of unaccelerated motion from another; *Tolman* proposes to do the same for the statement that observers not be able to distinguish an appropriately constructed model universe from the actual one [18.58], if inhabiting it as an appropriately transformed being and using appropriately constructed or transformed instruments. There is a confusion in *Tolman*’s reasoning. While it is quite natural to say that a desirable principle of nature, and a desirable constraint on measuring systems, is that it should not matter to the project of pursuing truth that one observer in the actual world is using one system of measurement and another observer in the actual world is using another system of measurement, *Tolman* seems here to be confusing that requirement with a requirement that miniature universes constructed from the materials of the actual universe be indistinguishable from the actual, full size, universe by the miniature observers inhabiting those miniature universes.

#### Buckingham’s *Physical Review* Paper and Reply to Richard Chace Tolman

It’s rather obvious that the notion of similar systems – one system being transformed into another system  $S'$  in such a way that it “corresponds” to  $S$  (“as regards the essential quantities”) – is relevant to evaluating the claim *Tolman* made in his 1914 *Principle of Similitude* paper [18.58] that the universe could be transformed overnight into an observationally indistinguishable miniature universe. The notion of similar systems is also relevant to *Stanton* and *Pannell*’s *Similarity of Motion* paper [18.6], in that it is a more general treatment of the methodology of model testing (“the principle of dynamical similarity” [18.6, p. 201]) given there. In the next paper that *Buckingham* wrote on the topic [18.2], in addition to presenting the generalized treatment found in the July 1914 version of *Physically Similar Systems*, he addressed both these related topics on which major papers had appeared in the earlier part of the year: experimental models and *Tolman*’s claims about the possibility of an observationally indistinguishable miniature universe. The October 1914 *Physical Review* featured *Buckingham*’s *On Physically Similar Systems: Illustrations of the Use of Dimensional Equations*; his manuscript is dated June 18th of that year [18.2].

In his 1914 *Physical Review* paper [18.2], *Buckingham* says that his purpose in presenting how the notion of physically similar systems can be developed from the principle of dimensional homogeneity in that paper was to provide the background against which to respond to *Tolman*’s proposed “principle of similitude” [18.2, p. 356]. He makes several points relevant to addressing *Tolman*’s proposal for a new principle in physics in

developing “the notion of physical similarity” and “the notion of physically similar systems”:

1. It is only “the phenomenon characterized by the relation [expressed by the equation whose existence was assumed at the start]” that “occurs in a similar manner” in both systems: “we say that the bodies or systems are *similar with respect to this phenomenon* (emphasis added).” *Buckingham* specifically points out that systems that are “said to be *dynamically similar*” might not be similar “as regards some other dynamical relation”; two dynamically similar systems might not “behave similarly in some different sort of experiment.”
2. There is a more general conception of similarity than dynamical similarity, and it too “follows directly from the dimensional reasoning, based on the principle of homogeneity.”
3. Tolman’s proposed *Principle of Similitude* is not clearly stated, but inasmuch as *Buckingham* understands it, it seems to him “merely a particular case” of the theorem *Buckingham* presents in the paper. *Buckingham* reasons as follows: The way *Tolman* proceeds is to select four specific independent kinds of quantity (length, speed, quantity of electricity, electrostatic force), subjects these four kinds of quantity to four arbitrary conditions, then finds the conditions that some other kinds of quantities are subject to “in passing from the actual universe to a miniature universe that is physically similar to it” [18.2, p. 356]. I take *Buckingham*’s point to be that, inasmuch as what *Tolman* is concluding is correct, it can be concluded using the principle of dimensional homogeneity without the aid of the “new” principle that *Tolman* proposed in his March 1914 *Physical Review* paper.

Having already remarked that the notion of similar systems used in constructing and using a model propeller is generalizable beyond mechanics, he then goes on to show how the principle involved in doing so – the “method of dimensions” [18.65, p. 696] – applies in problems ranging from electrodynamics (energy density of a field, the relation between mass and radius of an electron, radiation from an accelerated electron) to thermal transmission, and, finally, at a higher level, to the kind of *bird’s-eye view* question to which his interest tended to migrate: “the relation of the law of gravitation to our ordinary system of mechanical units.”

The question he asks about the role of the law of gravitation in determining units of measure is a bit different. It is about the number of *fundamental units*, and the question *Buckingham* asks can be put in terms of similar systems: if it is, in fact, true that in mechanics

three fundamental units suffice to describe mechanical phenomena (more if thermal and electromagnetic phenomena are to be described), then it would be correct to conclude that [18.2, pp. 372–373]:

“[A] purely mechanical system may be kept similar to itself when any three independent kinds of mechanical quantity pertaining to it are varied in arbitrary ratios, by simultaneously changing the remaining kinds of quantity in ratios specified by [the constraint of dimensional homogeneity . . .] For instance, we derive a unit of force from independent units of mass, length, and time, by using these units in a certain way which is fixed by definition, and we thereby determine a definite force which is reproducible and may be used as a unit. Now by Newton’s law of gravitation it is, in principle, possible to derive one of the three fundamental units of mechanics from the other two.”

*Buckingham* then describes a laboratory experiment from which a unit of time can be derived from units of mass and length – *if* one assumes Newton’s law of gravitation to hold. To be clear: *Buckingham* is granting that people have sometimes reduced the number of fundamental units to two, such as when a unit of time is derived from units for mass and length, when working on specific problems. What he is concerned to show is that, in order to do so, they have had to use assumptions about the law of gravitation. He is not unaware that the current state of physics indicates Newton’s law of gravitation is not the final word, and is pointing out the role that a law of gravitation plays in such reductions of the number of fundamental units to two. Put in terms of similar systems, the question is: How many degrees of freedom do we have in constructing a system  $S'$  that is similar to  $S$ ? How many quantities can be varied in an arbitrary ratio when we transform  $S$  into  $S'$ , a system that is physically similar to it?

*Buckingham* points out that, even in the domain of mechanics, it depends on what phenomenon the relation between quantities characterizes. As he emphasized, the notion of physical similarity and physically similar systems involves only similarity *with respect to* a specified relation. (Recall that the analysis started with the quantities involved in a given equation, where that equation describes a relation that relates a certain number of kinds of quantities such that any one was determined by all the others, and the relation characterized a phenomenon of interest.) In developing a general methodology, *Buckingham* had considered all possible relations that could exist among the given kinds of quantities. In the most general case, the law of gravitation is a constraint on how quantities are related. Recognizing this additional constraint reduces the

number of independent quantities by one. However, he explains, such generality is not always required in practice [18.2, p. 374]:

“But if for ‘all possible relations’ we substitute ‘all relations that do not involve the law of gravitation,’ we may ignore the law and proceed as if it were non-existent.”

This can actually be done in many cases, he says, since [18.2, p. 374]:

“in practice, physicists are seldom concerned with the law of gravitation: for all our ordinary physical phenomena occur subject to the attraction of an earth of constant mass and most of them occur under such circumstance that the variation of gravity with height is of no sensible importance.”

However, for precise geodesy and astronomy, one needs to be explicit about the law of gravitation.

Buckingham’s answer to the question Tolman’s paper raises about the possibility of constructing observationally indistinguishable miniature universes, thus, bifurcates into two cases, depending on whether or not the phenomenon that we are interested in observing in the miniature universe is influenced by the law of gravitation. If not, then it might not be impossible to construct a miniature universe, as Tolman suggests, that will be similar to the universe (as regards that phenomenon.) On the other hand, if the phenomenon is influenced by the law of gravitation, more things must be taken into account:

“the gravitational forces in the miniature universe must bear to the corresponding gravitational forces in the actual universe a ratio fixed by the law of gravitation.”

He points out that the effect of the law of gravitation on the phenomena of interest shows up in the process of constructing similar systems. If we erroneously try to independently choose three units rather than letting the third be determined by the first two fundamental units chosen, we run into trouble because the measured values for corresponding speeds and forces will not correspond to the values in the actual universe – unless, that is, the third unit is allowed to be fixed by the law of gravitation in terms of the first two.

The points about physically similar systems, systems of units, and the law of gravitation seem to be questions in the logic of physics. Yet, the main claim of Buckingham’s papers on physically similar systems can actually be stated in terms of a theorem about the *symbolism of relations* between physical quantities.

This is seen in the “convenient summary” with which he concludes the paper [18.2, p. 376]:

“A convenient summary of the general consequence of the principle of dimensional homogeneity consists in the statement that any equation which describes completely a relation subsisting among a number of physical quantities of an equal or smaller number of different kinds, is reducible to the form  $\Psi(\Pi_1, \Pi_2, \dots, \Pi_i, \text{etc.}) = 0$  in which the  $\Pi$ ’s are all the independent dimensionless products of the form  $Q_1^x Q_2^y \dots$ , etc. that can be made by using the symbols of all the quantities  $Q$ .”

The equation  $\Psi(\Pi_1, \Pi_2, \dots, \Pi_i, \text{etc.}) = 0$  in the quote from Buckingham above is what I called *The Reduced Relation Equation of 1914* in Sect 18.1 of this chapter.

#### 18.4.4 Precursors of the Pi-Theorem in Buckingham’s 1914 Papers

This chapter is devoted to the history of the notion of physically similar systems. Buckingham’s 1914 papers are considered a landmark in the development of our current notion of physically similar systems, due to the articulation of what a physically similar system is and how it is related to the symbolism used to express relations in physics. First, Buckingham showed that *The Reduced Relation Equation of 1914* followed from the principle of the homogeneity of a physical equation. Then, he showed how the notion of *physically similar systems* could be developed from it.

However, since Buckingham’s name has since become attached to the so-called *pi-theorem*, and the full contents of his 1914 papers are often ignored, being inaccurately viewed as doing little more than presenting the pi-theorem, I want to emphasize that what has become known as the pi-theorem itself is not actually due to Buckingham. There were, in fact, many precursors who proved the same result, with varying levels of generality.

##### Vaschy and Bertrand

The *pi-theorem* is referred to in France as the Vaschy–Buckingham Pi-Theorem. In 1892, Vaschy (1857–1899) published *Sur les lois de similitude en physique* [18.66, 67], in which he stated the result about the number of parameters required to state a given relationship that is often attributed to Buckingham. However, unlike Buckingham, Vaschy did not mention dimensions or dimensional equations. He spoke of quantities and units, and did so as though they were the same sort of thing, though he did speak of some units

as fundamental and others as derived. More precisely, *Vaschy's* theorem is [18.67]:

“Let  $a_1, a_2, a_3, \dots, a_n$  be physical quantities, of which the first  $p$  are distinct fundamental units and the last  $(n-p)$  are derived from the  $p$  fundamental units (e.g.,  $a_1$  could be a length,  $a_2$  a mass,  $a_3$  a time, and the  $(n-3)$  other quantities would be forces, velocities, etc.; then  $p = 3$ ). If between these  $n$  quantities there exists a relation  $F(a_1, a_2, a_3, \dots, a_n) = 0$ , which remains the same whatever the arbitrary magnitudes of the fundamental units, this relationship can be transformed in another relationship between at most  $(n-p)$  parameters, that is  $f(x_1, x_2, x_3, \dots, x_{n-p}) = 0$ , the parameters  $x_1, x_2, x_3, \dots, x_{n-p}$  being monomial functions of  $a_1, a_2, a_3, \dots, a_n$ .”

The parameters  $x_1, x_2, x_3, \dots, x_{n-p}$  play the same role as the dimensionless  $\Pi$ 's in Buckingham's theorem. *Vaschy* then shows how to obtain reduced relations for the pendulum and for a telegraph cable. What is notable is that he produces a pair of ratios, not just one ratio, in each case, and he expresses the result as an unknown function of these parameters ( $x_i$ 's) set equal to zero. He does not use the terminology of systems, but he is interested in laws of similitude (in the sense of the similarity laws of Sect. 18.3.1) that can be derived from them, citing one by W. Thomson (Lord Kelvin) in the case of the telegraph line. The conditions of *Vaschy's* theorem are not exactly the same as in Buckingham's theorem, but *Vaschy* does emphasize that his reasoning does not assume any particular system of units, and he does derive the key move to the *Reduced Relation Equation of 1914*. The case is strong for crediting *Vaschy's* paper with containing the *pi-theorem*.

Some have also argued that Joseph Bertrand provided an even earlier, though less general, proof of the pi-theorem in 1878, in *Sur l'homogeneite dans les formules de physique* [18.66, p. 209]. This is the same Joseph Bertrand (1822–1900) cited above for the much earlier 1847 work drawing attention to the principle of similitude, in which he mentioned “an infinite number of possible systems, which may be regarded as similar to” a given system, and provided a new basis for Newton's theorem of similarity using a result by Cauchy involving the principle of virtual velocities.

These two works by *Bertrand* [18.28, 68] thirty years apart reflect an important late nineteenth century development that permitted using a logical principle about *the equations of physics*, that is, the homogeneity of equations of physics, rather than a principle of physics itself. This late nineteenth-century development was the idea of coherence as a constraint on a system of units; the idea, that is, of a coherent system of units. Coherence of a system of units, and its importance in connecting dimensional analysis and similarity, is discussed in [18.69].

### Riabouchinsky

Sometime after 1914, Buckingham became aware that *Dimitri Riabouchinsky* (1882–1962) had also proved a mathematical theorem about the number of dimensionless parameters needed to express a given physical relation, using the methods of dimensional analysis, in 1911 [18.65]. *Riabouchinsky* (spelled *Riabouchinski* in Buckingham's papers), was a scientist who had provided the private funding for the Aerodynamic Institute of Koutchino associated with the University of Moscow, which had a wind tunnel; hence, *Riabouchinsky* was, like Buckingham, faced with the problem of understanding how to interpret model experiments. After becoming aware of *Riabouchinsky's* proof, *Buckingham* credited him prominently for the proof in his writings. In a paper in 1921, discussing the desire that had arisen for a more systematic procedure for obtaining the results that Rayleigh and others had obtained using dimensional methods, he wrote [18.70, p. 696]:

“Such a routine procedure is provided by formulating the requirement of dimensional homogeneity as a general algebraic theorem, which was first published by *Riabouchinski* (sic), and which will be referred to as the  $\Pi$  theorem.”

*Buckingham* speculated that he might have seen a notice of *Riabouchinski's* result in one of the Annual Reports of the British Advisory Committee on Aeronautics [18.71], and that [18.70, p. 696n]:

“Guided [...] by the hint contained in this abstract, the present writer came upon substantially the same theorem. [...] The theorem does not differ materially from *Riabouchinski's*, except in that he confined his attention to mechanical quantities.”

## 18.5 Physically Similar Systems: The Path in Retrospect

We are now in a position to survey the path from Newton's theorem about similar systems of bodies in the seventeenth century to Buckingham's development of the notion of similar systems from what I have called the *Reduced Relation Equation of 1914*, in the early twentieth century. Painting what we can see in retrospect in broad brush strokes, the picture of this path is that there are several key ideas that made the twentieth century notion of physically similar systems possible. The first of these is the notion of a function developed in the eighteenth century, and the second is the notion of a coherent system of units developed in the late nineteenth century.

