was George right in preferring death to life? This is a question that, as mentioned above, could be put in terms of QALYs. At a different level we can ask: Was George right in asking to have his life terminated? Here a QALY calculation runs short of answers for the host of questions that come to the fore. Did Lester have sufficient evidence to be able to assess objectively, in a "once and for all" manner, his brother's physical and emotional condition? Is such evidence to be used as the only deciding factor in a plea for death? Was Lester entitled to act upon his brother's request? Or was he just a murderer? Should a doctor have taken the responsibility of carrying out the termination of George's life by less extreme means (e.g., by giving George a lethal injection)? Were the actors involved in this episode violating a moral code, or any particular moral rule (e.g., it is wrong to kill) – besides violating legal rules? How do the two sets of rules interact with each other? If, for example, George Zygmanski lived, rather than in New Jersey, in the Netherlands (where doctors are by law entitled to help their patients to die), would this very fact lift moral responsibility, and bypass moral judgement for all and

each of the actors involved? These, and more, are the questions that make the debate on euthanasia so controversial.

A second real case involves an infant known to the public as *Baby Jane Doe* who was born on 11 October 1983 in New York suffering from multiple defects, including spina bifida (a broken and protruding spine), hydrocephaly (excess fluid on the brain) and microcephaly (an abnormally small brain; in this case part of the little girl's brain was actually missing, as a CAT-scan revealed). The baby's parents were told that immediate surgery on the spina bifida abnormality would have given their baby a 50–50 chance of surviving until her twenties. However, even in the case that she did survive that long, their daughter would have never have a chance to lead a normal life: She would be severely mentally retarded, physically impaired, paralyzed, epileptic, confined to bed, and in constant risk of serious diseases and infections. Without surgery, the baby would have died in 2 years.

In the face of all these, the parents chose not to let the doctors proceed with the surgery. They reasoned in intuitively QALYs terms: a 50% chance of life extension with severe disability (supposedly below the 0 score) achieved by means of risky surgical procedure is worse than a 100% chance of expected 2 years with severe disability with no surgical intervention.

The questions that can be addressed in this second case entail an even more complicated set of variables than the previous case. First, in asking whether the baby's parents were right, and justified, in making their decision, we have to take into account that the decision was made *on behalf of* their baby daughter. We should also acknowledge the fact that the parents' decision was probably made taking into account their own future – practical as well as emotional – in the upbringing of such a severely disabled individual. Secondly, in asking how and how far did the factual evidence offered by the doctors influence the parents' decision, the extent of the disability at stake added strain and uncertainty to the decision-making process. As a matter of fact, the medical profession was split over the evidence: For some doctors the baby's condition was not as hopeless as had been presented to the parents. In this uncertain scenario, Lawrence Washburn, a lawyer associated with some conservative right-to-life groups, brought the case to the Supreme Court in New York State to be reassessed, and a federal investigation was issued against the hospital to determine whether there had been discrimination against a handicapped person.

The relevant question seems here to be the following: Should everything possible be done in order to save a severely disabled life? Or else, should the severely disabled be left untreated since there is no ben-

efit in prolonging their lives? These questions cannot be appropriately addressed by resorting to QALY calculations (or in this case, DALY calculations: Disability Adjusted Life Year). Health benefits are important, as we noted above, but if the model QALYs are based on is to provide a guide to make decisions in real-social cases, issues of fairness should also be considered. If we want a moral of the type *the weaker is prey of the stronger* to mean that *the weaker should be defended against/protected from the stronger* we ought to import a story into the model (or put the model in the context of a story) such that fairness to the weaker becomes as important to the deduction of the model's outcomes as it is benefit. Prioritizing treatment on those who are most likely to benefit from it is not necessarily the fairest thing to do. This however does not necessarily mean that QALYs are unusable, it means that "they cannot entirely determine which decision is the right one," a limitation that has not always been acknowledged by QALYs' sympathizers [52.16, p. 196].

The two cases just described put us in front of real dilemmas: How can I put an end to the suffering of my paralyzed brother? Should I let my severely handicapped daughter die? Faced with the complexity of such questions, the *moral* that is supposedly written into models à la Rosser and Kind appears thin, besides being dubious. The objective conditions of a state of health combined with the benefit of treatment are not sufficient/adequate to conclude that a certain course of action is to be pursued. The *moral* of the model is not simply the logical conclusion of a deductive inference. To continue with the same example, the concept of a *bearable life* brings us to question, by adopting a vocabulary that not only includes reference to the biology of individuals, whether for a human being all we need to assess, when we consider bearability, is its QALY value.

*Quality of life* in the model is not equivalent to *quality of life* in the target system: It is a specific construct of the model that is simultaneously constrained (and over-constrained) by the model's chosen assumptions. The *world in the model* in the case of QALY perfectly exemplifies the double ontological regime that was pointed out at the beginning of this chapter (the model creates a world out of its own premises; the world outside the model is selectively targeted via the focus created by the model's assumptions).

What use can be made of models like Rosser and Kind's then? What reliable guidance do/can they offer to making objective decisions? Their contribution can be significant (once their formal framework has been checked for rigor and internal validity) provided that (1) their limited domain of application is acknowledged; (2) their contribution to decision making is not taken to be *ready-made* (a direct consequence of the *objectivity* of the cost-benefit analyses of the model). A lot of further work is needed to fill the gap between a model and the world the model is asked to help us with. A complex background of social, ethical, legal considerations is to be spelled out. Scientific considerations also enter this background – in the case of medicine, for example, by offering evidence and degrees of care that help individuals to weigh reasons for and against certain options, and by taking on some of the responsibility in suggesting certain options as the most or the least favorable.

Unrealistic assumptions in the models do not necessarily detract from the objectivity of decisions based on such models. They however both give boundaries to what we can be objective about, and force us to acknowledge the complex and controversial variety of issues brought forward by the particulars of real-life situations (as the cases described above point out) that the model intends to target [52.19].

## 52.2 Real Experiments, Not Models Please!

So far in this chapter we have showed the limits of using models in representing target systems (in our examples, real-life situations) and the costs in terms of including assumptions that make models work by becoming untrue to the systems they are meant to target. In the light of what we pointed out, would then rescuing their applicability and good use be too demanding a task? Are we, all in all, better off without them?

There is nowadays an established trend to prefer the results achieved by well conducted experiments in social science, and to trust their outcomes over those pursued by other methodologies. In particular, random-

ized control trials are by many considered the golden rule to doing good social science, namely science that produces results that are not only theoretically adequate, but reliable and useful when made available in practice (e.g., when informing a policy program).

A randomized controlled trial (RCT) is an experiment in which investigators randomly assign eligible subjects (or other units of study, e.g., classrooms, clinics, playgrounds) into groups. Each of the groups receives or does not receive one or more interventions (e.g., a particular treatment). Then the results are compared, and if the observed outcome is statistically

significant, then it can be concluded that it has indeed been caused by the experimenters' manipulation, that is, there is a high probability that the intervention actually works. Blind procedures (single, double, triple, to even quadruple) are often used to control bias.

Experiments of the type of RCTs ably answer the question *what works* that seems to be the question that most concerns the field of policy making. However, it is often the case that restricting policy making to answering this question ends up not only in policy failure, but also in an inability to understand and explain why something (e.g., an intervention, a treatment, etc.) does not work, and then possibly put it right. Here is where models can help, in particular causal models. Being able to formulate *why it works* questions give policies a better chance to work better, or to work at all. Let's see what these models consist of and – by means of a few examples – how and where they prove most useful.

### 52.2.1 Causal Models: How Can They Come to the Rescue

What is a causal model? Described in general terms, it is a representational tool that describes causal relations among a set of variables. These models suggest hypotheses about the presence of, and direction of influence between, these variables by mapping them by means of a variety of descriptive devices, such as path diagrams, flow graphs, or causal pies – to name just a few (see below for some graphic representations).

The definition of causal models, as set out above, appears though obscure if relevant bits of terminology are not explained. What counts as *causal relation*? What are the *variables* that enter such a relation? Where do the *hypotheses* that models suggest come from, or where are they grounded? Without entering too much in detail, to understand the functioning and the purpose of these models the following is, at the very least, essential.

First, what are the items we call *variables* in a causal relation? In the social sciences the relations could be kinds of situations (e.g., mothers' education and child survival, size of classes and children performance), or a type of *population* (e.g., children in a school, an audience in a theatre, the over-sixty in good health in a national statistic), or indicators (e.g., aggressive behavior, social isolation, fear of failure in the context of child abuse, or consumer price index, money supply, consumer confidence, retail trade sales in the context of the state of an economy). Variables can be depicted at different levels (individual, social, ecological) or can be described (and indeed constructed) by means of different theoretical tools, or concepts. Understand-

ing how they are depicted and/or described is important to understand and evaluate the causal relation in which they find themselves associated.

Second, a *causal relation* is not simply an association of variables. The goal of a causal model is not only to express co-variation, but to evaluate how and why co-variation occurs. This is what constitutes *the hypothesis* put forward by the model, that is a suggestion of why variable  $x$  influences variable  $y$  and how the way  $x$  and  $y$  are related contributes to a certain outcome (output  $z$ ).

So third, the hypothesis is set out to understand what makes the variables be relevant to each other and draw a structure that the model is meant to represent. The hypothesis is formulated by means of a series of assumptions grounded in some background knowledge, or some theory (when present). The better established is the background knowledge, or the better accepted the theory the model appeals to, the better grounded are the assumptions that help formulating the model's hypothesis. Neither background knowledge nor theory are guarantors that the hypothesis is correct (once and for all). There is no well-rehearsed recipe to build up a good causal model. This does not mean that there is no justification, or degrees of confidence, for how a model identifies or describes a causal relation. Typically (though not necessarily) the causal relations in these models are represented in a statistical form by means of systems of equations. However, it takes a good deal of judgment, detailed information, and awareness of local factors – some or none of which, often, available in advance, or in abstract/general terms – to achieve any degree of justification. Model building, especially in the social domain of inquiry, where theories are scanty and information routinely disputed, is itself hypothetical, and tentative.

So why are these models useful? Where and how are they most useful?

### 52.2.2 Class Size Reduction Programmes

In the 1990s there was growing concern about the poor performance of primary school children in California [52.20, 21]. A program was implemented to reduce class size in view of improving children performance. Not only it appeared plausible that children in small classes are more closely and easily looked after, and therefore learn more and better. There was also evidence that this is actually the case. The evidence was provided by the results of the STAR program, run in Tennessee starting in 1985. A 4 year RCT, involving 79 schools (around 7000 children from kindergarten to third grade) looked at how small(er) classes might lead to improved academic performance. Class size was brought down from an average of 22–25 children to an

average of 13–17, and children and teachers were randomly assigned to the smaller classes. The results of the RCT established that reducing class sizes improved a number of educational outcomes in children.

California endorsed these results, and in 1996 fed them into issuing a policy of class-size reduction that, however, resulted in failure. There were a number of reasons that accounted for the failure. The reduction program was implemented over too short a period (from spring to the following autumn). California needed to hire extra teaching staff, and given the short time of implementation the quality of teachers was not carefully assessed. Smaller classes meant more space that Californian schools did not have, which also meant that space was taken away from other activities in children’s curricula (with consequent decay in other areas of children’s education, such as music, arts, physical activities).

Was there any way to rescue the California program, and the intuitively plausible idea behind class-size reduction? We might think that, in order to achieve that, more experiments were needed, over longer periods, in different places in California, or in places other than California – in view of gaining more data and better evidence. But perhaps a change in strategy would be more appropriate, and more efficient in policy terms: What if the program needed a good causal model? Let us explore what this second option involves, and why it might have provided better results [52.22, 23].

First, if we compare the Tennessee and the California programs, two factors consistently emerge that, by being present in the former context and absent in the latter, contributed to either success or failure: space and quality of teaching. These two factors can be mapped into a number of purpose-built causal models. One of them is a *causal pie* showed in Fig. 52.1.

In this model, each slice representing a factor must be present if we want to have a pie (i. e., make the pol-

**Fig. 52.1** An example of pie diagram for improved learning scores (original drawing by Alex Marcellesi)

icy – reduce class size – hit the target – improved child education). The point of the pie model might go missing if we think of factors in terms of slices (indeed, even if we *eat* one slice there is still a lot of pie left). Perhaps a better representation of factors in the pie model is in terms of ingredients: all the ingredients are equally necessary to bake our pie; should one of the ingredients be missing then we end up with no good pie, or even worse, no pie at all [52.22, p. 63]. Of course, the pie model can be extended to include more factors than the two pointed out above, with the result of showing more accurately what is required for predicting whether a policy will work.

Another way of representing how the necessary factors interact and with what results is using *causal path* models.

In this type of model arrows link factors in cause-to-effect relations that include both positive and negative outcomes (Fig. 52.2). It can also be used to represent side effects to the policy to implement (which is something that causal pies are ill equipped to account for: these can just show what it takes for a pie to be baked, independently of whether I could get a sore tummy after eating it).

The graphic resolution of these models does not prevent from representing them quantitatively (e.g., Monte Carlo simulation).