Brian Hepburn identifies Leonhard Euler as a key eighteenth century figure linking Newton's age and ours, and has argued that the concept of a function was crucial to the development of what we now know as Newtonian mechanics. Whereas Newton's mechanics "dictated how motions are generated in time by forces" and "would treat of the actual process of moving bodies," Hepburn says, for Euler, in contrast, "the central object of investigation in mechanics is the [mathematical] function" [18.12]. He points out that equilibrium relations are the most important among relations, and hence that "sets of quantities" characterized "states" – I would amend this to "states of a system." The notion of a function allowed the concept of a system to be expressed in terms of the interrelatedness of some quantities – if one quantity changed, any of the others in the system might be affected, too. The notation of a function set to 0, that is,  $f(x_1, x_2, \dots, x_n) = 0$  can be used to express this interrelatedness. The notion of equilibrium and an equation of state, which are expressible by the functional notation, are important in this newer notion of a system; what this new notion of system eventually replaced was the notion of a system as a configuration of particles and/or bodies. The notion of a similarity law likewise progressed from simply a single ratio to express an invariant relation, to a function with multiple arguments, each of which was a dimensionless ratio.

When Bertrand invoked the principle of virtual velocities in 1847 [18.25, p. 380] to derive the principle of mechanical similitude, he was using the notion of a function, but he was still using considerations and principles of mechanics. By 1878, he could take a much more general approach, using a principle that was a constraint on the equation expressing relations between the physical quantities, rather than the system of bodies and particles itself. Independently, many others could do so, too: Vaschy in France and Riabouchinsky in Russia, and they were not the only ones. In physical chem-

istry, van der Waals and Onnes, thinking of collections of molecules as systems, could apply these more formal notions of similar systems to come up with a way to predict the behavior of one substance based on only its critical points, along with observations about how another substance behaved. The amazing success of this approach in physical chemistry seems to have encouraged extending the approach of similar systems to electromagnetic theory and the kinetic theory of gases.

That the time was right in 1914 for deriving the pi-theorem and the Reduced Relation Equation of 1914 is clear from the fact that so many had already done it by then. That Buckingham was the one to write what has become the landmark paper articulating the notion of physically similar systems, which he developed from the *Reduced Relation Equation of 1914* in the  $\Pi$ -theorem, then, appears to be a matter of timing, at least in part: when he was suddenly asked to devote time to the question of the value of model experiments using wind tunnels, it was the early twentieth century, when the notion of a system was readily expressible by the notation for a function, when coherent systems of units in every part of physics was something that could be assumed, and someone with a doctorate in physics would have a facility with formal methods applied to equations.

Around the same time, or shortly thereafter, *D'Arcy Wentworth Thompson* wrote his classic work, *On Growth and Form* [18.72], on the mathematicization of biology. In that work, he carried the use of similitude in physics over into biology and he, too, explicitly cites Newton (for his use of similitude), as well as Galileo (for his discussion of scaling and similitude), Boltzmann, Helmholtz and numerous publications on aerial flight. A detailed discussion of D'Arcy Thompson on similitude may be found in Chap. 6 (*The Physics of Miniature Worlds*) of *Wittgenstein Flies a Kite* [18.11, pp. 117–130].

How do things stand today, in the early twenty-first century? Certainly, there are pockets in many disciplines – physics, hydrodynamics, aerodynamics, the geological and other sciences, hydrology, mechanics, biology, and more – where researchers recognize the value of thinking in terms of physically similar systems. However, it is not really a staple of the basic curriculum. Few philosophers of science understand the concept or why it is significant. This article is offered to help improve at least the latter situation.

**Acknowledgments.** Work on this paper was supported in part by a Visiting Fellowship at the Center for Philosophy of Science at the University of Pittsburgh in

2010, during which my project was the history of the concept of physically similar systems. This paper also incorporates some earlier work published in Chaps. 6 (*The Physics of Miniature Worlds*) and 7 (*Models of Wings and Models of the World*) of *Wittgenstein Flies*

*A Kite: A Story of Models of Wings and Models of the World*. Thanks also to Brian Hepburn and George Smith for conversations about Newton's use of similar systems, and to Jasmin Ozel for translating parts of Forchheimer's *Hydraulik*.

# Hypothetical

## 19. Hypothetical Models in Social Science

Alessandra Basso, Chiara Lisciandra, Caterina Marchionni

The chapter addresses the philosophical issues raised by the use of hypothetical modeling in the social sciences. Hypothetical modeling involves the construction and analysis of simple hypothetical systems to represent complex social phenomena for the purpose of understanding those social phenomena.

To highlight its main features hypothetical modeling is compared both to laboratory experimentation and to computer simulation. In analogy with laboratory experiments, hypothetical models can be conceived of as scientific representations that attempt to isolate, theoretically, the working of causal mechanisms or capacities from disturbing factors. However, unlike experiments, hypothetical models need to deal with the epistemic uncertainty due to the inevitable presence of unrealistic assumptions introduced for purposes of analytical tractability. Computer simulations have been claimed to be able to overcome some of the structures of analytical tractability. Still they differ from hypothetical models in how they derive conclusions and in the kind of understanding they provide.

The inevitable presence of unrealistic assumptions makes the legitimacy of the use of hypothetical modeling to learn about the world a particularly pressing problem in the social sciences. A review of the contemporary philosophical debate shows that there is still little agreement on what social scientific models are and what they are for. This suggests that there might not be a single answer to the question of what is the epistemic value of hypothetical models in the social sciences.

### 19.1 Hypothetical Modeling as a Style of Reasoning

In *Styles of scientific thinking in the European tradition*, the historian of science A.C. Crombie [19.1] lists six styles of thinking that characterize modern scientific thought:

1. The method of postulation
2. The use of experiments
3. The hypothetical construction of analogical models
4. The taxonomic method
5. The use of statistics and probability
6. Historical derivation.

*Ian Hacking* re-labels Crombie's classification as one of the *scientific styles of reasoning* and adds a sev-

enth: The laboratory style, which lies between methods (2) and (3) in that it relies on “built apparatus” to produce phenomena about which hypothetical models may be true or false [19.2]. Each style of reasoning introduces new kinds of objects, new evidence and new ways of being a candidate for truth. For our purposes the relevant features of a style of reasoning are its stability across disciplinary contexts and its autonomy, in other words, once a style of reasoning becomes established, it determines its own criteria of what counts as good reasoning [19.2].

Hypothetical modeling refers to that scientific strategy in which the known properties of an artifact are put to use in order to elucidate the unknown properties of a natural phenomenon [19.1, p. 1087]. *Mary Morgan* [19.3] deploys the concept of style of reasoning to characterize the practice of theoretical modeling in economics and traces the history of how modeling gradually became the prevalent style of reasoning in economics, achieving its present features around the second half of the last century. It is these features that Morgan’s work, and ours too, endeavors to describe. Here, however, we are concerned with hypothetical modeling as it takes place in the social sciences at large. By treating this method as one style, we seek to highlight its distinctive characteristics, which cut across disciplines.

Unlike in economics, in other social sciences such as sociology and political science, until a few decades ago the use of hypothetical models was limited to relatively narrow areas of inquiry. Well known, contentious attempts at introducing economic-style, rational-choice models in sociology and political science sparked accusations of economics imperialism [19.4]. More generally, formal modeling was often perceived in opposition to the qualitative leanings of many social scientists. Critics complained that mathematical models could not capture the complexity of social and economic phenomena, which are often hard to quantify and measure and do not obey the kinds of exceptionless laws that were believed to characterize the natural sciences. Disciplinary resistance to the method of hypothetical modeling, however, is not at odds with the stability characteristic of styles of reasoning: It is the deployment of a style in a new field and domain of inquiry that is contested, but its features, those that make it a style, might remain untouched. Moreover, the critical attitude toward the method of hypothetical modeling is now changing, at least in some social sciences. For instance, *Clarke and Primo* [19.5, p. 1] claim that, “[m]odels have come to be the dominant feature of modern political science and can be found in every corner of the field”. *Edling* [19.6, p. 197], writes that “since mathematical sociology was firmly established in the 1960s, it has grown tremendously”.

The transfer of models and modeling techniques across disciplinary boundaries is contributing to the establishment of shared modeling standards. Recent fields such as network theory and agent-based modeling are united by common modeling tools rather than by a set of principles or subject matter. These tools are then being modified and adapted *in house*, as it were, to satisfy the specific epistemic and nonepistemic needs of each field. For example, the use of network theory in sociology looks rather different from the use of network theory in economics and this is in part due to their being embedded in different disciplinary cultures [19.7, 8]. Thus, it is possible to talk of *field-specific modeling practices* to emphasize what is distinctive about a specific discipline and to talk of *style of reasoning* to underline the distinctiveness of model-based reasoning vis-à-vis other scientific styles of reasoning, such as the laboratory style. Which aspect is emphasized depends on the purposes of one’s enquiry.

Here we are interested in the commonalities: Treating hypothetical modeling as a style of reasoning encourages us to look at its characteristic features vis-à-vis other styles of reasoning employed in social science. Philosophers of science sometimes talk of model-based social science, a label that captures the same kind of scientific activity. Here is how *Peter Godfrey-Smith* characterizes it [19.9, p. 726]:

“What is most distinctive of model-based science is a strategy of indirect representation of the world [...] The modeler’s strategy is to gain understanding of a complex real-world system via an understanding of a simpler, hypothetical system that resembles it in relevant respects.”

The terms *hypothetical modeling* and *model-based science* both refer to the scientific activity of understanding phenomena by building hypothetical systems, which at once are much simpler than the phenomenon under investigation and hopefully resemble it in some respect. The modeler studies these simpler, hypothetical systems in order to gain insights into the more complex phenomena they represent. These hypothetical systems can be of different kinds: They can be concrete objects such as the scale models of engineers, or they can be the set of mathematical equations very familiar to both physicists and economists. In this chapter our main focus is on models that are abstract in the sense that they do not exist as physical objects to be manipulated by the modeler. They are theoretical rather than empirical models. Empirical models are built for testing and measuring relationships between variables and are based on empirical data; they do not describe hypothetical systems. In this sense they are better thought of as belonging to the statistical style of reasoning.

The attribute *theoretical* should not be taken to suggest that theoretical models are always instantiations of general theories. Theoretical principles might be only one of the several ingredients that go into the construction of theoretical models [19.10]. Ideally, theoretical (or hypothetical) modeling and empirical modeling are tightly connected. The results of theoretical models are translated into empirical models and thereby subject to testing. In many cases, however, the evaluation of theoretical models proceeds without the results being directly confronted with data. This is how the historian and methodologist of economics *Roger Backhouse* explains the relationship between theoretical and empirical models [19.11, p. 138]:

“Empirical work starts with a set of economic relationships, formulated in such a way that they can be confronted with data using formal, statistical techniques. These relationships may be the theoretical results [...], but typically they will be different. The reason for this is the requirement that they can be confronted with data: They must refer to variables on which statistical data exist, or for which proxies can be found; functional forms must be precisely specified and amenable to statistical implementation.”

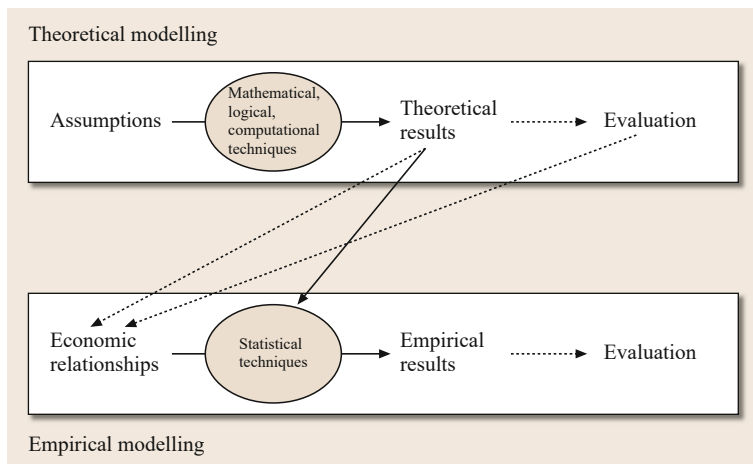

Backhouse’s account is about economics, but it can be generalized to other social scientific contexts in which theoretical results cannot be directly confronted with empirical data. In such cases, theoretical and empirical modeling might be only loosely connected with one another, for example, by way of the theoretical results informing empirical modeling and vice versa, as depicted in Fig. 19.1.

But which theoretical results are taken seriously enough to inform further empirical investigations? The

evaluation of hypothetical models often relies on other criteria such as credibility, insightfulness, explanatoriness or other modeling desiderata. This is one of the aspects that make hypothetical modeling partly autonomous from other styles of reasoning: The evaluation of hypothetical models and their results is based on criteria largely internal to the style, criteria that have developed together with the stabilization of the style.

In contemporary social science the diffusion of hypothetical modeling to tackle social scientific questions is taking place in parallel with an increasing reliance on computer simulations as well as on laboratory and field experimentation. Recall that Hacking takes the laboratory style to lie between the use of experiments and hypothetical models. The laboratory style differs from experimentation simpliciter in that it creates artificial environments about which the hypothetical models can be true or false. In the social sciences where laboratory experiments were believed to be virtually impossible, modeling was considered to be an attempt—to some fruitful, to others idle—to achieve theoretically what it is impossible to implement in the laboratory; even now, when both laboratory and field experimentation have become well-established practices in many social sciences, many questions of interest still cannot be studied experimentally. It is perhaps not surprising that models and experiments have been compared in order to understand their characteristic features as well as their common characteristics.

The discussion in Sect. 19.2 addresses the question of whether models are relevantly similar to experiments and, if not, where the deep differences lie. In Sect. 19.3, we examine the issue of whether computer simulations belong to the style of hypothetical modeling. In general terms, the question is whether or not computer simulation and analytical modeling are different ways of studying hypothetical systems. These comparisons

**Fig. 19.1** The relationship between theoretical and empirical modeling (after [19.11, p. 136])

allow us to highlight some of the main features of hypothetical modeling in the social sciences. Finally, we discuss the legitimacy of hypothetical modeling as a way of learning about social scientific phenomena. The debate reconstructed in Sect. 19.4 attempts to understand how hypothetical modeling deals with the specificities of the social sciences and to examine the conditions of its legitimacy. As will become clear, there is little agreement on the nature and function of theoretical models in social science. Perhaps this is not so much a sign of slow progress in understanding models as it is an indication that a substantive as well as a general account of the nature and function of models is not possible [19.12].

## 19.2 Models Versus Experiments: Representation, Isolation and Resemblance

The alleged impossibility of laboratory experimentation has for long been considered one of the features that sets the social sciences apart from the natural sciences. It was widely believed, among both scientists and philosophers, that experiments were the exclusive purview of the natural sciences: Many if not all questions of interest in the social sciences were thought not to be amenable to experimental investigation, owing to the difficulty of designing experimental settings capable of reproducing and confining the phenomena of interest. The broad scale of many social phenomena and the inevitable presence of disturbing factors of very different kinds (e.g., history, cultural background, value judgments, etc.) were seen as insurmountable obstacles to controlled experimentation. Obvious ethical issues also contributed to limit the range of feasible scientific experiments and continue to do so. Since the second half of the last century, however, the use of experimentation in social science has grown remarkably, both in the laboratory and in the field, thanks to technological and methodological developments, which allow control of many of the disturbing factors that were previously considered impossible to control for ([19.13], see also [19.14] for economics and [19.15] for political science).

The method of hypothetical modeling has been seen as an alternative to experimentation when experimentation is difficult or unfeasible [19.16, 17]. Both models and experiments are interpreted as devices for surrogate reasoning, which are examined to draw inferences about the target phenomena they aim to represent [19.18–20]. In the philosophical literature models and experiments have been compared in terms of the functions they play in scientific inquiry and in terms of their use for drawing inferences about the world. The

Most of the philosophical literature that we consider throughout the chapter is about economic modeling. This is because, in the social sciences, economic modeling is where hypothetical modeling has been most prevalent and hence has received the most philosophical attention. However, many of the insights from this literature apply across the social sciences. Not only because rational-choice models are widely employed in social sciences other than economics such as sociology and political science, but also because the indirect representation of phenomena through idealized models crosses disciplinary boundaries. If and when a given issue is peculiar to economics and cannot be generalized, it will be pointed out.

concepts of isolation, representation and manipulation are at the center of this comparison, which deals with functional, methodological and epistemic aspects of the two styles of reasoning.

Models and experiments can be seen as playing a similar function, i.e., that of isolating the phenomenon of interest from the interference of disturbing factors [19.16–19, 21, 22]. This analogy concerns the ideal model and the ideal experiment – or, as Cartwright calls it, the “Galilean experiment” – in which only the factor of interest is allowed to vary, leaving everything else constant. Ideally, experiments proceed by removing or controlling all potentially disturbing factors so as to allow scientists to create the conditions under which causal relations can be observed in isolation. An influential account of models holds that, like experiments, models aim at studying specific aspects of the phenomenon of interest (such as causal relations, capacities or mechanisms) in isolation from the interference of disturbing factors [19.3, 16, 17, 21, 23, 24]. On this account, the isolative function of the ideal model is akin to that of the ideal experiment. To emphasize this similarity, it has been suggested that models are *theoretical experiments* aimed at creating, theoretically, the kind of controlled conditions typical of the laboratory [19.18].

As an illustrative case, consider von Thünen’s well-known model of localization, which is described in the Appendix (Sect. 19.A). The model could be interpreted as the result of a process of isolation that zooms in on the relationship between spatial distance and land use. This is done by means of assumptions that neutralize the effect of other factors by assuming them to be constant, absent or negligible [19.23]. In the model the pattern of agricultural production around the city

depends exclusively on transportation costs, because all other factors that can influence land use, such as the presence of rivers or mountains, the different fertility of the soil and the presence of transport routes, are assumed away. Most of the assumptions listed in Sect. 19.A can be seen as having this function.

The investigations of this analogy by *Morgan* [19.19, 22] and *Mäki* [19.18] emphasize that the way in which models and experiments fulfill their isolating function is different. Experimenters control for disturbing factors by designing the experimental set-up so that disturbing factors are prevented from interfering with the mechanism of interest; this can be done both by physical interventions in the experimental environment and by choices regarding the procedure [19.22]. A social scientific experiment, for instance, might take place in a laboratory in which the subjects interact with the experimenter only via computer terminals, so as to minimize the possibility that the experimenter's expectations influence the subjects' behavior. Alternatively, in order to control for the effect on subjects' choices of the language employed to describe a number of alternatives, the experimenter might design the procedure so that the subjects, instead of all being presented with exactly the same description of the alternatives, are randomly assigned different descriptions, thereby ensuring that language will not have a systematic effect on aggregate choice behavior [19.15].

Hypothetical models try to achieve the same kind of control by means of theoretical assumptions, as in the case of von Thünen's model. The isolation achieved by assuming away all disturbing factors is only a theoretical exploration that does not provide a definitive answer to the question of what would happen in the real world in such a situation. It is open to debate what this difference amounts to and what its consequences are, in particular when it comes to using this style of reasoning for drawing inferences about the world. For *Morgan*, as we will see shortly, this dissimilarity is grounded in the different materials of which models and experiments are made, and this, in turn, has major epistemic consequences. In *Mäki's* account, however, the consequences of this dissimilarity are limited to the degree and strength of isolation that the two styles are able to provide and do not result in major differences concerning their use for making inferences about the world.

For *Mäki*, models are able to display a higher degree of control than experiments can do [19.18]. This is because experiments can isolate only to the extent to which it is practically feasible, and hence some interferences are left uncontrolled for or only weakly controlled for. Models, instead, can provide tighter isolation, because they are not subjected to these practical constraints and can simply assume all interferences

away. One implication of this is that the use of experiments to test models is bound to be imprecise.

In *Mäki's* account, however, the difference in the degree of control between models and experiments does not compromise the identification of further analogies. In particular, *Mäki* claims that "many theoretical models are (*thought*) experiments, and many ordinary experiments are (*material*) models", because both fall under the general concept of *scientific representation* [19.18, p. 303]. In *Mäki's* interpretation, something qualifies as a representation if (a) it is used as a representative of its target and (b) it resembles the target in some respects and to certain degrees. Hypothetical models, as we characterize them, are substitute systems that are examined in order to gather information about what they represent. Similarly, experiments are pieces of the world created in the laboratory that can be seen as material models, which again are not examined for their own sake, but rather for their value in gathering information about the world outside the laboratory. Models and experiments qua substitute representations face the question of whether it is legitimate to draw inferences from the representational tool to the real world. This can be thought of as an instance of the general problem of extrapolation, which concerns the generalization of the results obtained in a model or in an experimental situation to the world. For *Mäki*, in both cases the key to these problems rests on whether the world created in the laboratory or in the model resembles reality in the relevant respects and to a sufficient degree. In our example from von Thünen's work, the problem amounts to establishing whether the model is relevantly similar to reality so as to justify the claim that the distance from the market actually affects the distribution of economic activities as described in the model. In a laboratory experiment on individual choice behavior, the question arises as to whether the kind of task subjects are asked to perform and the artificial environment of their interaction are relevantly similar to situations that occur in the wild so as to warrant inferences from the experiment to the world. In *Mäki's* account, since models and experiments raise similar issues of resemblance, the ability to draw inferences about the world does not hinge on their respective features. Although models can sometimes be made closer to reality, the answer to the problem of extrapolation ultimately depends on what it means for a model to resemble a real situation, and on the ability to identify the relevant aspects and the sufficient degrees of resemblance [19.25]. Therefore, a margin of ambiguity in the notion of *sufficient relevant resemblance* remains.

*Morgan* takes a different stance on the problem of extrapolation [19.19, 22]. She emphasizes that models and experiments are similar in the way in which they are

used and manipulated, but argues that the distinct features that characterize these instruments provide them with different epistemic powers for investigating the world. Models and experiments are manipulated by introducing controlled variation of some of their aspects in order to check whether the results are affected by this change. These manipulations allow scientists to investigate the consequences of variations in the initial conditions on the result and/or the conditions under which a particular result of interest can be obtained. Von Thünen, for instance, after having illustrated his model as described in Sect. 19.A, continued his investigation by introducing the presence of a river and a smaller neighboring town, thereby altering two of the initial assumptions. Changing the model in this way enables investigation of how the newly introduced assumptions affect the pattern of land use in comparison to the initial scenario: The river facilitates the transportation of goods to the market and thus distorts the concentric pattern, whereas the presence of a smaller town generates its own concentric regions of land use. In *Morgan's* terms this can be described as a case of “experiment on models” [19.22]. The manipulation of models can be interpreted as a kind of experiment in which the scientists “interrogate” the model by modifying some of the initial assumptions. These questions can be motivated by theoretical issues, by the aim to explain or predict real-world situations or by the policy agenda the model is meant to guide. For instance, von Thünen’s manipulations of the basic model can be seen as being prompted by questions such as “what happens to the pattern of concentric rings if there is a river and/or a neighboring town?”

Yet when it comes to connecting the answers obtained in this process to the real world, models and experiments are substantially different for Morgan. She argues that experiments have greater epistemic power than models, because the experimental inferential leap is smaller than in the case of models. This dissimilarity is based on the different materials of which each is made: Experiments are concrete investigations, which deal directly with the world they are meant to study, whereas models are abstract and idealized. Economic experiments, for instance, deal directly with real people’s behavior, however constrained the behavior is by the experimental design. By contrast, models are abstract entities, which are made of different stuff than the reality they represent. For *Morgan*, the “materiality” of experiments can make inferences from experimental results to the world both easy and strong, because they are grounded on the material uniformity between the system on which the manipulation is conducted and the world about which the inference is made [19.19]. More precisely, Morgan maintains that, insofar as experiments share the same ontology with their target (which

is not obvious), we are more justified in claiming to learn something about the world from experiments than from models. Inference from the model to the world is much more difficult because the materials are not the same as the world’s.

Moreover, because of their materiality, experiments can create new phenomena that might be different or even contrary to theoretical expectations. When an unexpected experimental result is sufficiently stable across replications and manipulations of the experimental design, it qualifies as a *new* phenomenon, which requires theoretical explanation. For instance, behavioral regularities robustly observed in several economic experiments, such as co-operation in prisoner dilemma games, can be thought of as constituting new phenomena with respect to the expectations of rational choice theory. Such experimental phenomena have now become the target of sustained theoretical efforts to account for them. *Van Fraassen* makes a similar point, arguing that scientific instruments can be viewed not only as windows that allow us to see what happens in the world, but also as machines that create new genuine phenomena that would not occur in the wild and that theory needs to explain [19.26].

In *Morgan's* account, the creation of new experimental phenomena is only possible in the laboratory and does not belong to the style of hypothetical modeling [19.19]. Only real flesh and blood experimental subjects have the freedom to behave in other ways than expected. Experiments must allow a certain degree of freedom because, if the subjects’ behavior was fully determined, then the experiment would have no genuine potential to confirm or refute a theory. Therefore, according to Morgan, experiments have the potential to surprise and confound theory: They can illuminate unexpected or hidden consequences of a theory, but their results can also be in conflict with theoretical expectations. On the other hand, models cannot confound because the behavior of agents is pre-determined by the modeler’s assumptions [19.21]. In other words, the agents in the model lack the “potential for independent action”, which is what confers greater epistemic power to experiments [19.19].

Morgan’s ideas, however plausible, can be challenged. *Parker* rightly observes that it is not always the case that inferences are better justified when the representative tool and the target are made of uniform materials [19.27]. What is crucial is not the material, but the presence of relevant similarities, which can be material but also formal (in this respect, Parker’s point is similar to Mäki’s). The justification of inferences about the world depends on having good reasons to think that the relevant similarities are in place. Having experiment and target made of the same material does not guaran-

tee that all relevant similarities are in place, because it is possible that “same-stuff representations” fail to be relevantly similar to their target systems. Nevertheless, Parker agrees with Morgan that the material uniformity between experiments and the world can provide some epistemic advantage: Experimental and target systems that are made of the same stuff will often be similar in many relevant respects. In other words, being made of the same material does not guarantee that relevant similarities are in place, but it does make it more likely. As a consequence, inferences from experiments are more likely to be reliable than inferences from models.

A further challenge that models have to face arises from the fact that not all assumptions in a model can be thought to function as isolations. Assumptions introduced to make it possible, or easier, to handle the model analytically might impose constraints that are too tight to allow relevant similarities between the models and the represented aspects of the world. This is a point Cartwright makes specifically with regards to economic models: Although many economic models aim at mimicking Galilean experiments, they also include a number of assumptions that do not play the role of isolation, but are rather introduced for the purpose of mathematical tractability [19.21, 28]. If the models’ conclusions are due to assumptions that are completely unrelated to the world, then it is not clear what the model can tell us about the world.

*Derivational robustness analysis* has been proposed as a remedy for the problem of over-constraining assumptions [19.29, 30]. For Kuorikoski et al. derivational robustness analysis refers to the collective practice of building similar models of the same phenomenon that differ only in a few assumptions. The analysis of these groups of similar models can help to identify which assumptions are necessary for deriving a certain result: Results that are robust across a number of models are dependent on the shared, rather than on the differing, assumptions. Now if the over-constraining assumptions (or more generally the assumptions known to be unrealistic) are found to be unnecessary for deriving the result of interest, then there are reasons to think that this result is based primarily on the shared assumptions,

which are hoped to be realistic. Hence, according to Kuorikoski et al. even though robustness analysis is not a procedure of empirical confirmation, it can increase modelers’ confidence about their inferences from hypothetical models. Note that although Kuorikoski et al. are mainly concerned with analytical models, robustness analysis has also been claimed to be a crucial strategy in correcting for various sources of error that might affect the results obtained by computer simulations, as we will see in Sect. 19.3.

*Odenbaugh* and *Alexandrova* raise the valid objection that, although in principle robustness analysis might work, in practice it does not provide a defense of hypothetical models with over-constraining assumptions [19.31]. If, for example, in economic modeling, some of the core rational-choice axioms are never modified to check their effects on the modeling results and if these axioms are in fact wildly unrealistic, then robustness analysis turns out to be of limited use. Hence, although in principle hypothetical modeling might be aimed at isolating a mechanism of interest, there remains the problem that many assumptions do not have this isolating function. This situation can jeopardize the resemblance between the models and the represented target, which would warrant the inferences from the model to the world. We will return to these issues in Sect. 19.4.

In conclusion, both models and experiments can be considered as representations that are examined in order to draw inferences about what is represented. They differ in the kinds of representation involved: Models are abstract indirect representations, whereas experiments are concrete direct representations made of the same material as the target. It has been claimed that this has implications both for the kind and the degree of control that these devices are able to provide and for the way in which conclusions are drawn from them. On the one hand, theoretical models enable the investigation of phenomena that are difficult or impossible to reproduce in the laboratory; yet on the other hand, only experiments seem to have the genuine potential to bring to light new phenomena that require theoretical explanation (Table 19.1).