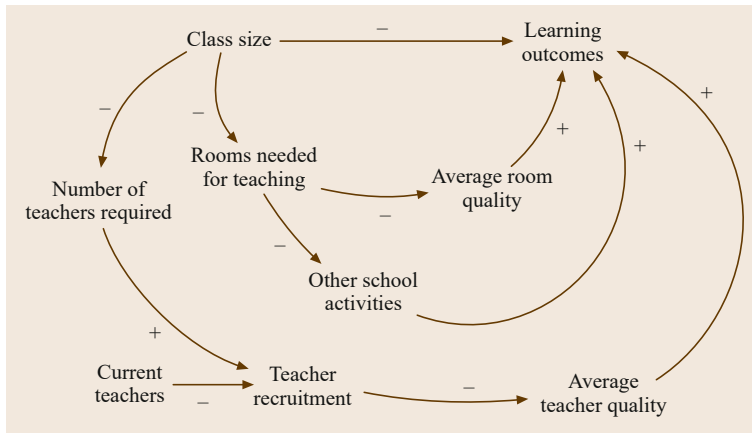

Good causal models will at the very least pick what factors are needed to get a policy to achieve (or maximize the chances to achieve) a certain outcome, and what other factors (positive or negative) might a policy bring into a purported setting of implementation, with what either beneficial or detrimental outputs. The point of using these models is to understand, in advance of implementing a policy, what is needed to increase the chances for a policy to work in specific settings or circumstances. The fact that a policy worked *there* is no evidence, or reason, that it would work *here*, let alone *anywhere* [52.22, Part II] – as the following example will clearly show.

### 52.2.3 TINP and BINP

RCTs provide strong evidence for the conclusions concerning a study population. In this sense, it is said that well-conducted RCTs are *internally valid*: on the basis of agreed upon premises certain conclusions must consistently follow for the target population. The agreed upon standards are usually identified by a number of formal requirements, which are taken to secure the consistency of results (the reasons why they obtain and why they are considered to be valid).

RCTs are often also expected to be *externally valid*: The *same intervention* adopted for the study population

**Fig. 52.2** A path diagram for improved learning scores (original drawing by David Lane)

has the *same result* when used with a new population deemed sufficiently similar. However, how can we decide whether the new population is sufficiently similar? Often apparent similarities can be misleading, and yet there is little guidance as to how to apply the findings of an RCT across contexts. Using causal models can be of some help here. Let us see how.

Children malnutrition in developing countries is, and has been for a while, a huge, pressing challenge. Globally an estimated 165 million children under 5 year of age are stunted (i. e., height-for age below), and more than 90% of them live in Africa and Asia. An estimated 101 million are underweight (weight-for-age below) [52.24].

Several international programs have been launched over the years to tackle the problem. One of them is the Bangladesh Integrated Nutrition Project (BINP), implemented in 1995 by the World Bank. It was a growth-monitoring pilot program, modeled on an acclaimed successful predecessor, the Indian Tamil Nadu Integrated Project (TINP).

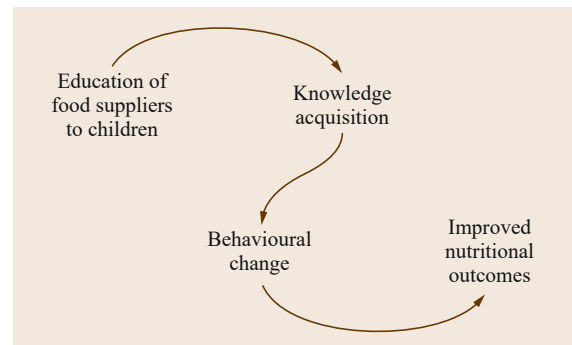

What these programs integrate are nutritional education, food supplementation and health measures, with a particular emphasis on the education aspect. They admitted children who were growing insufficiently (after being monitored at purpose-built local weighing centers) or showed evident signs of malnutrition. They also targeted the children's mothers, as well as mothers-to-be, in the belief that "ignorance, rather than poverty, was to blame for poor nutrition" [52.25, p. 5]. Both programs covered rural areas which had on average the worst nutritional records among children.

However, unlike TINP, the Bangladesh pilot program turned into failure when implemented at a national scale (and it reached almost negligible success at local scale too). After 6 years, and despite documented evidence that the educational message had reached the project population target, malnutrition did not fall at

any significant rate [52.26]. On the basis of evidence of unsatisfactory impact the World Bank discontinued the project.

Why things went wrong in Bangladesh, and not in Tamil Nadu? Were Bangladesh and Tamil Nadu not *sufficiently similar*?

To answer these question let us look at the project design in terms of a casual pathway model (of the type discussed with class-size reduction).

The causal chain, that reconstructs the rationale underlying the nutritional program, immediately reveals what went wrong in rural Bangladesh: here mothers are not the principal food providers. Men go to the market to buy food, and mothers-in-law administer food for everybody in the household.

Educated Bangladeshi mothers could not practice their newly acquired nutritional knowledge to make an impact on their children growth.

A further problem emerges if we look at the causal chain that goes from supplementary food to improved growth in children. In Bangladesh the food provided by the program was not often *supplementary*: Due to the very impoverished conditions of families, it was given *in substitution of* any food, if not ultimately given to somebody else than children (the *leakage effect*). This

shows at least two things: Even a well formulated causal chain should be open to revision and re-formulation in the light of emerging local or circumstantial factors; and the language used to categorize the intervening variables in the chain should be formulated at the appropriate level of abstraction to pick the relevant aspects that set the causal chain in motion, independently of the contextual multiple realizability of the categories themselves.

In summary, good causal models might provide the missing link between internal and external validity, and be a useful guide in moving from *there* to *everywhere* to *here*, in Cartwright-Hardie terminology. They can help us see that the *same* is not the *same* in different contexts, and understand why. They are also flexible enough to endorse the emerging dynamics of the systems they endeavour to understand.

#### 52.2.4 Children Mortality and Inflicted Death

There is one word missing from our discussion: *mechanism*. So far we have referred to causal chains, causal links, causal paths – none of which are equivalent to causal mechanisms. Mechanisms better resonate with the word *structure* that we encountered while describing the hypothesis that informs the working of a causal model. How do mechanism and structure go together [52.27, 28]?

Imagine a black box. What we call causes enter the box, and what exit the box are the effects. But what happens inside the box? What makes the causes *cause* the effects? Said plainly, mechanisms are what explain why *C* makes *E* happen. They account for what happens inside the black box. This is why they are sometimes called *generative* mechanisms. Causal models model these mechanisms – if they are to be used explanatorily to say why certain variables are related in a particular way and direction. They illustrate the rationale underlying a causal chain, or link, etc.

What about *structure*? A structure is a relatively stable arrangement of components that brings about a particular outcome. It is this type of arrangement that in philosophy of biology is often called *mechanism*. And it is this arrangement that a model tries to reproduce, in view of mapping why something happens the way it happens. A mechanism is what makes us see what a structure can achieve, what is its output. Conversely a structure is what allows a mechanism to function the way it does.

The expression *why something happens the way it happens* requires some unpacking. To say why something happens we need a mechanism able to explain why an identified structure of variables achieves an out-

come. To explain the way it happens we need, besides a mechanism, a number of further conditions (often local, or specific to circumstances) that account for the fact that something actually happens, and in the way it does (in the circumstances). Modeling a causal mechanism should then include the structure, its functioning, and the constellation of *support factors* that jointly account for the achievement of an outcome [52.22, p. 44].

Let us look at an example similar in some respects to the one discussed in the previous section [52.29, pp. 21–23, pp. 162–65]. In a seminal article Caldwell famously argued that mothers' education is [52.30, p. 408]:

“the single most significant determinant of these marked differences in child mortality. These are also affected by other socio-economic factors but no other factor has the impact of maternal education [...]”

Why? Caldwell does not only rely on empirically established statistical correlations between rates of mortality among children and the level of education of their mothers. He tries to unravel the mechanism that relates the two variables. Mothers' education is not as such a *cause* of anything, we need to explain how it comes to perform this causal role vis a vis a specific outcome (decreased mortality rates in children).

Caldwell argues that educated mothers are more capable to interact with “the modern world” (doctors and nurses) and been listened to; they become less “fatalistic” about illnesses and more pro-active (looking for alternatives in child care); and their education impacts on “the traditional balance of familial relationships with profound effects on child care” [52.30, pp. 409–410]. These are reasons that we would certainly expect to find in a good causal model explaining the role of education in child mortality decline, but on their own they do not constitute a *model* of why this is the case. To build a model, what is also needed is good knowledge of the causal context where those reasons make sense as contributing factors, and a good story (= a meaningful hypothesis) of how they interact and jointly make it believable that education can perform such a causal role. In the process of building such a model, we might well realize first that maternal education requires a host of further factors (socioeconomic, environmental, biological, and ecological) to make the mechanism effective, besides being believable as a model. Second, it also requires that the consequences of maternal education on decreased child mortality (better interaction with modern world, less fatalism about illnesses, beneficial changes in familiar relations) identify a stable enough arrangement of factors that can explain why in a certain

context maternal education is a believable/justifiable cause of decreased child mortality. Building causal models is no doubt complex, building good ones unforgettingly demanding!

And yet, building good causal models proves essential not only for social science knowledge practice, but also for its impact on policy making and social intervention. To give an example of such use and usefulness we can take a final look at the following area of application.

Inquiries in child abuse deaths normally take the approach of blaming human error or fault [52.31]. However these enquiries have not led to any substantial improvement in professional practice. This, according to Munro, is due to the fact that inquiries into inflicted deaths on children take human error not as the starting point, but as a conclusion. However, errors often occur within systems that are ill-equipped for preventing them. A *system approach* is then a more appropriate line of enquiry. This consists in tracing the causal chain that led to a death not so much back to the individual, but to the structural failure of the system that explains why the individual committed the error. This is not to abrogate responsibility but to understand it better, both at individual and system level, and to act on those aspects of the system that allow for mistakes to emerge.

Looking deeply into the causes of error entails identifying the interacting factors, the organizational context and the available resources that made an outcome possible: in other words, it entails an understanding of causes in the context of the social structure and underlying mechanism where individuals operate.

In adopting a system approach “the focus is on the interaction of the different layers of the system so that a more vivid picture is drawn of how the particular case fits into its context” [52.31, p. 12]. The *vivid picture* is what, using a different language, a *model* can provide by mapping the underlying structure of the case investigated and by means of it explaining its causal mechanism.

Modeling a case according to this approach (by means of whatever methods appear appropriate in mapping the context) can then prove to be a crucial help not

only in understanding what happened, but also in trying to prevent it from happening again.

Eight-year-old Victoria Climbié’s death in 2000 is an instructive case. Victoria was tortured and killed by her guardians, suffering 128 injuries during months of abuse and neglect. She was repeatedly hit with shoes, coat hangers, a hammer, a bike chain. In her last days she was made to sleep in winter in an unheated bathroom “bound hand and foot inside a bin bag, lying in her own urine and faeces” [52.32, p. 13]. In the end Victoria died of lung, heart, and kidney failure. During some of the period of her abuse she was seen by four local authorities’ social workers, two protection teams from the Metropolitan Police, a specialist from NSPCC (National Society for the Prevention of Cruelty to Children) and staff of two hospitals where she was admitted as a consequence of severe and suspicious injuries.

What went wrong, it is asked in the Report into her death? “A lack of good practice” is the answer, and a consequent breakdown of the entire system [52.32, p. 15]. Therefore the report’s recommendations are “clear accountability” (who is responsible, especially at the level of senior and experienced managers) and closer monitoring of compliance with principles and guidelines of good practice. Would these measures, had they been in place, “*detected* the poor quality of the service offered to Victoria?” This question, argues Munro, cannot be answered appropriately (and indeed it is not addressed as such in the report) without a “clearer understanding of the factors influencing the poor quality work” of those who were responsible for the failings in this case [52.31, p. 14]. Munro [52.31]:

“Until we understand why those errors looked the reasonable thing to do to the individuals at the time, we cannot devise solutions that ensure that, in the future, they will be more likely to opt for the right course of action.”

If devising good causal models that help us detecting *why something went wrong* (not only *what went wrong*) and designing safer systems of protection might even minimally contribute to prevent the death of a child, this seems a task well worth pursuing.

## 52.3 Conclusions

If models are to guide us in making good decisions, or implementing good social interventions, how can we handle the unrealism of the assumptions on which some of them are based? If models are imaginary structures from which we cannot immediately derive a *moral* concerning their target systems, how much supplementary work (and of what type) is needed on them to become an

actual help in learning about real situations? Do models constitute a good methodology of social intervention or policy, or are experiments better in providing socially useful information? Should experimental methodology be found lacking in some respects, could models (at least some types of models) be used, and be useful, to tell us where experiments go wrong? The examples pre-

sented in this chapter offered some suggestions as to how to answer these questions, and handle some of the controversial theoretical issues that emerge when models are used in social practice. The overall aim was to show that, if we learn how to use models and what to expect from their use, they are a real asset both for social scientific research and for social policy.

**Acknowledgments.** Nancy Cartwright, Eileen Munro, and Jeremy Hardie have provided most of the ex-

amples and case studies presented in this chapter, and which have been part of discussion in the research project *Evidence for Use* (Centre for Philosophy of Natural and Social Science, London School of Economics and Political Science).