**Table 19.1** Models, experiments, simulations: A comparative perspective (after [19.22, p. 49])

	<b>Ideal model</b>	<b>Ideal laboratory experiment</b>	<b>Ideal simulation</b>
<i>Kind of representation</i>	Indirect: Different material	Direct: Same material	Indirect: Different material
<i>Isolation and control</i>	Assumed theoretical isolation	Experimental material isolation	Assumed theoretical isolation
<i>Advantages</i>	Theoretical exploration in which experiments are difficult or unfeasible	Discovery of phenomena for science to explain	Representation of complex and/or dynamic problems and other problems that are not solvable analytically
<i>Challenges</i>	Tractability	Material and ethical constraints	Transparency

### 19.3 Models and Simulations: Complexity, Tractability and Transparency

Together with theoretical models and experimental analysis, computer simulations are key instruments in the toolkit of the social scientist. Urban evolution, flows of goods, crowd effects, the stock exchange, virtual financial markets and regulatory policies are just a few examples of what can be analyzed by means of computer simulation. More concrete examples of some of the newest applications include a simulated model of the entire European Union economy, which describes the interaction of a massive number of financial components involved in several markets simultaneously [19.32]. In Stockholm, a data set has been created for the years 1990–2003 to map the entire metropolitan area and simulate segregation effects [19.33].

Some of the characteristics of computer simulation and the ways in which they are employed invite a comparison of these instruments with the style of analytical modeling. The use of computer simulation, in fact, can be thought of as either complementing or replacing analytical models. In the literature some authors have emphasized the elements of continuity between the two methods; others have highlighted the differences. For instance, according to *Guala* [19.20] and *Morgan* [19.22], models and simulations are akin to each other in the way they are used to learn about the world and for the functions they fulfill. Others have argued that computer simulations open up novel methodological questions that did not arise in dealing with analytical models [19.34]. Below, we will explore both the similarities and the differences between these methods, with special focus on the features of computer simulation that have been debated in relation to their adoption in economics and the social sciences.

To see how models and simulations connect, consider how computer simulation originally entered the field of the social sciences. One pioneer in the study of social phenomena with the aid of the computer has been the political scientist Robert Axelrod. In 1980, *Axelrod* launched a competition between experts in game theory from different fields [19.35, 36]. The challenge was to come up with a strategy for an iterated prisoner's dilemma game to be played in a computer tournament. Axelrod paired strategies – fifteen in all – and had the participants play for two hundred rounds in an all-play-all tournament. At the end of the tournament, the winning strategy turned out to be one of the simplest and most ancient strategies of human co-operation, *tit for tat*. The strategy is to co-operate in the first round of the game and then replicate the opponent's moves, i. e., to co-operate in case of co-operation and defect as soon as the other player defects. The strategy is successful insofar as it reaps the benefits of co-operation and does

not lose too much from retaliation. After the results of the tournament's first round were circulated, a second round was held. Once again, *tit for tat* won the competition out of sixty-two rival strategies.

Axelrod's tournament is one of the first examples of the combination of game theory with the computer to study co-operation. There are several reasons why the encounter between game theory and the computer was so fruitful. First and foremost, game theory has traditionally focused on strategic rationality, i. e., on the epistemic criteria for the solution of interaction problems. The discipline is usually silent on dynamic aspects, i. e., on what happens at the population level when different strategies encounter one another repeatedly. Evolutionary game theory focuses on the latter aspect of the problem to expand and complement the domain of inquiry of traditional game theory. Computer simulations are particularly useful for this purpose, as they enable scientists to focus on frequency aspects of strategic interactions rather than on the quality of the strategies per se.

This point can be illustrated by an example. Imagine for a moment that each of the procedures sent by each game theorist to Axelrod represents the way in which the theorist would have played the game in real life. The number of possible combinations quickly becomes unmanageable (in the first tournament, which was repeated 5 times, there was a total of 240 000 choices). By means of computer simulation, it is possible to study which strategies survive, which become extinct and which co-exist. Through computer simulation, agents can be represented more realistically than before, for example, as individuals with bounded rationality and with learning and memory constraints.

Precisely because simulations study how social phenomena emerge and evolve through the interactions of single individuals and their environment, it has been claimed that they represent an invaluable tool in social science [19.37]. This is because the way the simulations analyze the occurrences of social phenomena reproduces the dynamics in which such phenomena occur in the social world. They provide bottom-up, mechanistic explanations [19.38, 39]. Through computer simulation, the role of individual, structural and institutional variables can be represented in a particularly realistic fashion, which has been claimed to help capture the complexity of their interdependence. Note, however, that the enthusiasm with which simulations have been welcome in some fields, such as analytical sociology, has not been unanimously shared. In fact, most notably in economics, simulations have been viewed with suspicion and their adoption not always encouraged. In order

to understand the diverging attitudes of economists and other social scientists, in what follows we will address the following questions:

1. What are the features that characterize computer simulation?
2. Do such features relate to a cluster of properties that distinguish computer simulation from other styles of reasoning such as analytical models?
3. Is economists' preference for analytical modeling over computer simulation justified on epistemic grounds?

Firstly, consider that even if we talk about computer simulations as distinct from analytical models, computer simulations are ultimately based on models. The way in which the two methods differ is that computer simulations obtain their solutions by means of a program that runs on a computer, whereas the solutions of analytical models can be obtained without the aid of a computer. This is simply because simulated models take into account a higher number of variables and consider nonlinear relationships, which are easier to explore with the computer. Broadly speaking, computer simulation refers to the entire process of formulating a *model*, transforming it into an algorithm that runs on a computer, calculating the output and analyzing the results [19.34, 40–42]. Moreover, the contrast between analytical models and computer simulations should not convey the idea that computers do not proceed analytically. Obviously they do (at least if we narrow our focus to models in the social sciences that do not require numerical analysis); the difference is that when computer simulations analyze complex systems, they usually proceed by averaging over a sufficiently high sample of cases rather than in the manner of mathematical proofs (more on this below).

Secondly, note that *computer simulation* is a coarse-grained label, which generalizes different ways in which simulations can be developed. Different taxonomies have been proposed in the literature [19.34, 43]. A preliminary, common distinction is between agent-based models (ABM) and equation-based models. The former proceed by implementing local rules, such as a decision rule in a sociological model; the latter, by translating equation-based models, such as partial or ordinary differential equations in physics, into a computer program. The boundaries between disciplines, however, are not strict. Agent-based models are frequently used in areas other than sociology, including fields that were previously dominated by analytical approaches, such as population ecology and theoretical physics.

A less common but still well-known interpretation defines computer simulation as a subset of a more gen-

eral class of simulations that deploy computers for their ends [19.44]. In this view, a physical model of a target system – e.g., a scale model such as those used in structural engineering – counts as a simulation that adopts a specific means of representation, i.e., a physical model rather than a computer model. An extensive body of literature examines the similarities between computer simulations and experiments and highlights the fact that simulations are closer to the style of experimental analysis than to the style of analytical modeling. For instance, according to *Morrison*, in their relations to models, simulations are akin to experiments [19.45]. According to *Parker*, however, simulations lie between models and experiments in that they display features of both experimentation and modeling [19.27] (for a review of the literature on the experimental interpretation of computer simulations, see e.g., [19.34]).

Taxonomical differences aside, in the most basic sense defined above, computer simulations are simply a tool in the hands of the scientists. They help to achieve the model's results in a manner similar to the way in which a calculator helps perform difficult mathematical operations. Moreover, simulations enable the modeler to represent the target system with a greater level of detail than is usually found in analytical models and to spell out in a particularly precise way the assumptions behind the working hypothesis [19.34, 40, 41].

To illustrate, let us compare in more detail the differences between two mathematical approaches to a study of the same phenomenon. The Lotka–Volterra model is a model in population ecology that also has had applications in the social sciences for the study of organization–environment relations [19.46]. The analytical version of the Lotka–Volterra model is a highly abstract representation of the ecological (organizational) system under study, which omits features such as the environment in which the species live (the market), a realistic level of satiation (competition), lifetime (supply) and so on. When the same problem is addressed by means of an agent-based computer simulation model, a particularly detailed representation of the system of interest is provided. Hence, it is claimed, not only can computer simulation help to avoid common errors in intuition, it might also reveal a system's relevant aspects that had been underestimated or disregarded. Furthermore, computer simulations have heuristic functions: They trigger our intuitions and can be helpful in exploring new hypotheses; not least, they enable us to visualize the results of a problem in particularly efficacious ways. A more detailed and concrete example of how computer simulation proceeds is given in Sect. 19.B.

Given the features discussed above, it would be natural to expect computer simulation to be called upon to

complement analytical models. In 1982 *Richard Feynman* was already justifying the adoption of simulations in physics on the following grounds [19.47, p. 468]:

“The present theory of physics [. . .] allows space to go down into infinitesimal distances, wavelengths to get infinitely great, terms to be summed in infinite order, and so forth. With computers we might change the idea that space is continuous to the idea that space perhaps is a simple lattice and everything is discrete (so that we can put it into a finite number of digits) and that time jumps discontinuously.”

Physical theories trade formal rigor for unrealistic assumptions, such as continuous space and infinite wavelengths. As Feynman suggests, computer simulations can help physicists reduce the constraints of mathematical tractability in favor of descriptive accuracy. Although similar considerations also apply to the social sciences at large, in economics the endorsement of computer simulation has been slower than in physics and other areas of science – with a few exceptions, such as the one we saw above from evolutionary game theory.

Why then is there such an uneven reception of simulation in the social sciences? Why have economists, who have the most established tradition of modeling, been reluctant to embrace simulation? *Lethinen* and *Kuorikoski* investigate the reason for economists’ preference for analytical models [19.42]. The authors claim that this tendency might even slow down progress in the subject and lead economists to dismiss results that would be reasonable to accept. According to *Lehtinen* and *Kuorikoski*, it is because simulations do not provide the kind of *understanding* that is perceived as legitimate in the economic community that this methodology is more often considered as a secondary option at best. Two key assets of economic theory, namely rationality and equilibrium analysis, have a marginal role in agent-based modeling, and these are aspects that economists do not seem willing to dispense with. This also partly explains why in other social sciences, where there is no strong commitment to a unified theoretical corpus, agent-based models are increasingly used. As we have seen, agent-based models allow a greater degree of flexibility in the behavioral rules ascribed to the agents. For many social scientists, this represents an asset rather than a liability. In economics, however, this flexibility is often considered a problem in that the choice of behavioral assumptions is ad hoc rather than guided and constrained by a unified theory (see [19.7] for a discussion of this issue).

In the paper *Robust simulations*, *Ryan Muldoon* addresses another source of concern related to the adoption of computer simulation in science, mainly in-

volving the problem of verifying results [19.48]. To adopt a term used in the literature, simulations are said not to be *transparent*. While it is possible to check each step in the derivation of an analytical model, the same does not apply to simulation. Errors might be concealed within the particular machine used to run the simulation or within the particular programming language or within the algorithm itself. According to *Muldoon*, the best strategy for increasing confidence in the results is to show that simulations provide robust results, i. e., results that are invariant to changes in the hardware, the programming language and the algorithm. Depending on the degree of confirmation a scientist needs to achieve, a robustness test investigates the source of possible mistakes similar to the way in which experimental scientists test their experimental results.

Probably for a combination of the reasons given above, recourse to computer simulation in economics has been legitimized mainly when models become too complex to be analytically solvable or when the volume of data collected is such that only high-powered computers can process them. But what precisely does it mean for a problem to be intractable, and how do computer simulations deal with that? An example that illustrates this issue with particular clarity is *Schelling’s* model of racial segregation (see Sect. 19.B). *Schelling’s* model explains the emergence of ethnic clusters in different metropolitan areas as a consequence of the preference of individuals for having a few neighbors of their own ethnic group. Agents have different information about their neighborhood, and, at any point in time, they can decide to move to another neighborhood that better suits their preferences. Agents move randomly in space, and when they move, they tend to generate further movements of those individuals whose neighborhood has now changed. The chain of possible effects triggered by each agent’s decision makes segregation processes particularly difficult to formalize analytically.

Note that the issue of tractability does not concern only the probabilistic nature of the problem. Analytical methods can in fact be used to calculate the development of a probabilistic system without the need to resort to simulation. In the case of *Schelling’s* model it is because agents have different information and because neighborhoods overlap with one another that analytical treatments are usually excluded. One way to proceed analytically would be, for instance, to assume that the entire city is a unique neighborhood. At that point, all agents would share the same information and the problem of overlapping neighborhoods would be solved. However, no one would move anywhere simply because there would be no neighborhood to go to. In this situation computer simulations can remedy the lack of analytical solutions by providing an approximation of

the process under investigation. At each step of the simulation the state of the system probabilistically depends on its configuration in the previous round. When the results aggregate we can observe whether an underlying dynamic emerges. Furthermore, every time we rewind the tape and run the simulation again, we can observe whether the macrophenomenon is stable despite the contingencies that characterize each particular stack of simulations. Finally, since the simulation environment is significantly flexible, we can consider a variety of factors and their impact, such as agents with different utility functions, or cities with different network structures [19.49].

Notice, however, that there is no reason why a way could not eventually be found to develop analytical solutions for Schelling's model. In fact, in evolutionary game theory, progress has been made in developing analytical solutions with Schelling's model, which rely on stochastic processes [19.50]. More generally, it is often the case that a certain problem does not have an analytical solution until a scientist finds one. When we look at the conditions that make a problem mathematically tractable or intractable we find that there are no neat boundaries between the two. Something that has been mathematically intractable up until today might become tractable tomorrow, thanks to progress in the discipline. But there are no neat criteria that define the tractability/intractability of a problem. Hence, the economists' claim that simulations should be limited to intractable problems, and that scientists should not leap to simulations when an alternative is possible, appears unjustified

after all. According to a less narrow perspective, the adoption of computer simulation might be welcomed even in cases in which an analytical solution is possible, but which is particularly demanding to find, time consuming and expensive with respect to research costs.

To conclude, this section opened with a number of questions on the nature of computer simulations and their relation to analytical models. As we have seen, the answer to the question of whether computer simulations constitute a different style of reasoning from that of analytical models depends on the level of analysis we consider. The differences between analytical and simulated models appear clearer when we look more closely at the two methods: Computer simulations are particularly apt to deal with complex systems, even though they do so at the cost of dispensing with analytical solutions. At a more general level, however, the two practices can be seen to be similar: They both concern the formulation of models and their manipulation for the achievement of results (Table 19.1). Computer simulation should not be taken as a remedy for the problems that affect analytical models, such as whether and under what conditions we are justified in transferring their results to real-world phenomena [19.51]. In these respects, computer simulations deal with issues similar to those dealt with using analytical models, if not with more complicated ones. This, however, does not constitute a reason to avoid their adoption. Rather it indicates that scientists' efforts are needed to meet the challenges that this new methodological tool offers to actual scientific practice.