The quality of life example is discussed in E. Montuschi, *Oggettività ed Evidenza Scientifica* (Carocci, Roma 2001), Chapter 5.

I am grateful to Federica Russo for reading and advising on the pre-final draft of this chapter.

# Models and

## 53. Models and Moral Deliberation

Cameron Shelley

It is clear that models embody or encode information about moral values and moral conduct that is frequently important in moral deliberation, that is, the process of solving moral problems. However, there is a diversity of views on how models perform this function. In part, this diversity is due to the well-known diversity of views on the concept of model itself. Naturally, scholars with different views of what a model is produce different accounts of their place in moral deliberation. As a result, the shared involvement of models in these accounts has been largely unnoticed. The purpose of this chapter is to review the main, varying accounts of models and model-based reasoning in moral deliberation. These accounts include models as rules, as mental models, schemata, analogies, empathy, and role models. These accounts emphasize different aspects of moral deliberation. Rule-based accounts tend to emphasize morally generalized information concentrated in a set of rules and a cognitive style based on calculation. Other accounts, such as analogies, empathy and role models, tend to emphasize morally particular

information spread out throughout a large set of source analogs, and reflect the emotional aspects of moral deliberation. Most accounts concentrate on information originating with the deliberators, although role models, conversely, emphasize models that originate outside the deliberators themselves. Hopefully, this chapter invites further work on the relationships among the accounts reviewed within.

Models play an important role in moral deliberation. For example, someone with a sick friend lacking health insurance may consider stealing drugs in order to help out. Reasoning with models may play a role in this deliberation: Would it not be right to steal a loaf of bread if the friend were starving? The latter situation serves as a model for the former in this case.

The purpose of this chapter is to review recent literature on the topic of models in moral deliberation. This objective immediately raises two concerns. First, the term *model* is quite flexible, that is, many things have been counted as models. Thus, the relevant literature includes approaches that bear only a kind of family resemblance to one another; cf. [53.1] on *moral hypotheses*. The approach in this chapter is to accept

this situation at face value and not attempt to restrict the subject matter beyond this accepted practice.

The second concern is what constitutes a *moral deliberation*. Here, the approach is more strict. A moral deliberation is a cognitive process whereby an individual attempts to solve a moral problem. A moral problem is a decision problem in which at least some options for action are morally permissible whereas others are not. The aim of deliberation is to identify the option that is morally preferable.

One effect of this characterization of moral deliberation is that it excludes moral theorizing, that is, reasoning about moral principles or moral values as such. The focus of this chapter is instead on models in individual decision-making. Of course, people may

reason about moral principles in the process of deliberation, but that is a complication that will be set aside here.

Another effect is that thought experiments are also excluded. Many well-known thought experiments, e.g., the trolley problem, rely on models. However, since

these experiments primarily concern the nature or content of moral intuitions or principles, they are not considered here.

The sections below deal with accounts of models in moral reasoning based on rules, schemata, mental models, analogies, empathy, and role models.

## 53.1 Rules

The view that moral deliberation is grounded in rule following is a significant part of modern ethical philosophy. *Immanuel Kant* [53.2], for example, argued that moral behavior requires people to form categorical rules of action and then abide by them. His famous statement of this view is, “Act only according to that maxim by which you can at the same time will that it should become a universal law.”

One of Kant’s examples of this process is a person who sets out to obtain money through a false promise of repayment. To test the morality of this intention, it is first framed as a maxim: if I falsely promise repayment, then I can get the money I want. Next, the maxim is reframed as a universal rule by removing the subjective element: If anyone falsely promises repayment, then they can get money.

Unfortunately, this rule cannot be willed as a universal law, that is, a rule that everyone may follow. If everyone felt free to obtain money by false promises, then no one would willingly lend money since they could not trust the promises of others who follow the same rule. In effect, a world in which everyone feels free to make false promises is a world where promising achieves nothing [53.3].

Kant does not argue that people ordinarily reason in this way when faced with moral problems. Instead, it is a recommendation about how people can distinguish moral intentions from others. However, it is clear that rule following is the foundation of moral deliberation in his view.

*John Stuart Mill* [53.4] also held that ordinary moral deliberation is comprised of rule following. As is well known, Mill held that actions are moral exactly when they conform to the Greatest Happiness Principle: “actions are right in proportion as they tend to promote happiness, wrong as they tend to produce the reverse of happiness.” Mill claims that this principle distinguishes right actions from others but does not hold that people actually reason in such terms when faced with moral problems.

However, he argues that people think in terms of *secondary principles* that aid them in making moral decisions. These he describes as *intermediate gener-*

*alizations* and as working in moral reasoning as landmarks and guideposts do in navigation. The difficulty of making calculations directly on the basis of the Greatest Happiness principle means that people need ready-made rules to follow in ordinary matters of conduct. It is only when such secondary principles lead to contradictions or other difficulties that the primary principle becomes crucial for practical decision making. Mill does not furnish any detailed examples but does continue on to cite common feelings about moral problems. For example, in the matter of justice, he says that, “it is mostly considered unjust to deprive any one of his personal liberty, his property, or any other thing which belongs to him by law” [53.4, Chap. 5]. This rule seems to be an example of a secondary principle that people apply in moral deliberations. Mill then explores its relationship to the primary principle.

Like Mill, *W. D. Ross* [53.5] held that moral deliberation consists in the following rules. Unlike Mill, Ross did not agree that there is a primary principle, such as the principle of Greatest Happiness, that reconciles conflicts among rules. Instead, Ross argued that people follow a set of what he called *prima facie duties* or rules of right conduct. Although he did not furnish an exhaustive set of these rules, he identified seven important ones:

1. Fidelity: People should keep promises and be honest.
2. Reparation: People should make amends for wrongs done to others.
3. Gratitude: People should repay others who have done them good turns.
4. Nonmaleficence: People should not harm others either physically or psychologically.
5. Beneficence: People should help others improve their well-being.
6. Self-improvement: People should improve their own well-being.
7. Justice: People should be fair and distribute benefits and burdens equitably.

In some moral decisions, these rules can be applied straightforwardly. For example, the decision to bribe

a police officer to fix a ticket can be considered to be a contravention of the duty to justice as it seeks to make the fixer an exception to traffic law.

In other situations, however, different duties will suggest incompatible courses of action. Consider an episode of the TV show *Seinfeld* where Jerry and his friends are shown a baby they consider ugly [53.6]. Although the duty of fidelity suggests that they should admit that the baby is ugly, the duty of nonmaleficence suggests that they should say that the baby is cute so as to avoid offending the happy new parents. Jerry and his friends decide that it is a *must-lie* situation in which the duty of nonmaleficence outweighs the duty of fidelity.

Ross' ideas about prima facie duties have been developed in the form of defeasible deontic logics. A deontic logic is a formal logic of permissions and obligations. A defeasible logic is one in which arguments proceed nonmonotonically, that is, where conclusions may be withdrawn or rejected in the face of new considerations.

For example, *Asher* and *Bonevac* [53.7] develop such a logic precisely in order to account for moral dilemmas where different prima facie duties entail contradictory actions. They consider an action from the *Odyssey* in which Odysseus orders Neoptolemus to trick Philoctetes out of a bow that the Greeks need to obtain victory against the Trojans. Neoptolemus obeys but regrets his action and later returns the bow to Philoctetes. Neoptolemus' reasoning could be understood as follows:

1. Neoptolemus has a prima facie obligation to obey Odysseus' order.
2. The order implies that Neoptolemus has an obligation to trick Philoctetes.
3. Neoptolemus tricks Philoctetes and takes the bow.
4. Neoptolemus has a prima facie obligation of fidelity, which implies that he has an obligation not to trick Philoctetes.
5. Odysseus' order is unjust, which implies that Neoptolemus has done an injustice to Philoctetes in obeying it.
6. In light of this second obligation and his unjust act, Neoptolemus has an obligation of reparation to Philoctetes, which implies that he should return the bow.
7. Neoptolemus returns the bow to Philoctetes.

The defeasibility of obligations consists of how conclusions about them (e.g., 2 above) can be withdrawn in the light of further evidence (e.g., 4 and 5 above) [53.8]. In other words, it is the arguments for each obligation that are defeasible, rather than the obligations themselves.

These deontic logics were not developed as cognitive models. Nevertheless, they clearly suggest how rule following might be employed as an account of moral deliberation. This impression is reinforced by the fact that such logics have been developed in the Artificial Intelligence community as accounts of moral reasoning for agents in general [53.9, 10].

## 53.2 Mental Models

A related tradition concerning reasoning about permissions and obligations is centered on mental models [53.11]. This research concerns how people understand and reason about states of the kind *If A, then C*, where *A* and *C* are about things that people ought to be doing or ought not to be doing. An overview of this research is provided by *Byrne* [53.12], which is summarized here.

A fundamental result in this literature is the *Wason selection task* [53.13]. In this task, people are given a rule in an if-then form, such as *If a card has a vowel on one side, then it has an even number on the other side*. They are then given four cards from a deck with numbers on one side of each card and letters on the other, e.g., *A, B, 2, 3*. The task is to select the cards that would indicate that the rule is violated. The correct answer is cards *A* and *3*. Notoriously, most people select the *A* but not the *3*.

Performance on this task changes distinctly when the if-then rule concerns permissions and obligations. Consider a rule such as *If Paul rides a motorbike, then he must wear a helmet* where *must* is understood as a legal obligation. In the analogous selection task, people are asked to select violations of this rule from the possible cases:

1. Paul rode a motorbike.
2. Paul did not ride a motorbike.
3. Paul wore a helmet.
4. Paul did not wear a helmet.

In this version, most people select both 1 and 4.

Since the two tasks have the same structure, the difference in performance demands explanation. On the mental models view [53.14], the explanation is that people tend to represent the tasks differently in their

cognition. In the abstract case, people consider only cases allowed by the rule. In the example above, that would be cards with vowels marked on one side and even numbers on the other side. Thus, the possibility of cards with vowels on one side but odd numbers on the other side is not considered.

In the deontic case, people consider both cases permitted by the rule and cases forbidden by the rule. In the motorbike example, people consider the case in which Paul rides a motorbike and wears a helmet, and also the case in which Paul rides a motorbike and does not wear a helmet. With this representation in mind, it is easier for people to realize the relevance of the condition in which Paul did not wear a helmet to violations of the rule.

A similar disparity arises in the application of the deductive argument forms *modus ponens* and *modus tollens*. These forms of argument can be schematized as follows:

- *Modus ponens*:

$$\frac{\text{If } A, \text{ then } B \\ A}{\text{Therefore, } B}.$$

- *Modus tollens*:

$$\frac{\text{If } A, \text{ then } B \\ \text{Not-}B}{\text{Therefore, not-}A}.$$

Both argument forms are deductions involving if-then rules. However, as with the Wason selection task, people's performance in applying these rules is quite different in assertive and deontic cases.

In the assertive case, people are given a rule such as *If Nancy rides a motorbike, then she goes to the mountains*, and a statement *Nancy rides a motorbike*, and are asked to identify what follows. Most people correctly infer that Nancy goes to the mountains. In other words, they apply a *modus ponens* argument. However, when given the statement *Nancy does not go to the mountains*, most people say nothing follows when it actually follows that *Nancy does not ride a motorbike*. In other words, they do not apply a *modus tollens* argument.

In the deontic case, however, people readily apply both forms of argument. When given the rule *If Paul rides a motorbike, then he must wear a helmet* and the statement *Paul rides a motorbike*, most people infer that *Paul wears a helmet*. When given the statement that *Paul does not wear a helmet*, most people say that it follows that *Paul did not ride a motorbike*. By the same token, when given the statement *Paul rides a motorbike*

*and does not wear a helmet*, most people agree that Paul broke the rule.

As before, the explanation for this disparity between assertive and deontic cases concerns mental models. In the assertive case, people think explicitly only about the case allowed by the rule whereas, in the deontic condition, they think explicitly about both the permitted and the forbidden conditions.

Sometimes, if-then rules can convey *counterfactual obligations*. For example, if-then rules can convey obligations that do not actually hold. Consider the rule, *If Mary had lived in the 1700s, then she would have had to have been chaperoned*. This rule concerns Mary, who did not live in the 1700s, and an obligation concerning her that would have applied the event that she did.

As Byrne [53.12, p. 84] points out, the mental model of counterfactual obligations is richer even than indicative ones. In an indicative, deontic rule, the permitted and forbidden cases are represented explicitly, e.g., *If your parents are elderly, then you have to care for them*:

- Your parents are elderly and you care for them (permitted).
- Your parents are elderly and you do not care for them (forbidden).

In a counterfactual, deontic rule, the permitted and forbidden cases are represented, but the additional fact about Mary is represented as well, e.g., *If Mary had lived in the 1700s, then she would have had to have been chaperoned*:

- Mary lived in the 1700s and she was chaperoned (permitted).
- Mary lived in the 1700s and she was not chaperoned (forbidden).
- Mary does not live in the 1700s and she is not chaperoned (factual).

Since the rule is understood as counterfactual, it prompts people to represent the factual condition explicitly.

The mental models account of moral reasoning is similar to the rule-based account in the obvious sense that both hold moral knowledge to be encoded in the form of if-then rules with deontic content. Reasoning with moral knowledge is equated with the construction of arguments in which these rules are obeyed or violated.

An important difference between the two is that the rule-based account provides a mechanism for the conduct of moral decision-making, that is, following the rules. The mental models account is restricted to explanation of how people understand deontic, if-then rules. It does not explicate how people might employ rules in the course of moral deliberations.

### 53.3 Schemata

Johnson [53.15] allows that some moral deliberation takes the form of rule following. However, he disputes that rule following comprises an accurate or adequate account of the phenomenon. Instead, he argues that imagination of a certain sort is applied when people interpret and explore morally problematic situations. More specifically, he argues that people apply schemata derived from bodily metaphors when engaged in moral deliberation.

Moral schemata come in families circumscribed by the metaphors on which they rest. One such family rests on the image MORAL INTERACTIONS ARE COMMODITY TRANSACTIONS, or *moral accounting*. The underlying metaphor is of transactions in the moral domain being modeled on financial transactions. In financial transactions, people exchange goods and money in order to build up wealth. In the moral domain, people exchange actions that enhance or detract from well-being. On this understanding, having a duty to someone is like owing that person a debt. Having a right is like a debt that someone owes you (i. e., a credit). This manner of moral reasoning turns up in expressions such as, *Larry owed him a debt of gratitude*, and *Thomas paid for his mistake*.

The projection of financial accounting with moral accounting is summarized in Table 53.1 [53.15, p. 42].

The moral accounting metaphor structures a conceptual system of rights and duties that inform moral decision-making.

Now, in order to make this system operative, a means for keeping accounts must be added. To accomplish this, Johnson proposes that accounting concepts are added to the financial domain to comprise what he calls the *commodity transaction* domain. This domain includes concepts of valuing actions and comparing evaluations. Such a system allows people to calculate that when providing a creditor with eight sheep it is appropriate to discharge a debt of one cow, for example.

**Table 53.1** Projection of financial transactions as moral actions

Financial domain	Moral domain
Wealth	Well-being
Getting money	Achieving a purpose
Earning money	Achieving a purpose by honest toil
Payment	Actions that increase well-being
Debts	Duties
Letters of credit	Rights
Debtor	Person with a duty
Creditor	Person with IOU
Inexhaustible credit	Inalienable rights
Contract	Exchange of rights

Commodity transaction concepts are added to the moral domain to comprise the *moral transaction domain*. The augmented domain incorporates concepts of a balance of rights and duties and transactional justice.

The projection of the commodity transaction domain to the moral transaction domain is summarized in Table 53.2.

The concept of transactional justice, grounded in the commodity transaction metaphor, allows people to weigh rights and duties, and to discriminate just outcomes from unjust ones.

With this conceptual grounding in view, people construct schemata that they may apply to make moral judgments in particular situations. Each schema represents a set of conditions that are met in a situation that motivates a decision on how to act morally. Johnson [53.15, pp. 47–49] elaborates five of these schemata as follows. (The expressions *something good* and *something bad* refer to things of positive and negative utility or worth.):

1. *Reciprocation: One good turn deserves another:*
  - Event: *A* gives something good to *B*.
  - Judgment: *B* owes something good to *A*.
  - Expectation: *B* should give something good to *A*.
  - Moral inferences: *B* has a duty to give something good to *A*. *A* has a right to receive something good from *B*.
  - Commercial inference: *B* pays *A* for getting something good by giving something good of equal price.
  - Example: *You have been so good to me, how can I repay you?*

**Table 53.2** Projection of commodity transactions to moral transactions

Commodity transaction	Moral transaction
Commodities	Actions, states
Utility of commodities	Moral worth of actions or states
Wealth, money	Well-being
Accumulation of wealth	Increase in well-being
Profitable	Moral
Unprofitable	Immoral
Giving/taking wealth	Performing moral/immoral actions
Account of transactions	Moral account
Balance of accounts	Moral balance of actions
Debt	Owing increase in well-being to others
Credit	Others owe increase in well-being to you
Fair exchange/payment	Justice

2. *Retribution: You will get what's coming to you:*
  - Event: *A* gives something bad to *B*.
  - Judgment: *B* owes something bad to *A*.
  - Expectation: *B* should give something bad to *A*.
  - Moral inference: *B* has the right to give something bad to *A*. *A* has a duty to receive something bad from *B*.
  - Commercial inference: *B* pays *A* back for receiving something bad by giving *A* something bad.
  - Example: *I will pay you back for that insult!*
3. *Restitution: I will make it up to you:*
  - Event: *A* gives something bad to *B*.
  - Judgment: *A* owes something good to *B*.
  - Expectation: *A* should give something good to *B*.
  - Moral inferences: *A* has a duty to give something good to *B*. *B* has the right to receive something good from *A*.
  - Commercial inference: *A* pays *B* by giving something good.
  - Example: *You owe me an apology for your rudeness!*
4. *Revenge: An eye for an eye, a tooth for a tooth:*
  - Event: *A* gives something bad to *B*. *A* will not give something good to *B*.
  - Judgment: *A* owes something bad to *B*.
  - Expectation: *B* should take something good from *A*.
  - Moral inferences: *A* has a duty to give something good to *B*. *B* has a right to receive something good from *A*.
5. *Altruism/charity: What a saint!:*
  - Commercial inference: *B* exacts payment from *A*.
  - Example: *I will make you pay for what you did!*
  - Event: *A* gives something good to *B*. *B* cannot give something good to *A* in return.
  - Judgment: *B* owes something good to *A*.
  - Expectation: *B* does not give something good to *A*. *A* accumulates moral credit even without a debtor.
  - Moral inferences: *A* has no duty to give something good to *B*. *B* has no right to receive something good from *A*.
  - Commercial inference: *B* receives something good from *A* without incurring a debt.
  - Example: *That was a selfless act.*

The charity schema is different because it results in an accounting imbalance. However, the donor may hope for rewards from parties other than the recipient of the charity, such as an enhanced reputation or good karma.

The moral accounting metaphor is not the only important metaphorical basis for moral deliberation. There is also what Johnson calls the EVENT STRUCTURE metaphor. On this metaphor, achieving a goal is like motion along a path. A right is like a right of way, a path that presents no obstacles. A duty is a requirement to cede right of way to others [53.15, pp. 42–43]. This metaphor also informs a set of schemata that people employ to make moral decisions. Several further moral schemata are discussed in [53.16].

## 53.4 Analogy

Perhaps the clearest application of models to moral deliberations comes with analogical or case-based reasoning. In such reasoning, instances of previously considered moral problems are applied to current ones. Such reasoning has long been a subject of psychological research [53.17].

For example, consider a moral analogy used during deliberations over the Cuban Missile Crisis in 1962 within the Kennedy administration [53.18]. Senior officials in the administration considered several ways to respond to the arrival of Soviet nuclear missiles in Cuba. One such option was to launch a surprise attack on Cuba in order to destroy the missiles before they could be used. Although initially favored by Robert Kennedy, the option was abandoned, in part, because of an analogical argument made by CIA Director John McCone and Under Secretary of State George

Ball. They argued that a surprise attack on Cuba would be morally akin to the surprise attack on Pearl Harbor by Japanese forces that brought the USA into the Second World War. The latter was admitted by all to be a saliently immoral act and the analogy helped to change the minds of several hawks in the administration, including Robert Kennedy.

In the analogy, the known or source (or base) analog is the Japanese attack on Pearl Harbor. The problematic or target analog is a surprise attack by American forces on Cuba. There are clear similarities between the two cases, including that both involve attacks without a declaration of war and both concern nations that are already unfriendly towards each other. Of course, there are notable differences. For example, Pearl Harbor was a sneak attack by an authoritarian regime against a democratic one, whereas a sneak attack by the USA

against Cuba would be the reverse. Also, some similarities appear unimportant, such as the fact that both attacks would be launched against islands.

Psychological research sheds some light on this situation. Analogical reasoning in general typically involves at least two processes, selection of source analogs and alignment of source and target analogs. The selection process is dominated by overt similarities. In this case, that would include the sneaky and the military nature of the attacks, and the fact that both attacks would be launched against islands. The alignment process is dominated by the construction of systemic mappings between source and target analogs [53.19]. The alignment between the two analogs could be captured roughly as in Table 53.3.

The analogy is represented as follows [53.20]. The top three rows are *attribute mappings*, that is, simple items from the source and target analogs that are aligned in the analogy. The middle three rows are *relational mappings*, that is, relations between the attributes of each analog that are aligned in the analogy. The bottom two rows are *system mappings*, that is, relations between the relations of each analog that align in the analogy.

The system mappings structure the entire analogy and capture the thrust of the comparison. The first system mapping suggests that Japan surprised the USA at Pearl Harbor in order to carry out its attack. Likewise, the USA would surprise Cuba in order to carry out its attack. The second system mapping suggests that for Japan to surprise the USA implies that Japan stands for the values of a dictatorship. Likewise, for the USA to surprise Cuba implies that the USA stands for the values of a dictatorship. This representation roughly captures the sentiment of George Ball who argued that a surprise attack [53.18, p. 63]:

“would cut directly athwart everything we have stood for in our national history, and condemn us as hypocrites in the opinion of the world.”

**Table 53.3** Analogy between Pearl Harbor attack and attack by USA on Cuba. The top three rows are attribute mappings, the middle three relational mappings, and the bottom two system mappings

Source (Pearl Harbor)	Target (Cuba)
Japan	USA
USA	Cuba
dictatorship	dictatorship
attack(Japan,USA)	attack(USA,Cuba)
surprise(Japan,USA)	surprise(USA,Cuba)
stand-for(Japan,dictatorship)	stand-for(USA,dictatorship)
in-order-to(surprise,attack)	in-order-to(surprise,attack)
imply(surprise,stand-for)	imply(surprise,stand-for)

As noted above, people are more likely to be influenced by an analogy if that analogy exhibits *systematicity* or *structural coherence*. This implies that the attributes and relations of each analog are included in, and structured by, the system predicates, and that the mappings are one-to-one and between similar items.

The influence of emotions in analogical deliberations is also illustrated in the Pearl Harbor example. *Tierney* [53.18] notes that the surprise attack on Pearl Harbor had become a canonical example in American culture of criminal conduct in warfare. Thus, the idea that the USA should engage in similar behavior was somewhat shameful. This aspect of the analogy reflects the element of hypocrisy that Ball refers to in the USA taking such an action. At a more personal level, the notion of imitating the actions of the Japanese high command was distasteful to President Kennedy. He had fought against the Japanese in the Second World War and regarded the prospect of another such conflict with displeasure. Moreover, the prospect of playing the role of *Tojo* was loathsome to him.

On the theory of emotional coherence [53.21], such emotional valences play an important role in deliberation. The negative emotional valence attached to surprise military attacks in the Pearl Harbor case would attach to the surprise-attack-on-Cuba scenario as well. That negative valence would, in turn, prompt decision makers to view it negatively as well.

The role of analogies in the larger picture of moral deliberation has long been a matter of debate. In the past, analogies have been viewed as a positive and indispensable part of moral deliberation. More recently, analogies have largely been viewed as inferior to rule-based deliberations because of their relative lack of generality and thus have been demoted to a secondary role [53.22]. Cognitive models of analogical deliberation place it in a variety of relationships with other forms of deliberative reasoning.

For example, *Dehghani* et al. [53.23] place analogies in a subordinate role relative to rule-based reasoning in their Moral Decision-Making (MoralDM) simulation. MoralDM contains two modules for deliberating about moral problems. The first is a first-principles reasoning module that implements a qualitative, utilitarian calculus. In short, it evaluates potential actions or nonactions based on its evaluation of the utility of their outcomes. The second is an analogical reasoning module that constructs analogies, if possible, from a knowledge base, analogies that are systematic and deal with a matter of similar magnitude to the problem at hand. The analogy module allows the system to make evaluations based on nonutilitarian grounds and to provide solutions to problems that the rule-based module is unable to solve.

Another simulation incorporating analogies and rules is W.D., named after W.D. Ross [53.10]. W.D. is primarily an implementation of Ross's notion of defeasible duties, discussed above, and thus is primarily a rule-based system. However, the problem of deciding when some duties supercede over others is treated not as an intuitive judgment but as a matter of case-based reasoning. More specifically, where the order of duties is not clear, W.D. reasons by identifying decisions that are most consistent with a set of solved cases. The method is inspired by Rawls's [53.24] account of reflective equilibrium and involves making generalizations drawn from solved cases, which are then tested by comparison to further cases un-

til a conclusion is reached. Although not intended as a cognitive model, W.D. illustrates how analogical deliberation may be viewed by scholars interested in ethical reasoning.

On Thagard's [53.21] coherence theory, analogical coherence is one among several sorts of considerations that participate in ethical deliberations. Such deliberations bring many kinds of mental representations into play, such as rules, explanations, means-ends relationships, along with analogies. Decisions are made based on resolving the course of action that best coheres with all such elements as they appear in the problem. On this account, analogies play not a subordinate role but are simply one consideration amongst others.