## 19.4 Epistemology of Models

Scientific models, both analytical and simulation-based, are used for a variety of purposes: Some are used for heuristic or pedagogical reasons; others for prediction or explanation of socio-economic phenomena; still others are built and used with some practical application in mind. The use of models for these purposes, however, has been considered far from unproblematic. Clearly, the source of the problem depends to some extent on the specific purpose to which models are put. For example, von Thünen's model can be thought of as yielding the prediction that, other things being equal, the production of goods that are cheap to transport will take place farther away from the central market. If this prediction is not fulfilled, it might be because the real situation we are considering is not as described in the model. This is something to be expected, if we consider that von Thünen's model abstracts away from many of the factors that in reality have an impact on the localization of

economic activities. The same model can also be seen as providing an explanation of the formation of a pattern of concentric rings around the market, if such is observed, by pointing to the transportation cost of the goods as the cause of the phenomenon. However, even if such a pattern is observed, the question remains as to whether the cause of its emergence is in fact the one theorized in von Thünen's model. Similar issues arise also with respect to Schelling's model, which assumes that the only factor affecting an agent's decision about where to live is the color of other people in a stylized neighborhood. Obviously, in the real world many other factors, such as housing prices and commuting distance, influence individuals' location choices.

Skeptical positions regarding the possibility of acquiring knowledge about the social world by means of hypothetical models are often based on the observation that models typically contain a number of false assump-

tions, and it is unclear how accurate predictions or true explanations can be derived from models that are partly false. No doubt, false assumptions are also employed in the natural sciences, and the role of scientific idealizations is likewise central to the philosophical debate about modeling in the natural sciences. The presence of false assumptions, however, has been regarded as being a particularly acute problem in the social sciences. It has been argued that whereas in the physical sciences it is possible to test idealized models by recreating the same conditions in the laboratory, in the social sciences this can rarely be done. Moreover, unlike the natural sciences, the social sciences typically lack general theoretical principles (or laws) that indicate how deviations from the model's assumptions will affect the result in the real world. For instance, suppose that our model of a falling object assumes that there is no air resistance. The effect of air resistance on the acceleration of a feather falling on the floor can be calculated with the appropriate formula of classical mechanics. In social science, there are only few, if any, general principles of this kind [19.21].

Nevertheless, hypothetical modeling is regarded as a legitimate style of reasoning in many quarters of the social sciences. Social scientists do distinguish between good and bad models in ways that do not necessarily have anything to do with an attempt at direct empirical testing. Both von Thünen's and Schelling's models enjoy a high standing in the social sciences, and their results are generally believed to be relevant, even if not fully or straightforwardly applicable to the real world. How then are such judgments made? And are they legitimate? The questions related to whether and when it is legitimate to use models for epistemic and practical purposes has been at the center of the philosophical debate. However, there is very little agreement among philosophers as to how to address these questions. Below, we reconstruct the discussion of how hypothetical modeling is and should be used in economics and the other social sciences by organizing the different perspectives around the functions of models that are taken as primary:

1. To make qualitative predictions
2. To isolate mechanisms or capacities
3. To learn about possibilities
4. To help with inferences
5. To design socio-economic mechanisms.

#### 19.4.1 Instrumentalism and Predictive Ability

According to an instrumentalist interpretation, if a model yields accurate predictions, then the truth or

falsity of its assumptions does not matter. This position is well exemplified by *Friedman's* position advocated in his famous essay *The methodology of positive economics* [19.52, p. 14]:

"In so far as a theory can be said to have *assumptions* at all, and in so far as their *realism* can be judged independently of the validity of predictions, the relation between the significance of a theory and the *realism* of its *assumptions* is almost the opposite of that suggested by the view under criticism. Truly important and significant hypotheses will be found to have *assumptions* that are wildly inaccurate descriptive representations of reality, and, in general, the more significant the theory, the more unrealistic the assumptions (in this sense)."

The Friedmanian version of instrumentalism has been very popular among economists; the result has been that the impression that abstract modeling was somehow at odds with a commitment to realism has been fostered. Independently of general philosophical arguments for or against instrumentalism about models, this version of instrumentalism seems unsuitable as a defence of social scientific modeling, especially when it comes to theoretical models. As discussed above, in the social sciences theoretical models can seldom be confronted with data to test their qualitative predictions and, when they are, their predictive record has not been spectacular. Thus, even if some models are used and defended because of the correctness of their qualitative predictions, instrumentalism about social scientific models is not widely entertained by philosophers, who have sought to offer alternative accounts of the epistemology of models.

#### 19.4.2 Isolation of Causal Mechanisms or Capacities

Another strategy for dealing with the problem of unrealistic assumptions is to argue that not every assumption has to be true, or descriptively accurate, in order for the model to tell something about the world. Even if there are differences between their philosophical commitments, influential advocates of this position include *Mäki* and *Cartwright* [19.16, 17, 23, 25, 28, 53–56]. As mentioned above, according to *Mäki*, unrealistic components of models serve to isolate a mechanism of interest from disturbing factors. It is precisely thanks to these falsehoods that the operation of a mechanism can be studied in isolation from interfering factors. In *Mäki's* interpretation, therefore, models with false components can deliver truths if and when the isolated mechanism resembles the real-world target in relevant respects and degrees [19.57].

Figure 19.2 depicts the way in which resemblance between model and target is supposed to explain why the model is a successful model of a given phenomenon. Success here is not only of a predictive kind. Mäki's account is meant to encompass explanation as well: His claim is that, if the model successfully explains a phenomenon, this is because it resembles the target in relevant respects and degrees. How this is established in practice constitutes an altogether different challenge, which as we will see partly induces some authors to question the extent to which models can in fact provide explanations. As an illustration of Mäki's position, consider again his interpretation of von Thünen's model (Sect. 19.A): The localization of agricultural activities is explained, at least in principle, in terms of the mechanism that relates distance and revenue; it is this mechanism which is to be judged either true or false. In other words, what matters is that the localization of economic activities depends on the distance from the market as described in the model, even if, due to the interference of other factors, we do not observe a concentric pattern. Mäki's account can be seen as a direct response to some criticisms of unrealistic models in social science, because it points out that the mere presence of false assumptions does not in itself prevent the possibility that the model is true about important aspects of the target system. Hence, unrealistic models should not be dismissed out of hand, but evaluated on a case-by-case basis.

According to Cartwright, models can be seen as isolating causal capacities. Many false assumptions are introduced with the purpose of building a hypothetical situation in which those capacities would act undisturbed from the effects of disturbing factors. Unlike Mäki, however, she maintains that abstract models, that is, models in which the operation of a capacity is examined by abstracting away from concrete situations or system-specific details, cannot be meaningfully interpreted as providing explanations of real-world phenomena. For such models to be used to understand real-world phenomena, they have to undergo a process of concretization: The factors that can potentially affect the operation of the isolated capacity in the concrete situation of interest should be reintroduced in the model.

Cartwright has been rather skeptical that many models in economics and in the social sciences more generally have the right features to be used for understanding the social world – for two main reasons [19.21]. First, socio-economic phenomena are often brought about by many causes, which do not combine vectorially making it hard if not impossible to predict their net effect when they interact. Moreover, these causes often do not have capacities stable

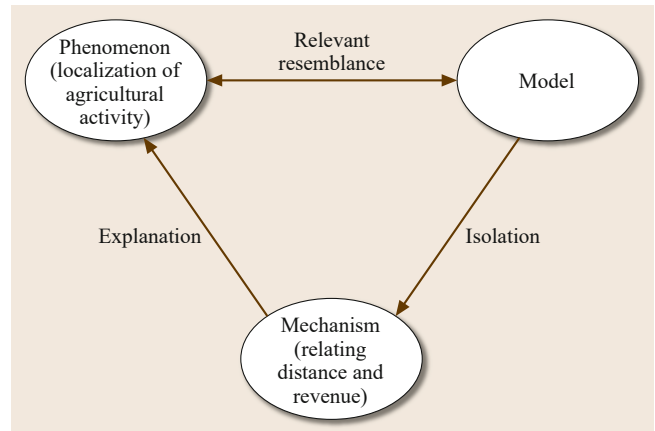

Fig. 19.2 Relevant resemblance between model and phenomenon as the basis for successful inference

enough to support generalizing from their behavior in the isolated model to their behavior in the world. Finally, compared to physics, the social sciences have few theoretical and empirical principles on which to rely for the derivation of conclusions about phenomena of interest. Therefore, deriving conclusions from these few theoretical and empirical principles requires a wide range of assumptions that do not serve the purpose of isolating capacities, but are instead needed to lend structure to the models while at the same time allowing the models to be (mathematically) tractable. Cartwright's concern is that the models' conclusions might be artifacts of these assumptions rather than genuine effects of the capacity in isolation. According to Cartwright, these assumptions are at risk of overly constraining the models, whose results, as a consequence, would often be artifacts of such over-constraining assumptions rather than genuine effects of the capacity in isolation. The scarcity of well-established theoretical principles is a problem that economics shares with the other social sciences. Nevertheless, one of the characteristics peculiar to economics is its strong commitment to a small set of axioms. Cartwright's worry might be less of a problem in fields that are ready to use a wide range of behavioral assumptions as well as to rely on agent-based modeling. This flexibility, however, might come at a cost: One often-heard criticism is that there is a flavor of the ad hoc in the way agent-based simulations are used in social science [19.7, 12].

### 19.4.3 Learning About Possibilities

Thus far, we have been taking for granted that models have specific real-world targets that they are taken to represent. Some social scientific models, however, do not seem to represent any specific target, and thus

they lack a representational link to the real world. Such target-less models deserve a discussion about whether they offer opportunities for learning about the world and, if they do, what kind of learning [19.44, 58–61]. Let us go back to Schelling’s model, which, according to *Grüne-Yanoff*, does not try to represent any particular city or any type of city, thereby making the issue of model-target similarity seem meaningless [19.59]. The only bit of the model that is informed by the real world is the assumption that people have preferences for not being in a minority. According to Grüne-Yanoff, evaluating the model as a representation by inquiring about its similarity to a city, or to cities in general, would force us to conclude that it is defective. The model, however, still offers opportunities to learn about the world, because it teaches us that, contrary to prior belief, residential segregation need not be brought about by racist preferences. By describing how it is possible for the phenomenon of segregation to come about rather than how the phenomenon has actually occurred, the model gives us a *how-possibly* explanation as opposed to a *how-actually* explanation [19.62]. For Grüne-Yanoff, learning from a model amounts to a justifiable change in one’s confidence in one or more necessity or impossibility hypotheses: We learn from Schelling’s model insofar as it justifiably changes “one’s confidence in hypotheses about racist preferences being a necessary cause of segregation” [19.60, p. 7]. Grüne-Yanoff’s approach makes sense of why social scientists often talk about models as indirectly providing insights about the world rather than offering specific hypotheses about real systems, and of why in some cases little effort is spent in applying models to those systems. However, the concept of learning, which is supposed to replace that of understanding or explanation, seems to be a heuristic rather than an epistemic one. Unless criteria are laid

out to specify how the model justifies one’s change in confidence, learning becomes a rather subjective affair [19.64, 65].

#### 19.4.4 Inferential Aids

According to an inferentialist approach to models, the question of how models can teach us about a target system is ill posed, because models are tools to help scientists’ inferential processes rather than autonomous entities capable of delivering information, learning or explanation [19.66–68]. Models are not abstract entities which social scientists manipulate to learn about something else; in fact, the very idea of manipulating an abstract entity sounds rather suspect. According to the inferentialists, models are tools that aid inferences from a set of assumptions to a conclusion; they help “to derive some conclusions about the empirical system, starting from information extracted from *this same system*” [19.67, p. 103; emphasis in the original]. As depicted in Fig. 19.3, the modeling activity (on the right-hand side) aids inferences from premises to conclusions about the phenomenon (on the left-hand side). Denotation, demonstration and interpretation refer to three stages of the modeling activity: First, aspects of the phenomenon are denoted by specific elements of the model, results are then derived within the model, and finally the results are interpreted again in terms of the phenomenon [19.63]. The special features of models as scientific tools are those that make them useful for inference-making by expanding our limited cognitive abilities. According to the inferentialist approach, the relationship between (good) representation and (correct) inference is inverted: It is its usefulness for drawing correct inferences that makes a model a good representation, not vice versa. In other words, while for

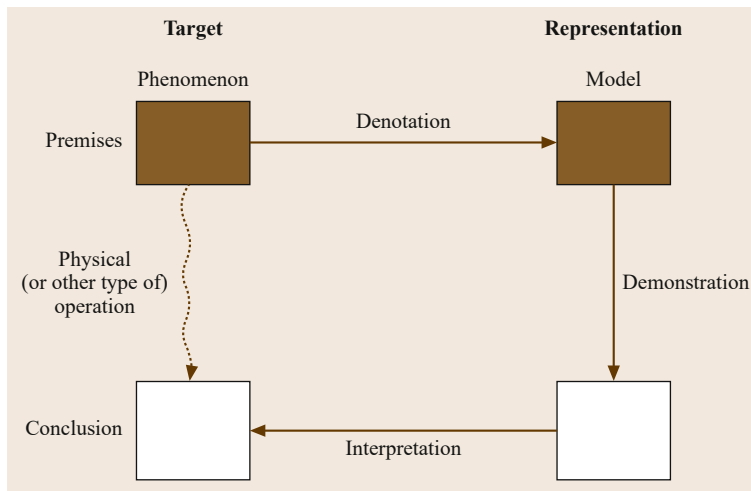

Fig. 19.3 The inferentialist view of models (after [19.63, p. 328])

representationalism a model helps draw correct inferences about its target only if it is a good representation, for inferentialism, if by using a model we are able to draw correct inferences about a target, then we can say that the model represents its target well enough. Saying this does not add much since there is nothing of substance in the relation of representation itself.

The difference between the two accounts can be further appreciated by comparing Fig. 19.2 and Fig. 19.3. Whereas in the inference described in Fig. 19.2 it is the symmetric relation of resemblance that makes a model a representation of the target phenomenon, in the case described in Fig. 19.3, it is first the activity of denotation and then that of interpretation that translate the inferences reached through the model into conclusions about a phenomenon. The goodness of a model, in turn, depends on the number and variety of successful inferences that it enables and on the ease with which it allows the user to draw those inferences. The inferentialist approach, however, raises the questions of how to establish whether the inferences are correct, and, if they are, what explains their success. Different answers are possible. De Donato and Zamora Bonilla maintain that what matters is success in prediction and intervention, but this answer casts doubt on a large portion of social scientific modeling: As mentioned above, few such models yield successful predictions and they rarely function as blueprints for interventions (however, see Sect. 19.4.5 for a counter-argument). In contrast, Kuorikoski and Ylikoski claim that explanatory success is itself explained by the model having captured some or another portion of the causal structure responsible for the phenomenon, bringing them close to the isolationist position.