## 53.5 Empathy

Empathy appears to be an obvious example of the deployment of models in moral deliberation. Informally, empathy involves placing oneself *in another's shoes*, that is, understanding how another person is feeling by imagining how it might feel to be in that person's position. Empathizing with someone may then create the sense that one is obligated to act, e.g., to help out. Thus, empathy is both model-based and moral in nature.

Explicating this characterization requires some caution. The notion of empathy is a relatively recent one, reaching back to accounts of *sympathy* given by David Hume and Adam Smith [53.25], but has been defined and adapted in a variety of ways. It has developed variously in different fields, including philosophy [53.26], social psychology [53.27], developmental psychology [53.28], cognitive science [53.29], and neuroscience [53.30]. Any treatment of empathy must begin by specifying how the term is to be understood.

In broad terms, empathy is one among many ways that people have of understanding or *reading* the minds of others [53.31]. One such way is to theorize about or *mentalize* what other people are thinking. This activity is focused on the beliefs and attitudes of others instead of on their immediate feelings. Since empathy is focused on feelings, it should be distinguished from detached consideration of the perspectives of others.

Also, empathy should be distinguished from *sympathy*. Both concern feelings and one's relation to other people. However, sympathizing with someone does not necessarily mean feeling the way the other person does [53.32]. It is possible to sympathize with a person who is angry or depressed, for instance, without feeling angry or depressed oneself.

Finally, empathy should be distinguished from emotional contagion [53.32]. For example, a study of people

on the Facebook social network showed that users exposed mainly to positive messages mainly produced positive messages, whereas people exposed mainly to negative messages mainly produced negative messages [53.33]. It seems that the users in this experiment just took on the mood of the producers of the messages that they read. Simple emotional contagion lacks the explicit identification of one person with another individual that defines empathy.

So, empathy can be taken more narrowly as understanding how another person feels by sharing a similar feeling through explicit identification with that person. In this narrow sense, empathy with another person can be modulated in various ways [53.32]. In other words, empathy with another person may be facilitated or inhibited by the following four factors:

1. Characteristics of feeling: It may be easier to empathize with someone experiencing a negative rather than a positive feeling, an intense rather than mild feeling, and feelings involving primary rather than secondary emotions.
2. Relationship with target: It may be easier to empathize with a person whom the empathizer likes or cares for, and for a person who is not upset with the empathizer.
3. Characteristics of the empathizer: Empathy seems to vary with the age, gender, and past experience of the empathizer. Men, for example, seem less likely than women to empathize with people who are perceived to deserve their suffering.
4. Situational factors: It is easier to empathize with someone when the cause of their feeling is known or evident, and salient. Someone crying for an ap-

parently trivial reason, for example, may not elicit empathy.

These characteristics of empathy suggest that it involves more than a shared feeling with another person. Empathy comprises an assessment of a situation in general and the place of the empathizer within it in particular.

*Barnes and Thagard* [53.26] argue that empathy is realized through analogy. That is, empathy involves a systematic mapping between the empathizer (the source) and the target. Consider the experience of watching a figure skater fall during a televised performance. Few viewers will have ever attempted a triple Salchow or anything resembling it but many will empathize with the skater nevertheless. Often, it is written all over their faces. This empathy may arise because viewers are able to construct an analogy with a different episode involving themselves, e.g., falling down during a foot race at school. A representation of this analogy can be seen in Table 53.4.

In this analogy, the empathizer constructs a systematic set of mappings in which a personal experience resulting in disappointment is compared with the experience observed for the skater. The empathizer recalls an episode of falling and injuring a knee during a race, resulting in losing the race. In one of the mappings, disappointment felt by the empathizer is mapped to the disappointment displayed by the skater. Moreover, the mapping allows the empathizer to transfer the effect of that recollected disappointment to the scene on television.

This view of empathy helps to account for some of its features noted above. It is easier to map simi-

**Table 53.4** Analogy between a racer and a figure skater

Source (foot race)	Target (figure skating)
racer	skater
track	ice
knee	groin
race	competition
disappointment	disappointment
hit(racer,track)	hit(skater,ice)
injure(racer,knee)	injure(skater,groin)
lose(racer,race)	lose(skater,competition)
feel(racer,disappointment)	display(skater,disappointment)
cause(hit,injure)	cause(hit,injure)
cause(injure,lose)	cause(injure,lose)
cause(lose,feel)	cause(lose,display)

lar feelings, for example, and feelings that are more intense. Also, people can empathize only if they have some past experience for which a strong analogy can be constructed.

On this description, empathy is not itself a form of moral deliberation [53.34]. That is, feeling empathy for someone need not change the attitudes or actions of the empathizer [53.35, pp. 327–335]. It is possible, for example, for a juror to feel empathy for an accused person without denying that the behavior of the accused was wrong and criminal. However, empathy does sometimes move people to compassion, that is, feeling sorry for a distressed person and offering assistance. People are more likely to give money to beggars, perhaps, if they can imagine themselves in the others' place. It is this connection with compassion, and perhaps other affective dispositions to assist others, that gives empathy a role in moral deliberation.

## 53.6 Role Models

The term *role model* first appears in the scholarly literature in 1957 in connection with the practice of medical students who often choose a senior figure in the profession to imitate and to use as a standard for evaluating their own performance [53.36]. However, the concept was quickly generalized to any individual who served as a reference that others might emulate or measure themselves against. In the literature, a role model can refer to a person who serves as a model with respect to a single role, e.g., doctoring. A person who serves as a reference individual for general purposes could be considered a *hero* or *idol* instead. However, the distinction is not always observed.

Typically, a role model is a person who is regarded by the modeler as someone who has attained higher sta-

tus or position, possesses superior knowledge or skills, and has achieved more than the modeler. Modelers may set themselves the goal of emulating the behavior of the model, of internalizing the attitudes of the model, or both [53.37]. It is also possible for people to adopt inferior persons as role models in the event they are seeking to save themselves from moral degradation or immoral deeds [53.38].

In the social psychology literature, the study of role models has concentrated on the impact of choosing a model on the socialization of the modeler, ways in which the comparison affects the modeler's self-assessment and conduct [53.38]. For present purposes, role models are of interest when modelers choose them for their excellence in moral values or conduct.

The process of deliberating by applying a role model seems to be analogical [53.39], that is, modelers place themselves in analogical correspondence to the model, as discussed above. The stronger the analogy, the more apt the role model.

Some moral role models exhibit an excellence of character that the modeler seeks to emulate. For example, Rosa Parks is widely considered to be a role model for people who advocate for civil rights. She refused to vacate her seat in the whites-only area of a city bus in the 1955 Montgomery bus boycott. The incident is still held up today as an exemplar of a courageous person protesting social injustice [53.40].

Rosa Parks could serve as a role model for a young American black woman seeking to protest inequality for black Americans. However, she could also serve as a role model for people of other ethnic backgrounds who are concerned about other social injustices. For ex-

ample, a white male might take part in a public rally to advocate for a path to citizenship for American immigrants from Latin America, in spite of the disapproval of his neighbors. The two episodes do not much resemble each other but the protestor may take the view that if Rosa Parks can brave the disapproval of racist police and citizenry, then he can endure the frowns of his neighbors as well. The systemic coherence between the source and target still makes this mapping a strong one. Also, the analogy transfers an emotional sense of resolve that is important in galvanizing action.

In some ways, a role model is the reverse of empathy. In the case of empathy, a person imagines what it would be like to be in another person's place. In the case of role models, a person imagines what it would be like if another person were in the modeler's place. Thus, it is not surprising that both sorts of deliberation should be similar, that is, analogical, in character.

## 53.7 Discussion

The use of models is clearly important to moral deliberation and it can be represented in many different ways. These ways include rules, schemata, mental models, analogies, empathy, and role models. The diversity among these approaches illustrates both the complexity of moral deliberation and the breadth of the concept of *model*. In view of the discussion above, it is instructive to consider this diversity further.

One obvious difference in accounts of models in moral deliberation is the emphasis they place on the role of emotions. Approaches based on rules, schemata, and mental models emphasize the cognitive component of moral deliberation with models. That is, the primary concern is with the concepts that the deliberator has and uses in the process of deliberation. Approaches based on analogies, empathy, and role models, however, emphasize more of the affective aspect of moral deliberation, though without neglecting its conceptual side. Some of this diversity may harken to the view, perhaps originating in the Enlightenment, that moral deliberation should be a matter of dispassionate calculation. As a psychological matter, moral deliberation is often emotionally charged, and no complete account of it can overlook this fact.

Similarly, accounts of moral deliberation vary according to the importance they grant to universal versus particular considerations. In the rules approach, for example, deliberations qualify as moral because they employ a small set of rules that concern moral values. The rules are combined dynamically in various ways in order to derive conclusions about moral problems that

work to guide the modeler. The rules are universal in the sense that they can be applied to many different situations.

In the analogical approach, models may be drawn from a large population of source analogs that each apply to perhaps relatively few situations. These analogs are particular in the sense that the guidance they provide is more limited. Also, analogs do not combine with the same readiness and flexibility as rules. Approaches based on rules and mental models fall on the universal side of this spectrum, whereas analogies, empathy, and role models fall on the particular side, with schemata being somewhere in between.

Another source of diversity among accounts here concerns the location of resources for deliberation. Most accounts are *internalist* in the sense that they represent deliberators as reliant solely on resources internal to them during the process of deliberation. The rule account, for example, assumes that the deliberator has rules sufficient to reach a conclusion, with the alternative being a simple failure to resolve the moral problem at all. The schemata, mental models, and analogies accounts are similar in this regard.

Other accounts are *externalist* in the sense that they represent deliberators as relying also on resources that are external to them. The role model account, for example, assumes that people consider the qualities, feelings, and actions of other people in the course of deliberation. Similarly, people who empathize with others look outside themselves for the means to resolve moral problems they face.

As Magnani [53.1] notes, resources that support moral deliberation, *moral mediators*, are not limited to other people and would extend to our technological means and to cultural resources. For example, Dehghani et al. [53.41] explore how people use analogies with cultural narratives to make prosocial moral choices. Stories of the moral decisions made by cultural heroes illustrate

for people how moral problems may be appropriately resolved. In effect, the heroes function sometimes as fictional role models. The external dimension of models in moral deliberation could be further explored.

## About the Authors

### Mark Addis

St Mary's University  
School of Arts and Humanities  
Twickenham, UK  
[mark.addis@stmarys.ac.uk](mailto:mark.addis@stmarys.ac.uk)

Chapter G.33

Mark Addis is Professor of Philosophy at Birmingham City University. He is also a Research Associate at the Centre for Philosophy of Natural and Social Science at the London School of Economics and has been a visiting professor at the Department of Culture and Society at Aarhus University. His current research interests include the philosophies of mind and science.

### Atocha Aliseda

Chapter C.10

For biographical profile, please see the section "About the Part Editors".

### Francesco Amigoni

Chapter G.36

For biographical profile, please see the section "About the Part Editors".

### Margherita Arcangeli

Humboldt-Universität of Berlin  
Department of Philosophy  
Berlin, Germany  
[margheritarcangeli@gmail.com](mailto:margheritarcangeli@gmail.com)

Chapter D.21

Margherita Arcangeli graduated in Philosophy at the Università di Roma Tre (BSc 2006, MSc 2008) and obtained her PhD (2011) at the Institut Jean-Nicod, where she was also a postdoctoral researcher. Her areas of research are philosophy of mind, philosophy of science, epistemology, philosophy of language, and aesthetics. Two of her more specific topic-areas are imagination and thought experimentation.

### Cristina Barés Gómez

Universidad de Sevilla  
Grupo de Investigación en Lógica,  
Lenguaje e Información  
Sevilla, Spain  
[crisbares@gmail.com](mailto:crisbares@gmail.com)

Chapter C.14

Cristina Barés Gómez received her PhD from the University of Seville in 2012. She has worked at the National Research Center (CSIC), Spain, and is member of the Logic, Language and Information group of Seville University. She works on natural language negation, the transmission of knowledge through language (evidentiality), abduction, and defeasible reasoning.

### Alessandra Basso

University of Helsinki  
Department of Political and Economic  
Studies  
Helsinki, Finland  
[alessandra.basso@helsinki.fi](mailto:alessandra.basso@helsinki.fi)

Chapter D.19

Alessandra Basso is a PhD student at the Academy of Finland Centre of Excellence in the Philosophy of the Social Sciences. Her research focuses on the philosophy of measurement and the philosophy of the social sciences, in particular of economics.

### William Bechtel

University of California San Diego  
Department of Philosophy and Center for  
Circadian Biology  
La Jolla, USA  
[wbechtel@ucsd.edu](mailto:wbechtel@ucsd.edu)

Chapter F.27

William Bechtel is a philosopher of science who focuses on cell and molecular biology and neuroscience, especially circadian biology, and cognitive science. His research has examined biologists' reasoning strategies in developing mechanistic explanations and constructing computational models to understand their often complex, dynamic behavior. Recently he addressed how scientists employ diagrams and graphs in such reasoning.

**Mathieu Beirlaen**

Ruhr University Bochum  
Institute for Philosophy II  
Bochum, Germany  
[mathieubeirlaen@gmail.com](mailto:mathieubeirlaen@gmail.com)

Chapter C.11

Mathieu Beirlaen received his PhD from Ghent University in 2012. He has worked at Ghent University, at the National Autonomous University of Mexico, and is currently working as a postdoctoral researcher in the Workgroup for Non-Monotonic Logics and Formal Argumentation, Ruhr University Bochum. He has worked on philosophical logic at its intersection with meta-ethics, philosophy of science, and formal argumentation.

**Alisa Bokulich**

Boston University  
Center for Philosophy and History of  
Science  
Boston, USA  
[abokulich@bu.edu](mailto:abokulich@bu.edu)

Chapters A.4, H.41

Alisa Bokulich is Professor of Philosophy at Boston University and Director of the Center for Philosophy and History of Science, where she organizes the Boston Colloquium. She is Associate Member of Harvard's History of Science Department and Series Editor for *Boston Studies in the Philosophy and History of Science*.

**Tibor Bosse**

VU University Amsterdam  
Department of Computer Science  
Amsterdam, The Netherlands  
[t.bosse@vu.nl](mailto:t.bosse@vu.nl)

Chapter I.50

Tibor Bosse has been an Assistant Professor in the Agent Systems Research Group at the Department of Computer Science at VU University Amsterdam since 2006. His research focuses on computational (agent-based) modeling and simulation of social and cognitive processes. The models developed are used for both theoretical purposes and for practical applications, for instance, in the domains of ambient intelligence and serious gaming.

**Juliana Bueno-Soler**

University of Campinas  
School of Technology  
Limeira, Brazil  
[juliana@ft.unicamp.br](mailto:juliana@ft.unicamp.br)

Chapter C.15

Juliana Bueno-Soler received her PhD from the University of Campinas in 2009. She has worked at the Federal University of ABC in São Paulo and is currently Assistant Professor in Differential Calculus and Statistics at the University of Campinas. Her research now focuses on non-classical logics and probability theory.

**Angelo Cangelosi**

Plymouth University  
Centre for Robotics and Neural Systems  
Plymouth, UK  
[acangelosi@plymouth.ac.uk](mailto:acangelosi@plymouth.ac.uk)

Chapter F.28

Angelo Cangelosi is Professor of Artificial Intelligence and Cognition and the Director of the Centre for Robotics and Neural Systems at Plymouth University (UK). His main research expertise is on language grounding and embodiment in humanoid robots, developmental robotics, human-robot interaction, and neurobotics. He is Editor-in-Chief of the *IEEE Transactions on Autonomous Development*, and of *Interaction Studies*.

**Walter Carnielli**

University of Campinas  
Centre for Logic, Epistemology and the  
History of Science  
Campinas, Brazil  
[walter.carnielli@cle.unicamp.br](mailto:walter.carnielli@cle.unicamp.br)

Chapter C.15

Walter Carnielli received his PhD in Mathematics from the University of Campinas in 1982. He has worked as researcher at the University of California in Berkeley, USA and at the Universities of Münster and Bonn in Germany. He is the author of circa 80 scientific papers and 20 books and works on theory and application of contemporary logic, focused on foundations of reasoning.

**Antonio Cicchetti**

Mälardalen University  
Department of Innovation, Design, and  
Engineering  
Västerås, Sweden  
[antonio.cicchetti@mdh.se](mailto:antonio.cicchetti@mdh.se)

Chapter G.32

Antonio Cicchetti is Associate Professor in Software Engineering at Mälardalen University, Sweden. His research interests include software engineering of industrial systems by means of model-driven engineering techniques. In particular, he investigates several research problems related to the design of domain-specific languages, multi-view-based systems, model transformations, and model version management.

**Marcelo E. Coniglio**

University of Campinas  
Centre for Logic, Epistemology and the  
History of Science  
Campinas, Brazil  
[coniglio@cle.unicamp.br](mailto:coniglio@cle.unicamp.br)

Chapter C.15

Marcelo Esteban Coniglio obtained his PhD in Mathematics from the University of São Paulo in 1997. In 1998, he joined the University of Campinas (UNICAMP) faculty. In 2004 he obtained his Habilitation (Livre-Docência) in Logic from UNICAMP, and since 2013 he has been Full Professor in the Department of Philosophy of IFCH/UNICAMP. His current research focuses on non-classical logics.

**Ralf F.A. Cox**

University of Groningen  
Department of Psychology  
Groningen, The Netherlands  
[r.f.a.cox@rug.nl](mailto:r.f.a.cox@rug.nl)

Chapter F.30

Ralf Cox received his PhD in Social Sciences (Cum Laude) at the Radboud University Nijmegen in 2007. He is currently employed at the University of Groningen. His research focus is on complex dynamical systems in psychology. Specifically he studies how self-organization, embodiment, and interaction-dominant dynamics underlie cognitive and motor performances and developmental processes.

**Edoardo Datteri**

Università degli Studi di Milano-Bicocca  
Dipartimento di Scienze Umane per la  
Formazione "R.Massa"  
Milano, Italy  
[edoardo.datteri@unimib.it](mailto:edoardo.datteri@unimib.it)

Chapter G.37

Edoardo Datteri is a researcher in the philosophy of science. His main interests include the epistemology, methodology, and history of robotic simulations in artificial intelligence, biorobotics, and bionics. He has also worked on the modeling and implementation of anticipation-based algorithms of visuomotor coordination for humanoid robots at the BioRobotics Institute of the Scuola Superiore Sant'Anna, Pisa.

**Paul Davidsson**

Malmö University  
Department of Computer Science  
Malmö, Sweden  
[paul.davidsson@mah.se](mailto:paul.davidsson@mah.se)

Chapter G.35

Paul Davidsson is Professor of Computer Science at Malmö University, Sweden. He received his PhD in 1996 from Lund University, Sweden. Davidsson is currently the Director of the Internet of Things and People Research Centre. His research interests include agent technology, simulation, information systems, and data mining. Major application areas are transport systems, building automation, and energy systems.

**Ruud J.R. Den Hartigh**

University of Groningen  
Department of Psychology  
Groningen, The Netherlands  
[j.r.den.hartigh@rug.nl](mailto:j.r.den.hartigh@rug.nl)

Chapter F.30

Ruud J.R. Den Hartigh received his PhD from the University of Groningen and the University of Montpellier in 2015, with the distinction Cum Laude. He is currently Assistant Professor in the Department of Psychology at the University of Groningen. His primary research focus is on capturing performance processes in sports and beyond by applying the dynamical systems approach.

**Alessandro Di Nuovo**

University of Enna "Kore"  
Faculty of Engineering and Architecture  
Enna, Italy  
[alessandro.dinuovo@unikore.it](mailto:alessandro.dinuovo@unikore.it)

Chapter F.28

Alessandro Di Nuovo obtained the Laurea (2005) and the PhD (2009) degrees in Informatics Engineering from the University of Catania. Currently, he is Senior Lecturer with Sheffield Hallam University and Assistant Professor with the University of Enna 'Kore'. Previously, he was Research Fellow with Plymouth University (2012–2015). His current research specializes in cognitive robotics models and their social applications.

**Santo Di Nuovo**

University of Catania  
Department of Education  
Catania, Italy  
[s.dinuovo@unict.it](mailto:s.dinuovo@unict.it)

Chapter F.28

Professor Santo di Nuovo has Laurea degrees in Philosophy and Psychology. Since 1990 he has been Full Professor of Psychology at the University of Catania. He is Head of the Department of Education. He is President of the Academy of Fine Arts of Catania and Vice-president of the National Conference on Academic Psychology. His main research interests are experimental psychology, artificial intelligence, methodology and assessment, and clinical-rehabilitative and forensic psychology.

**Gordana Dodig-Crnkovic**

Chapter G.32

Chalmers University of Technology  
Department of Applied Information  
Technology  
Göteborg, Sweden  
[dodig@chalmers.se](mailto:dodig@chalmers.se)

Gordana Dodig-Crnkovic is Professor of Computer Science who is sharing her time between Chalmers University of Technology, University of Gothenburg and Mälardalen University, Sweden. Her research interests include computing paradigms, natural computing, social computing and social cognition, info-computational models, foundations of information, computational knowledge generation, computational aspects of intelligence and cognition, theory of science/philosophy of science, and computing and philosophy.

**Matthieu Fontaine**

Chapter C.14

Universidad Nacional Autónoma de México (UNAM)  
Instituto de Investigaciones Filosóficas  
Ciudad de México, Mexico  
[fontaine.matthieu@gmail.com](mailto:fontaine.matthieu@gmail.com)

Matthieu Fontaine obtained his PhD from the Université Lille 3 – Charles-de-Gaulle, France, where he worked under the supervision of Professor Dr Shahid Rahman. He has been postdoctoral fellow at the Universidad Nacional Autónoma de México for 2 years. He is specialized in the philosophy of logic and argumentation. His work more specifically focuses on fictionality, hypothetical objects, and abduction.

**Joachim Frans**

Chapter E.24

Vrije Universiteit Brussel  
Centre for Logic and Philosophy of  
Science  
Brussels, Belgium  
[joachim.frans@vub.ac.be](mailto:joachim.frans@vub.ac.be)

Joachim Frans studied philosophy at Vrije Universiteit Brussel and Ghent University. Currently, he is a member of the Centre for Logic and Philosophy of Science at Vrije Universiteit Brussel, where he is completing a PhD on explanation in mathematics.

**Roman Frigg**

Chapter A.3

London School of Economics and Political  
Science  
London, UK  
[r.p.frigg@lse.ac.uk](mailto:r.p.frigg@lse.ac.uk)

Roman Frigg is Professor of Philosophy in the Department of Philosophy, Logic and Scientific Method, Director of the Centre for Philosophy of Natural and Social Science (CPNSS) at the London School of Economics and Political Science. He holds a PhD in Philosophy from the University of London and Master's degrees in Theoretical Physics and Philosophy from the University of Basel, Switzerland.

**Tjerk Gauderis**

Chapter C.12

Ghent University  
Centre for Logic and Philosophy of Science  
Gent, Belgium  
[tjerk.gauderis@ugent.be](mailto:tjerk.gauderis@ugent.be)

Tjerk Gauderis obtained his PhD at Ghent University in 2014 with a dissertation on the formation of hypotheses which incorporated published papers in the fields of logic (abduction), philosophy of science, artificial intelligence, epistemology, and the history of physics. He is currently Associated Postdoctoral Fellow of Ghent University and an IT professional who specializes in computer aided-design, artificial intelligence, and machine learning.

**Axel Gelfert**

Chapter A.1

National University of Singapore  
Dept. of Philosophy  
Singapore, Singapore  
[axel@gelfert.net](mailto:axel@gelfert.net)

Axel Gelfert received his PhD in History and Philosophy of Science from the University of Cambridge in 2006. He is currently an Associate Professor in the Department of Philosophy at the National University of Singapore. He has authored two books.

**Charlotte Gerritsen**

Chapter I.50

Netherlands Institute for the Study of  
Crime and Law Enforcement  
Amsterdam, The Netherlands  
[cgerritsen@nscr.nl](mailto:cgerritsen@nscr.nl)

Charlotte Gerritsen is a postdoctoral researcher at the Netherlands Institute for the Study of Crime and Law Enforcement (NSCR). Her research explores possibilities of applying techniques from the area of artificial intelligence, such as agent-based modeling and simulation, to the field of criminology. She has published over 40 scientific papers for the leading international conferences and in journals in this area.

**Valeria Giardino**

Chapter E.22

UMR 7117 CNRS – Université de Lorraine  
Laboratoire d'Histoire des Sciences et de  
Philosophie – Archives Henri-Poincaré  
Nancy Cedex, France  
[valeria.giardino@univ-lorraine.fr](mailto:valeria.giardino@univ-lorraine.fr)

Valeria Giardino obtained her PhD from the University of Rome 'La Sapienza'. She has held a Marie Curie Fellowship in Paris and was a visiting researcher at Columbia University, the University of Seville, and the Freie Universität in Berlin. She is researcher at the Archives Henri Poincaré in Nancy. Her main research is on diagrammatic reasoning and the cognitive foundations of mathematics.

**Fernand Gobet**

Chapter G.33

University of Liverpool  
Department of Psychological Sciences  
Liverpool, UK  
[fernand.gobet@liv.ac.uk](mailto:fernand.gobet@liv.ac.uk)

Fernand Gobet received his PhD in 1992 from the University of Fribourg, Switzerland. He is Professor of Cognitive Psychology at the University of Liverpool. His main research interests are the psychology of expertise, the acquisition of language, computational modeling, and scientific discovery. He has written ten books.

**William Goodwin**

Chapter H.40

University of South Florida  
Department of Philosophy  
Tampa, USA  
[wgoodwin@usf.edu](mailto:wgoodwin@usf.edu)

William Goodwin is Associate Professor of Philosophy at the University of South Florida. He works in the field of philosophy of science, with particular interests in chemistry, climatology, Kuhn, and Kant.

**Bartłomiej Górný**

Chapter D.20

Comarch S.A.  
Krakow, Poland  
[bartlomiej.gorny@comarch.com](mailto:bartlomiej.gorny@comarch.com)

Bartłomiej Górný received his MS degree in Computer Science as well as his PhD degree from AGH University of Science and Technology, Cracow, Poland. He is currently Support Manager in BSS Telco Operations Business Unit in Comarch S.A. (Software House and IT Systems Integrator), Cracow, Poland. His main research interests include artificial intelligence and especially diagnosis of dynamic systems.