#### 19.4.5 Models as Blueprints for the Design of Socio-Economic Mechanisms

Philosophers of social science have not only been interested in the fit between hypothetical models and the phenomena they seek to represent, but also in the inverse relation, namely, in the role of hypothetical models in the design of socio-economic mechanisms. An example of successful institutional design guided by theoretical models – and of the broader phenomenon of economic engineering – is the auction mechanism, which a group of economists was asked to draw up for the efficient distribution of radio-electronic frequencies by the federal communications commission (FCC). *Guala* regards the FCC example as an instance in which, rather than the theoretical model trying to represent a real-world phenomenon, the real world is molded so as to resemble the model as closely as possible [19.69, p. 456; emphasis in the original]:

“According to a widely shared view of scientific knowledge, the main task of the theorist is to explain spontaneously occurring and experimental processes, by designing an appropriate model [...] The FCC case belongs to an altogether different kind of scientific activity, proceeding in the opposite direction, *from models to mechanisms and processes.*”

Obviously, the process from the model to the design of the mechanism is not a straightforward one. In the FCC auction mechanism, for example, there was no simple way of implementing existing and highly abstract auction models because the real-world situation had specificities that needed to be taken into account. This required tinkering with models as well as probing them experimentally in a back-and-forth process that led to the design of the mechanism that was eventually implemented. Interestingly, it is precisely the case of the FCC auction mechanism that *Alexandrova* uses to argue that models do not provide explanations that are directly applicable to real-world situations [19.70].

According to *Alexandrova*, the theoretical models were only indirectly implicated in this successful case of economic engineering; rather it is the experimental efforts that should be credited with the achievement. By choosing this example, she seems to suggest that there is nothing relevantly different between using models to *explain* the working of existing institutions and using them to design new institutional arrangements; in both cases, the models merely provide templates for the formulation of causal hypotheses. In particular, *Alexandrova* proposes the view that models are “open formulae” taking the following form: “In a situation of type  $x$  with some characteristics that may include  $C_1 \dots C_n$ , a certain feature  $F$  causes a certain behavior  $B$ ”, where  $x$  is a variable that needs to be specified,  $F$  and  $B$  refer to cause and effect and the  $C_i$  refers to the conditions under which  $F$  causes  $B$ . It is only when  $x$  is specified that the open formula becomes a causal claim [19.70, 71].

The reason is that often it is either impossible to know whether the modeling assumptions are satisfied in a particular context of application, or it is known that they cannot be satisfied at all. To illustrate, let us return to von Thünen’s model. While the open formula would be something like *in a situation such as type  $x$ , transportation costs  $T$  cause the location of economic activities according to pattern  $L$* , a causal hypothesis would say that *in a situation in which the transportation costs depend only on the kind of good to be transported and on the distance from the market ( $c_i = f(d)$ ), the costs cause a concentric distribution of economic activities around the market (plus other conditions)*. This

hypothesis needs to be subjected to empirical or experimental testing. The characterization of the kind of situation in which  $F$  causes  $B$  need not correspond to the assumptions of the model, however. So the causal hypothesis will not specify that the town has no spatial dimension (assumption (5) in Sect. 19.A), as we already know that this assumption cannot be satisfied by any real-world system.

Whether or not it is in fact the experimental efforts that ultimately identified the successful auction mechanism, the FCC case points to the possibility that highly abstract models, which are not representations of any real-world phenomenon to begin with, can nevertheless be used as guides to the design of successful institutional arrangements. As *Guala* suggests, such uses of models distinguish the engineering ambitions of the social sciences – an aspect of model-based social science connected with wider debates about the allegedly unique capacity of the social sciences to influence their object of study [19.69].

#### 19.4.6 Where Do We Go From Here?

The question of when it is legitimate to use theoretical models for epistemic and practical purposes is not yet settled. It appears to be rather uncontroversial that different *kinds* of models are suitable for aiding different *kinds* of inferences: Some models can be used to make inferences about specific targets (the pattern of con-

centric rings around a particular city) or about generic targets (the localization of agricultural activity), while other models do not have a target at all. Whereas in the latter case the inferences might be of the how-possibly kind, in the former cases, the model might be said to be explanatory or to help with explanatory inferences, provided other conditions are also met. The challenge is to identify such conditions. Although, according to a very general principle, for purposes of explanation and possibly reliable prediction and control, a model should somehow capture the relevant features of the phenomenon it targets, different bits of the model need to be empirically confirmed, depending on the kind of inferences at stake. This is where model manipulation in the form of robustness analysis becomes important: The manipulation of modeling assumptions helps to identify which components of the model are crucial for obtaining the result we are interested in. It is these components that need to be empirically valid, not the whole. This seems to hold also when the model's crucial assumptions are satisfied, not because they accurately describe relevant features of their target, but because the conditions for those assumptions to hold true have been created by design. Although the real world, however engineered, will rarely, if ever, approximate the model in every detail, at least in some successful instances it can be molded so that the relevant features – those that drive the modeling result – are in place.

### 19.5 Conclusions

The social sciences are now undergoing significant methodological change. Experimentation both in the laboratory and in the field has become an important addition to social scientists' toolkit, not only for theory testing, but also for theory formation and policy design. There are also important new developments related to the availability of large databases, as well as means to analyze them that were previously unavailable. In all this, not only has modeling become more widespread, but also new modeling techniques such

as agent-based simulation are making headway. It has even been suggested that computational science may entail a new reorganization of the sciences around computational templates that cut across the natural and social sciences [19.72]. The place of modeling within the arrays of styles that characterize the social sciences is significantly changing, and it remains to be seen how the different styles will interact to produce scientific knowledge about social and economic phenomena.

## 19.A Appendix: J.H. von Thünen's Model of Agricultural Land Use in the Isolated State

Von Thünen's model of agricultural land use describes how the distance from a market affects the distribution of agricultural productions around a city [19.73]. This model is considered to be one of the first examples of modern economic modeling, and it is still a classic model in geography and urban economics from which an entire tradition of models of land use in urban spaces has originated. Von Thünen's model has also received some attention in the philosophy of economics, and thanks to its analytical simplicity, it is particularly suitable for illustrating some of the ideas discussed in this chapter [19.3, 23, 74].

Von Thünen's localization model is based on a set of assumptions that describes a homogeneous and isolated agricultural space in which a single town is located:

1. The area is a plain, i. e., there are no mountains or valleys
2. There are no streets or navigable rivers
3. The plain is completely cut off from the outside world
4. Climate and fertility are uniform across space
5. The town is located centrally and has no spatial dimension
6. All markets and industrial activities take place in the town
7. Production costs are constant across space
8. Transportation costs are directly proportional to the distance, the weight and the perishability of the goods
9. Selling prices are fixed and the demand is unlimited
10. Farmers have complete information and they act to maximize their revenue.

Under these assumptions, a pattern of concentric rings around the town emerges. Dairying and intensive farming (vegetables and fruit) occupy the ring closest to the town, because these products are perishable and incur the highest transportation costs. Timber and firewood are located in the second ring, because wood is heavy and hence difficult and costly to transport. The third ring consists of extensive farming of crops, such as grain for bread, that are more durable than fruit and less heavy than wood. On the outermost ring stock farming and cattle ranching take place, because animals can walk to the city to be sold at the market and thus have low transportation costs.

This result can also be described in analytical terms by determining which production is most profitable at different distances from the town.

The revenue  $r$  of each agricultural production consists in its selling price  $p$  minus its production and transportation costs. Since the selling price and the unitary production and transportation costs are fixed, the revenue depends only on the distance from the city

$$r^i(d) = (p - c)x - tdx \quad i = \{A, B, C\},$$

where  $x$  is the quantity of the good,  $c$  the production cost per unit,  $t$  the transportation cost per unit and  $d$  the distance from the market. The apex  $i$  indicates the kind of agricultural production: Dairying and intensive farming  $A$ , timber and firewood  $B$ , and extensive farming  $C$ .

The slope of each revenue curve depends on transportation cost and distance  $-td$ .

The descending curves in Fig. 19.4 represent the revenue of each production depending on its distance from the town; e.g., at distance  $a$  it becomes more profitable to produce product  $B$ .

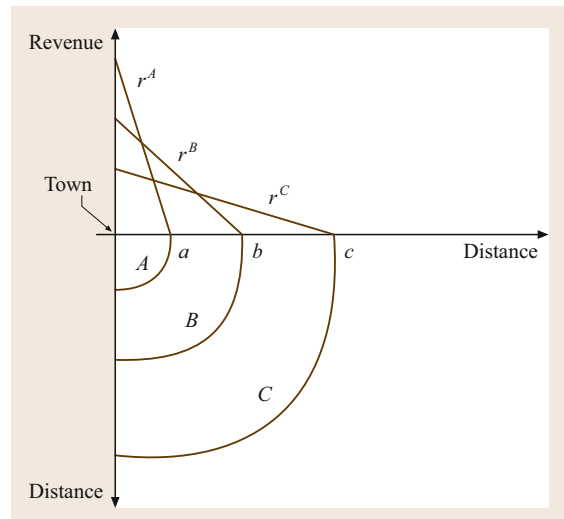

Fig. 19.4 The production revenue and the land use in von Thünen's model (after [19.75, p. 76])

## 19.B Appendix: T. Schelling's Agent-Based Model of Segregation in Metropolitan Areas

Thomas Schelling's work on racial segregation paved the way for the use of simulations in the study of social phenomena. In his seminal work, *Schelling* studied how macro-phenomena, such as segregation, can emerge as an unintended effect of the combination of many interrelated decisions [19.76]. Racial sorting is a case in point. Segregation has been proven to occur as a side effect of the preference of individuals for having a few neighbors of the same ethnic group, rather than as the consequence of a preference for segregation itself.

Schelling represented the segregation process by means of a checkerboard and dimes and pennies, standing respectively for a certain metropolitan area and for the individuals of two different groups (Fig. 19.5). The model is based on a set of assumptions that describe an

idealized metropolitan area and its inhabitants. Examples of such assumptions are:

1. There are only two kinds of agents, Blacks and Whites
2. Agents' decisions only depend on preferences regarding their neighbors
3. The city is uniform, i. e., there are no architectural or topological boundaries that constrain individual choices
4. Agents move randomly in space
5. There are no costs of moving from one point to another.

On the checkerboard it is possible to track the movements of the agents and to observe how the configuration of the neighborhood changes over time.

The resulting dynamics reflect the individual decisions to move to areas whose composition meets the agents' preferences. Rather than obtaining analytical solutions, Schelling's model explores the conditions under which segregation emerges by means of local rules. What it shows is that, regardless of the initial position of the agents and the spatial configuration, given a certain range of people's preferences, clusters of neighbors of the same color eventually emerge.

Even though agent-based models do not need to be implemented on a computer, nowadays they are of-

Fig. 19.5 Schelling's checkerboard: Initial and final configuration (after [19.76, p. 155–157])

```
globals [

```

Fig. 19.6 Netlogo code of Schelling segregation model (after [19.77])

ten used together. The premise is to build a model that captures the relevant variables of the agents' decisions, such as personal preferences and responses to other agents' behavior and to the context. Next, a way has to be found to implement the model and the other components that characterize the system – such as the network structure – in a computer code. Call the set of relevant factors that are external to the model its *environment*. Together, the model and the environment constitute the algorithm that runs on the computer.

Figure 19.6 shows an extract of the algorithm of the segregation model implemented on NetLogo. Each run of the program corresponds to a step in the simulation, which in turn represents a change in the system. The evolution of the system can be represented graphically by means of software that transforms the numerical analysis into visual representations (Fig. 19.7).

# Model-Based

## 20. Model-Based Diagnosis

Antoni Ligęza, Bartłomiej Górny

Diagnostic reasoning is an activity aimed at finding the causes of incorrect behavior of various technological systems. In order to perform diagnosis, a typical diagnostic system should be equipped with the expert knowledge of the domain and statistical evidence of former failures. More advanced solution combines model-based reasoning (MBR) and abduction. It is assumed that a *model* of the system under investigation is specified. Such a model allows us to simulate the normal behavior of the system. It can also be used to detect incorrect behavior and perform sophisticated reasoning in order to identify *potential causes* of the observed failure. Such potential causes form a set of possible diagnoses. In this chapter, formal bases for the so-called model-based diagnostic reasoning paradigm are presented and application examples are discussed in detail. A method of modeling system behavior with the use of causal graphs is put forward. Then, a systematic method for discovering all the so-called *conflict sets* (disjunctive conceptual faults) is described. Such conflict sets describe sets of elements in such a manner that in order to explain the observed misbehavior at least one of them must be faulty. By selecting and removing such elements from all conflicts sets – for each conflict set one such element – the proper candidate diagnoses are generated. An example of the application of the proposed methods to the three-tank dynamic system is presented and some bases for on-line generation of diagnoses for dynamic systems are outlined, together with some theorems. The chapter introduces an easy and self-contained material being an introduction to modern model-based diagnosis, covering static and dynamic systems.

*Diagnostic reasoning* can be considered as a *cover name* for man and machine inference activities aimed at discovering what is wrong when some systems do not work as expected [20.1–3]. In fact, it constitutes a set of mutually complementary paradigms of inference with the ultimate goal to produce a set of rational explanations of the observed misbehavior of some systems under consideration. Diagnostic reasoning often combines *causal reasoning* with domain experience including statistical and *expert knowledge*. Hence, diagnostic reasoning makes use of the so-called *shallow knowledge* and in the case of the *model-based diagnosis* the *deep knowledge*.

*Shallow knowledge* refers to empirical knowledge based on numerous observations and experience, typical for practitioners, usually encoded with rules and taking the form of the so-called *expert system* [20.4]. The diagnosed system is usually considered as a *black box* where only inputs and outputs are known, and the expert system covers the operational knowledge about its behavior, properties, and possible failures in the form of if–then rules. The development of the rules is based on experience documented with accumulated records.

On the other hand, *deep knowledge* refers to the contents of the box (the term *white box* is sometimes used) and mathematical models of system behavior. Hence, deep knowledge is the knowledge of the internal structure, components, and their interactions. It allows us to simulate the behavior of the system for any admissible input conditions.

Diagnosis is usually carried out by domain experts, and expert knowledge hardly undergoes any smart formalization. Nevertheless, some most successful approaches mimic diagnostic reasoning by the combination of *abduction/deduction* including causal inference, *model-based reasoning* (MBR), and *case-based reasoning* (CBR). Let us briefly explain the meaning of these terms in practice.

*Abduction* [20.5, 6] consists in looking for valid explanations for observed effects. In general, it is not a valid inference rule. The result of abductive inference is a set of hypotheses explaining what is observed; the hypotheses must be consistent with the knowledge at hand.

*Deduction* [20.6–8] consists in looking for consequences of some assumptions and initial knowledge at hand. In general, it is a valid inference rule. The result of deductive inference is a set of facts true under the assumptions and background knowledge.

*Model-based reasoning* [20.1, 2] refers to reasoning about system behavior and properties on the basis of its mathematical model. Note that no practical experience or observations are necessary. Complete information on the system can be gathered during a single session of model investigation.

In contrast to deep knowledge and MBR, *CBR* [20.9–11] is in opposite to using deep knowledge and MBR. It consists in gathering a number of *cases* (in the case of diagnosis – failure descriptions and fault identifications) to be stored and used as patterns for solving new problems. Case-based reasoning looks for an identical case which occurred in the past, or a *similar* one; in the latter case, reasoning by analogy can be used.