**Isar Goyvaerts**

Chapter E.24

Università degli Studi di Torino  
Dipartimento di Matematica "Giuseppe  
Peano"  
Torino, Italy  
[igoyvaer@unito.it](mailto:igoyvaer@unito.it)

Isar Goyvaerts received his PhD from Vrije Universiteit Brussels (Belgium) in 2013. He is currently a Marie Curie Fellow of the Istituto Nazionale di Alta Matematica based at Università degli Studi di Torino (Italy). Besides research in algebra, he has great interest in teaching mathematics and enjoys divulging mathematical topics to a broader audience.

**Teruaki Hayashi**

Chapter I.48

University of Tokyo  
Department of Systems Innovation  
Bunkyo-ku, Tokyo, Japan  
[teru-h.884@nifty.com](mailto:teru-h.884@nifty.com)

Teruaki Hayashi is an Engineering PhD candidate at the University of Tokyo. He is studying Innovators Marketplace and the methods for refining ideas through communications and constraints in action planning. Recently he has been contributing to projects for data driven innovation and decision-making, integrated with communication for creative activities.

**Cyrille Imbert**

Chapter G.34

Université de Lorraine  
Archives Poincaré  
Nancy, France  
[cyrille.imbert@univ-lorraine.fr](mailto:cyrille.imbert@univ-lorraine.fr)

Cyrille Imbert received his PhD in 2008 from Université Paris 1 and has worked ever since as a permanent CNRS Research Fellow at Archives Poincaré (Nancy, France). He works in the field of general philosophy of science, with emphasis on scientific explanation, modeling, and computational issues, and in the (formal) social epistemology of science, with the use of models and computer simulations.

**Hiroyuki Kido**

University of Tokyo  
Department of Systems Innovation  
Bunkyo-ku, Tokyo, Japan  
[kido.hiroyuki@gmail.com](mailto:kido.hiroyuki@gmail.com)

Chapter I.48

Hiroyuki Kido graduated from Niigata University and received his Master's degree from Hokkaido University. He received his PhD from Tokyo Institute of Technology in 2011. Presently, he is Assistant Professor of the School of Engineering at the University of Tokyo. He won the JSAI (the Japanese Society for Artificial Intelligence) Best Paper award in 2012.

**Franziska Klügl**

Örebro University  
School of Science and Technology  
Örebro, Sweden  
[franziska.klugl@oru.se](mailto:franziska.klugl@oru.se)

Chapter G.35

Franziska Klügl received her PhD and her Habilitation in Computer Science from the University of Würzburg (Germany) in 2000 and 2009. Since 2011, she has been working as Professor in Information Technology at Örebro University, Sweden. Her research interests are engineering and application of agent-based simulation and multiagent systems with a special focus on human-computer interaction.

**Peter C.R. Lane**

University of Hertfordshire  
School of Computer Science  
Hatfield, UK  
[p.c.lane@herts.ac.uk](mailto:p.c.lane@herts.ac.uk)

Chapter G.33

Peter Lane has a PhD in Computer Science from the University of Exeter and a BA in Mathematics and Computation from Oxford University. He worked at Nottingham University before taking up his current position at the University of Hertfordshire. His research interests cover aspects of machine learning, including cognitive modeling, data mining, and scientific discovery.

**Antoni Ligęza**

AGH University of Science and Technology  
Applied Computer Science  
Krakow, Poland  
[ligeza@agh.edu.pl](mailto:ligeza@agh.edu.pl)

Chapter D.20

Professor Antoni Ligęza from AGH – University of Science and Technology in Cracow, Poland, works on knowledge engineering (artificial intelligence), knowledge representation and reasoning, rule-based systems, technical diagnostics, constraint programming, logics, and systems science. He has been a visiting researcher at LAAS/Toulouse, the University of Nancy I, the University of the Balearic Islands, the University of Girona, and the University of Caen. He is the author of about 200 research papers.

**Chiara Liscianra**

University of Groningen  
Faculty of Economics and Business,  
Department of Economics, Econometrics  
and Finance  
Groningen, The Netherlands  
[c.liscianra@rug.nl](mailto:c.liscianra@rug.nl)

Chapter D.19

Chiara Liscianra is doing postdoctoral research at the Tint Centre of Excellence in the Philosophy of the Social Sciences, the University of Helsinki. She received her PhD from Tilburg University in 2013. After her stay at Tilburg, Chiara spent 1 year as a Research Fellow at Munich Center for Mathematical Philosophy, Munich University.

**Elisabeth A. Lloyd**

Indiana University  
Department of History and Philosophy of  
Science and Medicine  
Bloomington, USA  
[ealloyd@indiana.edu](mailto:ealloyd@indiana.edu)

Chapter H.42

Elisabeth A. Lloyd's focus is dual: both philosophy of evolution and climate science. She works on the logical structure of evolutionary models and their confirmation, as well as the methodology and testing of biological and climate models. Her book (2005) has led to changes in sex research, including her participation in research on human female sexuality.

**Giuseppe Longo**

Centre Cavallès  
Ecole Normale Sup.  
Paris, France  
[giuseppe.longo@ens.fr](mailto:giuseppe.longo@ens.fr)

Chapter H.38

Giuseppe Longo is a mathematician and Directeur de Recherche, CNRS at Ecole Normale Supérieure, Paris. He is a former Professor of Mathematical Logic, University of Pisa. He spent 3 years in Berkeley, MIT and Carnegie Mellon (USA) as researcher and Visiting Professor. He has worked on applications of mathematics to computer science and recently extended his research interests to theoretical biology.

**Miles MacLeod**

University of Twente  
Department of Philosophy  
Enschede, The Netherlands  
[m.a.j.macleod@utwente.nl](mailto:m.a.j.macleod@utwente.nl)

## Chapter A.5

Miles MacLeod is a philosopher of science with a PhD in History and Philosophy of Science from the University of Vienna. He works and publishes on themes connected to model-building practices in the biological and bioengineering sciences, scientific cognition, and interdisciplinary collaboration. He studies these model-building practices for the most part using qualitative methods.

**Giovanna Magnani**

University of Pavia  
Department of Economics and  
Management  
Pavia, Italy  
[g.magnani@unipv.it](mailto:g.magnani@unipv.it)

## Chapter I.51

Giovanna Magnani is a Post Doc research fellow at the Department of Economics and Management of the University of Pavia. She earned her PhD in Economics and Management in December, 2015. She was visiting PhD candidate at the University of Queensland (Australia) between January and June 2014. She has participated in several international conferences and is co-author of a monograph on International Entrepreneurship.

**Caterina Marchionni**

University of Helsinki  
Department of Political and Economic  
Studies  
Helsinki, Finland  
[caterina.marchionni@helsinki.fi](mailto:caterina.marchionni@helsinki.fi)

## Chapter D.19

Caterina Marchionni obtained her PhD from the Erasmus Institute for Philosophy and Economics, Erasmus University Rotterdam. Currently she is Academy Research Fellow at the Academy of Finland Centre of Excellence in the Philosophy of the Social Sciences (TINT), University of Helsinki. Her research mainly concerns modeling, explanation, and interdisciplinarity.

**Davide Marocco**

Plymouth University, School of Computing  
Electronics and Mathematics  
Plymouth, UK  
[davide.marocco@plymouth.ac.uk](mailto:davide.marocco@plymouth.ac.uk)

## Chapter F.28

Davide Marocco received his PhD in Artificial Intelligence from the University of Calabria, Italy, in 2004. He is Associate Professor (Reader) of Cognitive Robotics and Intelligent Systems at Plymouth University, UK and Coordinator of the CUDA Teaching Centre. His research interests are focused on cognitive robotics and evolutionary robotics models of behaviour, and evolution of communication and language.

**Massimo Marraffa**

University of Rome 'Roma Tre'  
Department of Philosophy,  
Communication and Media Studies  
Rome, Italy  
[massimo.marraffa@uniroma3.it](mailto:massimo.marraffa@uniroma3.it)

## Chapter H.43

Massimo Marraffa is Associate Professor of Philosophy of Science at University Roma Tre (Rome, Italy). His research focuses primarily on issues in the philosophy of the mind and the philosophy of psychology, on which he has published books, articles, and book chapters in Italian and English.

**Mary Ann Metzger**

University of Maryland UMBC  
Department of Psychology  
Baltimore, USA  
[metzger@umbc.edu](mailto:metzger@umbc.edu)

## Chapter F.29

Mary Ann Metzger received her PhD in Psychology from the University of Connecticut, Storrs, CT, USA in 1970 and then did postdoctoral work at the laboratory of William K. Estes, Rockefeller University, New York, NY. She is an Emerita Associate Professor in the Department of Psychology, University of Maryland UMBC, Baltimore, MD. Her work focuses on the development of dynamic models of cognition.

**Gerhard Minnameier**

Goethe University Frankfurt am Main  
Faculty of Economics and Business  
Administration  
Frankfurt am Main, Germany  
[minnameier@econ.uni-frankfurt.de](mailto:minnameier@econ.uni-frankfurt.de)

## Chapter B.8

Gerhard Minnameier received his PhD from Johannes Gutenberg University at Mainz in 1999, where he also habilitated in 2005. He has been Professor of Vocational and Economics Education at RWTH University Aachen, and since 2011 Professor of Business Ethics and Business Education at Goethe University Frankfurt am Main. His key research areas are cognitive structures and learning, especially in the moral domain.

**Maël Montévil**

Chapter H.38

Laboratoire MSC  
 Université Paris 7 Diderot  
 Paris, France  
*mael.montevil@gmail.com*

Dr Maël Montévil works at the crossroad of biology, physics, and philosophy of science in order to contribute to a deeper understanding of biological phenomena. He obtained his PhD from École Normale Supérieure with Giuseppe Longo, was a Postdoctoral Associate in Tufts University School of Medicine with Ana Soto and Carlos Sonnenschein, and in IHPST, Université Paris 1 Panthéon-Sorbonne.

**Eleonora Montuschi**

Chapter I.52

Università Ca'Foscari Venezia  
 Department of Philosophy and Cultural  
 Heritage  
 Venice, Italy  
*eleonora.montuschi@unive.it*

Eleonora Montuschi is Associate Professor in the Department of Philosophy and Cultural Heritage at Ca' Foscari University of Venice and Senior Research Fellow at the London School of Economics and Political Science. Her research interests include philosophy of science and social science, objectivity, the theory and practice of evidence, and methodological issues in the social sciences.

**John Mumma**

Chapter E.23

California State University San  
 Bernardino  
 Department of Philosophy,  
 San Bernardino, USA  
*jmumma@csusb.edu*

John Mumma is an Assistant Professor of Philosophy at California State University San Bernardino. His research interests are in the philosophy of geometry, the philosophy of mathematics, and the philosophy of logic.

**Angel Nepomuceno-Fernández**

Chapter C.13

Universidad de Sevilla  
 Grupo de Investigación en Lógica,  
 Lenguaje e Información  
 Sevilla, Spain  
*nepomuce@us.es*

Angel Nepomuceno-Fernández is a Full Professor of Logic and Philosophy of Science and the principal investigator of the Group of Logic, Language and Information at the University of Seville. His work focuses on nonclassical logics, particularly dynamic epistemic logic and other multimodal logics.

**Nancy J. Nersessian**

Chapter A.5

Harvard University  
 Dept. of Psychology, William James Hall  
 Cambridge, USA  
*nancynersessian@fas.harvard.edu*

Nancy J. Nersessian received her PhD from Case Western Reserve in 1977. She is Regents' Professor (Emerita), Georgia Tech and Research Associate at Harvard University. Her research focuses on the creative modeling practices of scientists and engineers. She is a Fellow of AAAS, the Cognitive Science Society, and a Foreign Member of the Royal Netherlands Academy of Arts and Sciences.

**James Nguyen**

Chapter A.3

London School of Economics and Political  
 Science  
 London, UK  
*j.nguyen1@lse.ac.uk*

James Nguyen is a PhD candidate in the Department of Logic, Philosophy and Scientific Method at the London School of Economics and Political Science. He works on the nature of representation in science.

**Yukio Ohsawa**

Chapter I.48

University of Tokyo  
 Department of Systems Innovation  
 Bunkyo-ku, Tokyo, Japan  
*ohsawa@sys.t.u-tokyo.ac.jp*

Yukio Ohsawa is a professor at the University of Tokyo. His research started from natural language analysis, and, via working in non-linear optics and artificial intelligence, he initiated studies on *chance discovery*, i.e., discovery of events meaningful for decision-making, and extended them to methods for innovation. He has edited and authored several books on the topics of change discovery and innovation.

**Naomi Oreskes**

Chapter H.41

Harvard University  
Department of the History of Science  
Cambridge, USA  
[oreskes@fas.harvard.edu](mailto:oreskes@fas.harvard.edu)

Naomi Oreskes is Professor of the History of Science and Affiliated Professor of Earth and Environmental Sciences at Harvard University.

**Woosuk Park**

Chapter B.9

For biographical profile, please see the section "About the Part Editors".