The process of fault diagnosis of technical systems typically requires the use of different methods of knowledge representation and inference paradigms. The most common scenario of such a process consists of the detection of the faulty behavior of the system, classification of this behavior, search for and determination of potential causes of the observed misbehavior, that is, generation of potential diagnoses, verification of those hypothetical diagnoses, and selection of the correct one, and finally a repair phase.

There exist a number of approaches and diagnostic procedures having their origin in very different branches of science, such as mechanical engineering, electrical engineering, electronics, automatic control, or computer science. In the diagnosis of complex dynamical systems, approaches from automatic control play an important role ([20.12–14]; a good state of the art can be found in the handbook [20.3]). The point of view of computer science, and especially artificial intelligence (AI) is presented, for example, in [20.1, 2, 15]. A good comparative analysis of some selected approaches was presented in [20.16] and in [20.17]. A recent, comprehensive in-depth study aimed at comparison of approaches emerging from AI and from classical automatic control is presented in [20.18].

This chapter is devoted to the presentation of some selected approaches originating from AI, located in the area of *model-based reasoning* (or MBR) and based on *consistency-based reasoning* [20.7, 19–22]. The presentation is based on the authors' experience and some former publications including [20.23–29]. Many concepts and results were prepared during the work on [20.30].

## 20.1 A Basic Model for Diagnosis

Consider the mathematical point of view on the diagnostic process. Taking such a viewpoint, the problem of building a diagnostic system, including issues of representation and acquisition of diagnostic knowledge, as well as the implementation of diagnostic reasoning engine, can be considered as one way of searching an inverse function or relation.

In fact, the problem of searching for diagnoses can be considered as an inverse task to extended simulation task; some specific features are as follows: (i) one observes a faulty behavior of the analyzed system (and thus, apart from the knowledge about correct behavior, also the one about faulty behavior should be accessible), and then (ii) taking into account the observed state (output), the main goal is not the reconstruction of the input (control) but rather the causes of the failure manifestations. Such causes can be considered as faulty components of the system, or, at some more detailed level, as wrong (faulty) parameter values produced by these components.

For simplicity, assume that one of  $n$  system components can become faulty, where each elementary fault is of binary character – such a component can just work or do not work correctly. Let  $D$  denote the set of potential elementary causes to be considered and let  $D = \{d_1, d_2, \dots, d_n\}$ . Faulty behavior of the system can be stated (detected) through the observation of one or more symptoms of failure. Assume that there are  $m$  such symptoms to be considered and their evaluation is also binary. Let  $M$  denote the set of such symptoms, where  $M = \{m_1, m_2, \dots, m_m\}$ . The detection of a failure consists in the detection of the occurrence of at least one symptom  $m_i \in M$ . In general, some subset  $M^+ \subseteq M$  of the symptoms can be observed to be true in the case of a failure. The goal of the diagnostic process is the generation of a diagnosis being any set  $D^+ \subseteq D$ , such that taking into account the *domain expert knowledge* and the *system model* it explains the observed misbehavior.

Let  $KB$  denote the *knowledge base* – in our case, the model of the system behavior. Furthermore, let  $D^-$  denote the components that are assumed to work correctly,  $D^+ \cup D^- = D$ , and let  $M^-$  denote the failure manifestations that are absent,  $M^+ \cup M^- = M$ . More formally, any valid candidate diagnosis  $D^+$  must satisfy the following conditions

$$D^+ \cup D^- \cup KB \models M^+ \cup M^-, \quad (20.1)$$

and

$$D^+ \cup D^- \cup KB \cup M^+ \cup M^- \not\models \perp. \quad (20.2)$$

Condition (20.1) means that the diagnosis must explain the observed misbehavior in view of the accessible knowledge about the system. Condition (20.2) means that the diagnosis must be consistent with the accessible knowledge about the system and the currently observed manifestations.

In the general case, the result of the diagnostic process can consist of one or more potential diagnoses; these diagnoses – subsets of the set  $D$  – can be single-element sets (i. e., the so-called *elementary diagnoses*) or multielement ones. For simplicity, in a number of practical approaches, only single-element diagnoses are taken into account. In the case of complex, multielement diagnoses, the discussion is frequently restricted to the so-called *minimal diagnoses*, that is, subsets of  $D$  which explain the observed misbehavior in a satisfactory way and simultaneously such that all elements of them are necessary for the justification of the diagnosis.

For the sake of general consideration, it can be assumed that there exists causal dependency between elementary faults represented by the elements of  $D$  and failure symptoms represented by the elements of  $M$ . Hence, there exists some relation  $R_C$  (i. e., a *causal relation*), such that

$$R_C \subseteq 2^D \times 2^M, \quad (20.3)$$

that is, any failure being defined as a subset of  $D$  is assigned one or more sets of possible failure symptoms; in certain particular cases, the failure – although occurred – may also be unobservable.

Such approach, however, is indeterministic: a single failure may be assigned *several different* sets of symptoms of the observed misbehavior. Therefore, it is frequently assumed that the causal dependency  $R_C$  is of functional nature, that is,  $R_C$  is, in fact, the following function

$$R_C : 2^D \rightarrow 2^M. \quad (20.4)$$

In this approach, any failure causes some unique and well-defined set of symptoms to occur. In this case, the task of building a diagnostic system consists in finding the inverse function, that is, the so-called *diagnostic function*  $f$ , where  $f = R_C^{-1}$ .

Unfortunately, in the case of many realistic systems, the function  $R_C$  is not a one-to-one mapping, so there does not exist the inverse mapping in the form of a function.

Consider a simple example of such a system; let it be the set of  $n$  bulbs connected serially (e.g., a set

for a Christmas tree). An elementary diagnosis  $d_i$  is equivalent to the  $i$ th bulb being blown. However, the set of manifestations of the failure  $M = \{m_1\}$  is a single-element set, where  $m_1$  indicates that the bulbs are not switched on. Even in the case, when the analysis is restricted to considering single-element elementary diagnoses, there exists  $n$  potentially equivalent diagnoses; each of them causes the same result with  $m_1$  being true. If multielement diagnoses are admitted, then there exist  $(2^n - 1)$  potential diagnoses.

In practice, the development of a diagnostic system consists in finding the inverse relation  $R_C^{-1}$ , and more precisely it searches for this inverse relation during the diagnostic process. In many practical diagnostic systems, the diagnostic process is interactive, and additional tests and measurements can be undertaken in

order to restrict the area of search. In the case of the serially connected bulbs, such an approach may consist in the examination of certain bulbs or rather groups of them (an optimal strategy is that of dividing the circuits into two equal parts).

Note that complex diagnostic systems use a variety of technologies to deal with complexity; these include hierarchical strategies for the identification of faulty subsystem, interactive diagnostic procedures with the use of supplementary tests, and observations aimed at restricting the search area, accessible statistical data in order to establish the most probable diagnoses, and apply heuristic methods in diagnosis. One of the basic and frequently applied heuristics is considering only elementary diagnoses. Another, more advanced one consists in considering only minimal diagnoses.

## 20.2 A Review and Taxonomy of Knowledge Engineering Methods for Diagnosis

### 20.2.1 Knowledge Engineering

Knowledge engineering (KE) methods occupy an important position both in technological system diagnosis and in medical diagnosis [20.4]. They originate from the research in the domain of AI, and, in particular, from those concerning knowledge representation methods and automated inference. These methods are good examples of practical applications of AI techniques. They are mostly based on the algebraic, logical, graphical, and rule-based knowledge representation and automated inference methods [20.2, 28].

A characteristic feature of KE methods is that they use mostly the *symbolic* representation of the domain and expert knowledge as well as *automated inference* paradigms for knowledge processing. They can also make use of numerical data and models (if accessible) as well as uncertain, incomplete, fuzzy, or qualitative knowledge. A common denominator and core for all the methods is constituted by mathematical logic.

The key issue of KE is knowledge representation and knowledge processing; some other typical activities include knowledge acquisition, coding and decoding, analysis, and verification [20.4, 6]. Because of a specific character of KE methods originating mostly from symbolic methods for knowledge manipulation in AI, the taxonomy of such methods is different than those of the methods developed in the automatic control area [20.3] and it constitutes some extension and complement. This extension is oriented toward taking into account specific aspects of KE methods, while the taxonomy takes into account both the applied tools and the *philoso-*

*phy* of specific approaches. In particular, in the case of KE methods, some essential issues of diagnostic approaches are the following ones:

- Source and the way of specification of diagnostic knowledge (model-based approaches vs experience, statistics, and expert systems)
- Applied knowledge representation methods (algebraic, numerical, logical, graphical)
- Applied inference methods (abduction, deduction, search)
- Inference control mechanism (systematic search, heuristic search).

The diagnostic knowledge can, in fact, be of two different origins. First, it can be the so-called *shallow knowledge*, having the source in input–output observations and experience. Such kind of knowledge is also called *expert knowledge* in case it is appropriately significant, and frequently its acquisition consists in interviewing some domain experts. In this case, the knowledge of the system model (the structure, principles of work, mathematical models) is not required. The specification of such kind of knowledge may take the external form of a set of observations of faults and assigned to them diagnoses, learning sequence of examples, or ready-to-use rules coming from an expert. The approaches based on the use of shallow knowledge are generally classified as *expert systems methods*.

Secondly, knowledge may be originating from the analysis of mathematical models (the structure, equations, constraints) of the diagnosed system; this knowl-

edge is referred to as the so-called *deep knowledge*. In case such knowledge is accessible, the diagnostic process can be performed with the use of the model of the system being analyzed, that is, the so-called *model-based diagnosis* is performed. The deep knowledge takes the form of a specific mathematical model (adapted for diagnostic purposes) and perhaps some heuristic or statistical characteristics useful to direct diagnostic reasoning.

Most frequently, the specification of deep knowledge includes definition of the internal structure and dependencies valid for the analyzed system in connection with the set of elements, the faults of which are subject to diagnostic activities, as well as the specification of the current state of the system (observations). The approaches based on the use of deep knowledge are classified as *model-based approaches*. Obviously, a wide spectrum of intermediate cases comprising both of the above approaches in appropriate proportions are also possible.

Knowledge representation methods include mostly symbolic ones, such as facts and inference rules, logic-based methods, trees and graphs, semantic networks, frames, scenarios, and hybrid methods [20.3, 28]. Numerical data (if present) may be represented with the use of vectors, sequences, tables, etc. Mathematical models (e.g., in the form of functional equations, differential equations, constraints) may also be used in modeling and failure diagnosis.

Reasoning methods applied in diagnosis include logical inference (deduction, abduction, consistency-based reasoning, nonmonotonic reasoning, and induction) as well as originating in logical methods for knowledge processing in rule-based systems (forward chaining, backward chaining, bidirectional inference), pattern matching algorithms, search methods, case-based reasoning, and other. In the case of numerical data, various methods of learning systems, both parametric and structural ones, are also applied.

The control of diagnostic inference is mainly aimed at enhancing efficiency, so that all the diagnoses (in the case of complete search) or only the most probable ones (in the case of incomplete search) are generated as fast as possible, so that the obtained diagnoses are ordered from the most likely ones to the most un-

likely ones. The applied methods include blind search, ordered search, heuristic search, use of statistical information and methods, use of qualitative probabilities, use of supplementary tests in order to confirm or reject search alternatives as well as hierarchical strategies.

The following taxonomy of diagnostic approaches is based on the KE point of view, and it takes into account mainly the type and way of diagnostic knowledge specification and the applied methods of knowledge representation.

### 20.2.2 Expert Methods

1. Methods based on the use of numerical data:
  - Pattern recognition methods in feature space
  - Classifiers using the technology of artificial neural networks
  - Simple rule-based classifiers, including fuzzy rule-based systems
  - Hybrid systems.
2. Methods using symbolic data and knowledge (classical knowledge engineering methods, simple algebraic formalisms, graphic- and logic-based methods, and ones based on domain expert knowledge):
  - Diagnostic tests
  - Fault dictionaries
  - Decision trees
  - Decision tables
  - Logic-based methods including rule-based systems and expert systems
  - Case-based systems.

### 20.2.3 Model-Based Methods

1. Consistency-based methods:
  - Consistency-based reasoning using purely logical models (*Reiter's theory* [20.22])
  - Consistency-based reasoning using mathematical, causal models, and qualitative models.
2. Causal methods:
  - Diagnostic graphs and relations
  - Fault trees
  - Causal graphs (CGs)
  - Logical abductive reasoning
  - Logical CGs.

## 20.3 Model-Based Diagnostic Reasoning

*Model-based diagnostic reasoning* appears as a relatively new diagnostic inference paradigm which is based on a formal theory presented in the paper by Reiter [20.22]. The main idea of this paradigm consists in the comparison of the observed system behavior and the one which can be predicted with use of the knowledge about system model. On one hand, such kind of reasoning does not require an expert knowledge, long-term data acquisition or experience, or a training stage of the diagnostic system. On the other hand, what is required is the knowledge about the *system model* allowing for the prediction of its normal correct behavior. More precisely, what is called for is the *model of correct behavior* of the system, that is, a model which can be used to simulate the normal work of the system in the case of lack of any faults.

An idea of such a diagnostic approach is presented in Fig. 20.1.

Both the real system and its model process the same input signals In. The output of the system Out is compared to the expected output Exp generated with the use of the model. The difference of these signals, the so-called residuum  $R$ , is directed to the diagnostic system DIAG. The residuum being equal to zero (with some predefined accuracy) means that the currently observed behavior does not differ from the expected one, that is, the one obtained with the use of the model; if this is the case, it may be assumed that the system works correctly.

In case some significant difference of the current behavior of the system from the one predicted with the use of the model can be observed, then it must be stated that the observed behavior is *inconsistent* with the model.

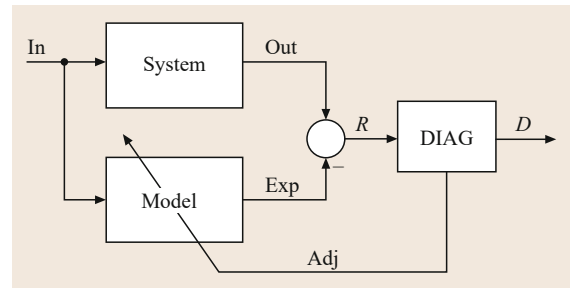

Fig. 20.1 A presentation of diagnostic activity

Detection of such behavior (or *misbehavior*, in fact) implies that a fault occurs (under the assumption that the model is correct and appropriately accurate), that is, *fault detection* takes place.

In order to determine potential diagnoses, an appropriate reasoning allowing for some modifications of the assumptions about the model must be carried out (in the figure, it is shown with the use of the arrow meaning a somewhat specific *tuning* of the model); in case, it is possible to relax the assumption about correct work of the system components in such a way that the predicted behavior would be consistent with the observed one, then the modified model defines which of its elements may have become faulty. In this way, a potential diagnosis  $D^+$  can be obtained (or a set of alternative diagnoses). The diagnoses are represented with sets of system components which (potentially) are faulty, and such that assuming them faulty explains in a satisfactory way the observed misbehavior by regaining the consistency of the observed output with the output of the modified model.