**Alfredo Paternoster**

Chapter H.43

Università di Bergamo  
Department of Letters, Philosophy,  
Communication  
Bergamo, Italy  
[alfredo.paternoster@unibg.it](mailto:alfredo.paternoster@unibg.it)

Alfredo Paternoster is Associate Professor of Philosophy of Language at University of Bergamo, Italy. His research focuses primarily on issues in philosophy of the mind, philosophy of cognitive sciences, and philosophy of language, on which he has published books, articles, and book chapters in Italian and English.

**Pieter Pauwels**

Chapter I.45

Ghent University  
Department of Architecture and Urban  
Planning  
Ghent, Belgium  
[pipauwel.pauwels@ugent.be](mailto:pipauwel.pauwels@ugent.be)

Pieter Pauwels is a postdoctoral researcher at the Department of Architecture and Urban Planning at Ghent University. He holds a Master's degree (2008, Ghent) and a PhD degree (2012, Ghent) in Engineering Architecture. His research focuses on information system support for architectural design thinking. He works full time on topics affiliated to BIM, design thinking and linked data in architecture and construction.

**Demetris Portides**

Chapter A.2

For biographical profile, please see the section "About the Part Editors".

**Athanasios Raftopoulos**

Chapter F.26

For biographical profile, please see the section "About the Part Editors".

**Ferdinand Rivera**

Chapter E.25

San José University  
Department of Mathematics & Statistics  
San Jose, USA  
[ferdinand.rivera@sjsu.edu](mailto:ferdinand.rivera@sjsu.edu)

Ferdinand Rivera is Professor in the Department of Mathematics and Statistics and Chair of the Department of Elementary Education at San Jose State University. He conducts research in school-based mathematics cognition, focusing on the emergence and development of structural thinking and deep mathematical understanding in children, adolescents, and adults.

**Abilio Rodrigues Filho**

Chapter C.15

Federal University of Minas Gerais  
Department of Philosophy  
Pampulha, Belo Horizonte, Brazil  
[abilio@ufmg.br](mailto:abilio@ufmg.br)

Abilio Rodrigues Filho is Professor of Philosophy at the Federal University of Minas Gerais, Belo Horizonte, Brazil. He received his PhD from the Pontifical Catholic University of Rio de Janeiro, Brazil. His main areas of interest are logic, philosophy of logic, paraconsistency, and intuitionism.

**Federica Russo**

Chapter H.44

University of Amsterdam  
Department of Philosophy  
Amsterdam, The Netherlands  
[f.russo@uva.nl](mailto:f.russo@uva.nl)

Federica Russo received her PhD from the University of Louvain (Belgium) in 2005. Since then, she has held several research and teaching positions in Belgium, Italy, UK, and USA. She is currently Assistant Professor in Philosophy of Science at the University of Amsterdam. Her research interests span the social, biomedical, and policy sciences, with particular attention on questions about causality and modeling.

**Flavia Santoianni**

Chapter I.49

University of Naples Federico II  
Department of Humanities Section of  
Philosophy  
Naples, Italy  
[flavia.santoianni@unina.it](mailto:flavia.santoianni@unina.it)

Flavia Santoianni is Full Professor of Education at University of Naples Federico II. She is Director of the international open access journal *RTH Research Trends in Humanities* and has published 26 books and several articles. Her books have been translated into English and Spanish. Her research interests concern bioeducational sciences, teaching and learning, and design of learning environments.

**Viola Schiaffonati**

Chapter G.36

For biographical profile, please see the section "About the Part Editors".

**Gerhard Schurz**

Chapter B.7

Heinrich Heine University  
Department of Philosophy, DCLPS  
Dusseldorf, Germany  
[schurz@phil.uni-duesseldorf.de](mailto:schurz@phil.uni-duesseldorf.de)

Gerhard Schurz is Professor of Philosophy and Director of the Düsseldorf Center for Logic and Philosophy of Science (DCLPS) at the University of Düsseldorf. Before 2002 he was Associate Professor at the University of Salzburg and Visiting Professor at the University of California at Irvine and at Yale University. His research areas cover philosophy of science, logic, epistemology and cognitive science.

**Nora Alejandrina Schwartz**

Chapter D.17

For biographical profile, please see the section "About the Part Editors".

**Cameron Shelley**

Chapters I.47, I.53

For biographical profile, please see the section "About the Part Editors".

**Fernando Soler-Toscano**

Chapter C.13

Universidad de Sevilla  
Grupo de Investigación en Lógica,  
Lenguaje e Información  
Sevilla, Spain  
[fsoler@us.es](mailto:fsoler@us.es)

Fernando Soler-Toscano is Associate Professor at the University of Seville, Spain. His background is both in philosophy and computer science. His research focuses on formal models of abductive reasoning in dynamic epistemic logic. He also works on algorithmic complexity measures. He is a foreign collaborator of the Lisbon Center for Philosophy of Sciences and a member of the Paris Reasoning group.

**Peter D. Sozou**

Chapter G.33

London School of Economics and  
Political Science  
Centre for Philosophy of Natural and  
Social Science  
London, UK  
[p.sozou@lse.ac.uk](mailto:p.sozou@lse.ac.uk)

Peter Sozou received his PhD from Birkbeck College, University of London, in 1994. He has worked on computer vision, behaviour, theoretical biology, health, reproductive medicine, and computational scientific discovery. He is based at the LSE, and is interested in a range of problems in decision-making. During the writing of this chapter he was a researcher at the University of Liverpool.

**Susan G. Sterrett**

Chapters D.18, H.39

Wichita State University  
Department of Philosophy  
Wichita, USA  
[susangsterrett@gmail.com](mailto:susangsterrett@gmail.com)

S.G. Sterrett is the Curtis D. Gridley Distinguished Professor of the History and Philosophy of Science, Department of Philosophy, Wichita State University in Wichita, Kansas. She has an undergraduate degree in engineering from Cornell University, and degrees in Mathematics (MA) and Philosophy (MA, PhD) from the University of Pittsburgh. She has also taught at Duke University and Carnegie-Mellon University.

**Ryan D. Tweney**

Chapter D.16

Bowling Green State University  
Department of Psychology  
Bowling Green, USA  
[tweney@bgsu.edu](mailto:tweney@bgsu.edu)

Ryan D. Tweney has a PhD in Experimental Psychology. His research has ranged widely over psycholinguistics, the role of confirmation 'bias' in thinking, problem solving, and the history of science and of psychology, to which he has applied cognitive models of thinking. His current research centers on James Clerk Maxwell's use of mathematical representations, and the relation of such representations to model-based reasoning in science.

**Paul L.C. Van Geert**

University of Groningen  
Department of Psychology  
Groningen, The Netherlands  
*p.l.c.van.geert@rug.nl*

Chapter F.30

Paul van Geert is Emeritus Professor at the University of Groningen in the Netherlands, where he held the Chair of Developmental Psychology (1985–2015). He has a pioneering role in the application of dynamic systems theory across the areas of language, cognitive, and social development, and has held visiting professorships at Harvard University and various European Universities.

**Bart Van Kerkhove**

Vrije Universiteit Brussel  
Centre for Logic and Philosophy of  
Science  
Brussels, Belgium  
*bart.van.kerkhove@vub.ac.be*

Chapter E.24

Bart Van Kerkhove has been a member of the Centre for Logic and Philosophy of Science at Vrije Universiteit Brussel since 2000 and received his PhD there in 2005. Since 2008, he has also been a part-time lecturer of the Philosophy Department, teaching various courses, including Logic and Philosophy of Science, Themes from Analytic Philosophy and Philosophy of Mathematics.

**Fernando R. Velázquez-Quesada**

Universidad de Sevilla  
Grupo de Investigación en Lógica,  
Lenguaje e Información  
Sevilla, Spain  
*frvelazquezquesada@us.es*

Chapter C.13

Fernando R. Velazquez-Quesada received his PhD from the Institute for Logic, Language and Computation of the University of Amsterdam. His research focuses on logical representations of individual and collective attitudes towards information (such as knowledge, beliefs, or preferences) as well as the different actions that affect them (as diverse forms of inference, communication, and interaction).

**Harko Verhagen**

Stockholm University  
Department of Computer and Systems  
Sciences  
Kista, Sweden  
*verhagen@dsv.su.se*

Chapter G.35

Harko Verhagen is Associate Professor of Computer and Systems Sciences at Stockholm University, Sweden, where he received his PhD in 2000. His research interests include social simulation, social believability in computer games, IT supported learning, outsourcing, hybrid social systems, normative multiagent systems, and theories of agency. Major application areas are computer games, socio-cognitive technical systems, and social simulations.

**Jonathan Waskan**

University of Illinois at  
Urbana-Champaign  
Department of Philosophy  
Urbana, USA  
*waskan@illinois.edu*

Chapter F.31

Jonathan received his PhD in 1999 through the Philosophy-Neuroscience-Psychology program at Washington University in Saint Louis. He has held teaching and research appointments at William Paterson University, the University of Illinois at Urbana-Champaign (and the Beckman Institute), and the Rotman Institute at the University of Western Ontario. His research largely concerns mental models and their role in scientific explanation.

**John Woods**

University of British Columbia  
Dept. of Philosophy, Vancouver Campus  
Vancouver, Canada  
*john.woods@ubc.ca*

Chapter B.6

John Woods has done pioneering work in the logic of fallacious reasoning, the logic of fiction, argumentation theory, conflict resolution in the abstract sciences, the logic of abduction, Aristotle's earlier logic, naturalized logic, the logic of inconsistency robustness and the logic of legal reasoning. Fellow of the Royal Society of Canada, John Woods is a Life Member of the Association of Fellows, The Netherlands Institute for Advanced Study.

**Alison Wylie**

University of Washington  
Department of Philosophy and  
Anthropology, Savery Hall  
Seattle, USA  
*aw26@uw.edu*

Chapter I.46

Alison Wylie is a philosopher of science who works on issues raised by archaeological practice and feminist research. She has co-edited and authored two books, and contributes to collections on topics.

## Detailed Contents

<b>List of Abbreviations</b> .....	XXXVII
------------------------------------	--------

### Part A Theoretical Issues in Models

#### 1 The Ontology of Models

<i>Axel Gelfert</i> .....	5
1.1 Kinds of Models: Examples from Scientific Practice .....	6
1.2 The Nature and Function of Models .....	8
1.3 Models as Analogies and Metaphors .....	10
1.4 Models Versus the Received View: Sentences and Structures .....	12
1.4.1 Models and the Study of Formal Languages .....	13
1.4.2 The Syntactic View of Theories .....	13
1.4.3 The Semantic View .....	14
1.4.4 Partial Structures .....	15
1.5 The Folk Ontology of Models .....	16
1.6 Models and Fiction .....	18
1.7 Mixed Ontologies: Models as Mediators and Epistemic Artifacts .....	20
1.7.1 Models as Mediators .....	20
1.7.2 Models as Epistemic Artifacts .....	21
1.8 Summary .....	21
<b>References</b> .....	22

#### 2 Models and Theories

<i>Demetris Portides</i> .....	25
2.1 The Received View of Scientific Theories .....	26
2.1.1 The Observation–Theory Distinction .....	27
2.1.2 The Analytic–Synthetic Distinction .....	29
2.1.3 Correspondence Rules .....	30
2.1.4 The Cosmetic Role of Models According to the RV .....	32
2.1.5 Hempel's Provisos Argument .....	33
2.1.6 Theory Consistency and Meaning Invariance .....	34
2.1.7 General Remark on the Received View .....	35
2.2 The Semantic View of Scientific Theories .....	36
2.2.1 On the Notion of Model in the SV .....	38
2.2.2 The Difference Between Various Versions of the SV .....	40
2.2.3 Scientific Representation Does not Reduce to a Mapping of Structures .....	42
2.2.4 A Unitary Account of Models Does not Illuminate Scientific Modeling Practices .....	44
2.2.5 General Remark on the Semantic View .....	46
<b>References</b> .....	47

<b>3</b>	<b>Models and Representation</b>	
	<i>Roman Frigg, James Nguyen</i>	49
3.1	Problems Concerning Model–Representation	51
3.2	General Griceanism and Stipulative Fiat	55
3.3	The Similarity Conception	57
3.3.1	Similarity and ER–Problem	58
3.3.2	Accuracy and Style	62
3.3.3	Problems of Ontology	64
3.4	The Structuralist Conception	66
3.4.1	Structures and the Problem of Ontology	66
3.4.2	Structuralism and the ER–Problem	68
3.4.3	Accuracy, Style and Demarcation	70
3.4.4	The Structure of Target Systems	71
3.5	The Inferential Conception	76
3.5.1	Deflationary Inferentialism	76
3.5.2	Inflating Inferentialism: Interpretation	80
3.5.3	The Denotation, Demonstration, and Interpretation Account	82
3.6	The Fiction View of Models	83
3.6.1	Models and Fiction	84
3.6.2	Direct Representation	86
3.6.3	Parables and Fables	88
3.6.4	Against Fiction	89
3.7	Representation–as	91
3.7.1	Exemplification and Representation–as	91
3.7.2	From Pictures to Models: The Denotation, Exemplification, Keying–up and Imputation Account	93
3.8	Envoi	96