## 20.4 A Motivation Example

In this section, a simple example of a system is introduced. The work of the system is analyzed. It is used to show:

1. The basic concepts, such as system inputs, system outputs, internal variables, system components.
2. System structure and model.
3. How can the model-based diagnostic reasoning be performed?

Let us consider the multiplier–adder system, as introduced in [20.22]. The scheme of the system is presented in Fig. 20.2. The presented system is, in fact, a nontrivial demonstration and benchmark system be-

Fig. 20.2 A simple multiplier–adder system

ing a combined multiplier–adder; it is widely explored in the domain literature [20.2, 28]; it is also used for the

illustration of the FDI and DX procedures along with the [20.16, 17] papers.

The system is composed of two layers. The first one contains three independent multipliers  $m1$ ,  $m2$ , and  $m3$ . It receives the input signals  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$  and produces values of *internal variables*, namely  $X$ ,  $Y$ , and  $Z$ . The second layer is composed of two adders, namely  $a1$  and  $a2$ . It receives the values of the internal variables and produces the output values, namely  $F$  and  $G$ . Only inputs (of the first layer) and outputs of the system (of the second layer) are directly observable (i. e., they can be measured). The intermediate variables are hidden and cannot be measured.

Note that the system has five *internal components*; this can be written as

$$\text{COMP} = \{m1, m2, m3, a1, a2\}. \quad (20.5)$$

Note that any of the components can be a cause of single failure; hence, the set of potential diagnoses  $D$  considered in Sect 20.1 can be considered as  $D = \text{COMP}$ . The components are interconnected, as shown in Fig. 20.2. The system has also five *inputs*, three *internal variables*, and finally, two *output variables*.

In the following, we shall refer mostly to the classical diagnostic problem as follows. The current state of the system is that the inputs are:  $A = 3$ ,  $B = 2$ ,  $C = 2$ ,  $D = 3$ , and  $E = 3$ . It is easy to check that – if the system works correctly – the outputs should be  $F = 12$  and  $G = 12$ . Since the current value of  $F$  is incorrect, namely  $F = 10$ , the system is faulty. At least one of its components must be faulty.

Now, let us ask, which component (or components) is/are faulty. Note that, the fault of a component (or multiple faults of several components) affects the value of variable  $F$  (it is smaller than expected), but simultaneously does not affect the value of variable  $G$  (12 is the correct value for the observed inputs).

The simplest approach may be based on the observation that the fault must be caused by an error of a component responsible for producing the value of  $F$ . In fact, one can expect a *causal influence* of the following type: faulty component leads to the faulty value. In order to perform the search, a simple *CG* presented in Fig. 20.3 may be useful.

The bottom nodes of the graph correspond to faults of components. The three top-level nodes correspond to the observed values of output variables; in particular, the rightmost node marked with  $F - G$  corresponds to the mutual relationship of signals  $F$  and  $G$ ; in fact, for the observed inputs, the values should be equal, and, since they are not, one can also expect a double

Fig. 20.3 A simple CG for the multiplier–adder system

fault, where one component influences  $F$  (observed to take value lower than expected) and  $G$ , and the other fault improves the value of  $G$  so that it is correct. Such a phenomenon is referred to as the effect of *compensation*.

Let us perform a diagnostic analysis at the intuitive level first. When considering the signal flow inside the system, it can be observed that components of disjunctive conceptual fault (DCF)<sub>1</sub> = { $m1, m2, a1$ } (here, DCF stands for *disjunctive conceptual fault* – a set defining a *conflict*; the definition of these terms will be provided later on) are the only ones influencing signal  $F$ . Similarly, components DCF<sub>2</sub> = { $m2, m3, a2$ } are the only ones influencing signal  $G$ . Finally, components of DCF<sub>3</sub> = { $m1, a1, a2, m3$ } are the ones responsible for the symmetry of signals  $F$  and  $G$ . This is also visualized with the CG presented in Fig. 20.3.

Now, we are at the core of model-based diagnostic reasoning. Since the value of  $F$  is incorrect, at least one of the components of DCF<sub>1</sub> must be faulty. In other words, assumption that all the elements of DCF<sub>1</sub> are correct is inconsistent with the observations. The set is called a *conflict set* [20.22] or a *disjunctive conceptual fault* (DCF) [20.29]. If considering single-element potential diagnoses, all the three elements of DCF<sub>1</sub> are candidate diagnoses. (In fact,  $m2$  is not a valid candidate for a single-element diagnosis; it also influences the value of  $G$ , while no deviation of that value is observed.)

But there is another problem to be explained. The observed values of  $F$  and  $G$  considered together are inconsistent with the model. Note that if all the components were correct, then  $Z = C \times E$  calculated by  $m3$  must be equal to 6, and since  $G$  is observed to be 12,  $Y$  (calculated backward and under the assumption that  $a2$  is correct) must also equal 6; hence, if  $m1$  is correct, then  $X$  must be 6 as well, and if  $a1$  is correct,  $F$  would be equal to 12. Since it is not the case, at least one of the used components must be faulty, that is, DCF<sub>3</sub> is

also a conflict set (a disjunctive conceptual fault) – at least one of its components must be faulty.

Now, in order to *regain consistency* of the observations with the system model, one must remove some of the assumptions that all the components are correct. We look only for *minimal* such explanations, since typically we prefer the simplest possible diagnoses. And there are four such explanations:

- $\{a1\}$  is a single-element candidate diagnosis; it repairs both  $DCF_1$  and  $DCF_3$
- $\{m1\}$  is another single-element candidate diagnosis; it repairs both  $DCF_1$  and  $DCF_3$
- $\{a2, m2\}$  is a two-element candidate diagnosis;  $m2$  repairs  $DCF_1$ , while  $a2$  repairs  $DCF_3$
- $\{m2, m3\}$  is another two-element candidate diagnosis;  $m2$  repairs  $DCF_1$ , while  $a2$  repairs  $DCF_3$ .

## 20.5 Theory of Model-Based Diagnosis

The theory of diagnostic reasoning using the system model and based on the analysis of inconsistency of the observed system behavior with the one predicted with the use of system model was described by Reiter [20.22]. The basic ideas of this theory are presented in brief in the following.

A basic definition in this theory is the definition of a *system*.

### Definition 20.1

A *system* is a pair (SD, COMP) where:

1. SD is a set of first-order predicate calculus formulas defining the system, that is, the *system description*
2. COMP is a set of constants representing distinguished elements of the system (its components).

An example of such a system – the multiplier–adder – has already been presented in this chapter and shown in Fig. 20.2.

The model of the system SD describes its correct behavior. The distinguished elements appear in the model (SD) and they are the only elements which are considered to become faulty – the potential diagnoses will be built from these elements only. In order to do this, the system model is completed with formulas of the form  $\neg AB(c_i)$  which means that component  $c$  works correctly (AB stands for *abnormal behavior*).

The current behavior of the system is assumed to be observed and values of certain variables can be mea-

It is straightforward to observe that in the case of the two-element diagnoses, the *compensation* phenomenon is observed.

The diagnoses – in principle – are obtained as the so-called *hitting sets* for all the conflict sets at hand. Such a hitting set takes one element from each conflict. Hence, the conflicts are removed (repaired), and the collection of taken in such a way components form a candidate diagnosis. In the case of the first two – it was the same element taken from both the conflict sets, so that single-element diagnoses are yielded.

In the following sections, an attempt to present the formal theory underlying *model-based diagnosis* is presented, and an approach to systematic generation of all conflict sets on the base of CG is put forward. Then the multiplier–adder example is revisited, and the formal analysis of it is presented.

The representation of these observations can be formalized in the form of a set of first-order logic formulas; let us denote this set as OBS (OBS stands for *observations*).

Note that an assumption of the form

$$\{\neg AB(c_1), \dots, \neg AB(c_n)\}$$

means, in fact, that each component of the analyzed system works correctly. Hence, a set of the form

$$SD \cup \{\neg AB(c_1), \dots, \neg AB(c_n)\}$$

represents correct behavior of the system, that is, the behavior which can be observed under the assumption that all the components are not faulty. In the case at least one of the components  $c_i \in COMP$  becomes faulty, the set of formulas of the form

$$SD \cup \{\neg AB(c_1), \dots, \neg AB(c_n)\} \cup OBS$$

will become *inconsistent*. The diagnostic process consists in searching for components which may have become faulty, and as such, explain the misbehavior of the system.

For intuition, a diagnosis in Reiter's theory is a hypothesis stating that some set of system elements being a subset of COMP became faulty. Making such an assumption must lead to regaining consistency of the observed system behavior with the one predicted with use of the model. For simplicity, only *minimal diagnoses* will be considered explicitly.

### Definition 20.2

A diagnosis for the system with observations specified by (SD, COMP, OBS) is any minimal set  $\Delta \subseteq \text{COMP}$ , such that the set

$$\text{SD} \cup \text{OBS} \cup \{\text{AB}(c) \mid c \in \Delta\} \cup \{\neg \text{AB}(c) \mid c \in (\text{COMP} - \Delta)\}$$

is consistent.

Roughly speaking, one may say that a diagnosis for some system failure which results with observed misbehavior is any minimal set composed of system components, such that assuming all them to be faulty, and assuming that all the other elements work correctly, is satisfactory for regaining the consistency of the observed behavior with a system model.

Direct search for diagnoses in the form of minimal sets of components sufficient for regaining consistency between the observed and predicted behavior based on the analysis of the set of formulas given by (20.6) would be a tedious task from the computational point of view. In the case of multiple faults, one would have to search for all single-element subsets, then two-element subsets of COMP, etc., and each time such a subset should be verified if it constitutes a diagnosis; some simplifications may consist in the elimination of any superset of a diagnosis found earlier. In Reiter's theory, further improvements are proposed.

The idea of a *conflict set* (or just *conflict* for simplicity; recall also the name *disjunctive conceptual fault* introduced in Sect. 20.4) is of key importance for the theory of consistency-based diagnostic reasoning with use of the system model. A conflict set is any subset of the distinguished system elements, that is, COMP, such that all items belonging to such a set cannot be claimed to work correctly (i. e., at least one of them must be faulty) – it is just the assumption about their correct work which leads to inconsistency.

Assume that we consider a system specified as a pair (SD, COMP), where SD is the theory describing the work of the system (i. e., *system description*) and where  $\text{COMP} = \{c_1, c_2, \dots, c_n\}$  is the set of distinguished system elements. Any of these elements can become faulty, and the output of diagnostic procedure is restricted to be a subset of the elements of COMP.

In diagnostic reasoning, it is assumed that the correct behavior of the system is fully described by the theory of SD. Assumptions about the correct work of system components take the form

$$\neg \text{AB}(c_1) \wedge \neg \text{AB}(c_2) \wedge \dots \wedge \neg \text{AB}(c_n).$$

Hence, assuming that the observed behavior is described with the formulas of the set OBS and in the case

of lack of any faults, the set given by

$$\text{SD} \cup \{\neg \text{AB}(c_1), \dots, \neg \text{AB}(c_n)\} \cup \text{OBS} \quad (20.6)$$

should be consistent. In the case of failure, however, the set of formulas (20.6) turns out to be inconsistent. In order to regain consistency, one should withdraw some of the assumptions about the correct work of system components of the form  $\neg \text{AB}(c_i)$ . Such an approach leads to one or several sets of the form  $\{c^1, c^2, \dots, c^k\} \subseteq \text{COMP}$  of components such that at least one of them must have become faulty. From a logical point of view, the assumptions about such a conflict set are equivalent to stating that the formula

$$\text{AB}(c^1) \vee \text{AB}(c^2) \vee \dots \vee \text{AB}(c^k) \quad (20.7)$$

is true. Obviously, formula (20.7) is true if  $\text{AB}(c^i)$  holds for at least one  $i \in \{1, 2, \dots, k\}$ .

After Reiter [20.22], let us introduce a formal definition of a *conflict set* (*conflict*).

### Definition 20.3

A *conflict set* for (SD, COMP, OBS) is any set  $\{c^1, \dots, c^k\} \subseteq \text{COMP}$ , such that

$$\text{SD} \cup \text{OBS} \cup \{\neg \text{AB}(c^1), \dots, \neg \text{AB}(c^k)\}$$

is inconsistent.

For intuition, a conflict set (under the given observations and system model) is a set of components, such that at least one of its elements must be faulty. Any conflict set represents, in fact, a disjunction of potential faults. A conflict set is *minimal* if any of its proper subsets is not a conflict set. Note that if the analysis is restricted to minimal conflicts, then removing a single element from such a conflict set makes this set become no longer conflict. In other words, the system regains consistency.

Now, let us define an important concept, that is, a *hitting set*.

### Definition 20.4

Let  $C$  be any family of sets. A *hitting set* for  $C$  is any set  $H \subseteq \bigcup_{S \in C} S$ , such that  $H \cap S \neq \emptyset$  for any set  $S \in C$ .

A hitting set is minimal if and only if any of its proper subsets is not a hitting set for  $C$ .

For intuition, a hitting set is any set having a nonempty intersection with any conflict set; it is minimal if removing from it any single element violates the requirement of nonempty intersection with at least one conflict set.

Having defined the idea of a conflict set and a hitting set, we can present the basic theorem of Reiter's theory [20.22]:

**Theorem 20.1**

$\Delta \subseteq \text{COMP}$  is a diagnosis for (SD, COMP, OBS) if and only if  $\Delta$  is a minimal hitting set for the family of conflict sets for (SD, COMP, OBS).

Since any superset of a conflict set for (SD, COMP, OBS) is also a conflict set, it can be shown that  $H$  is a minimal hitting set for (SD, COMP, OBS) if and only if  $H$  is a minimal hitting set for all minimal conflict sets defined for (SD, COMP, OBS). This observation (proved in [20.30]) leads to the following theorem being a fundamental result of Reiter's theory:

**Corollary 20.1**

$\Delta \subseteq \text{COMP}$  is a diagnosis for (SD, COMP, OBS) iff  $\Delta$  is a minimal hitting set for the collection of minimal conflict sets for (SD, COMP, OBS).

To summarize, the role of conflict sets in Reiter's theory is that they provide specifications of components, such that for each conflict set, at least one element must be faulty. By restricting the analysis to

minimal conflicts, one makes sure that by removing any single element from such a set leads to the elimination of conflict. Hence, the union of all such elements (i. e., a hitting set) allows for regaining global consistency; it then constitutes a (potential) diagnosis. Of course, for the considered system failure described with (SD, COMP, OBS), there can exist many diagnoses explaining the observed misbehavior.

In the case of the multiplier–adder system presented in Fig. 20.2, the following conflicts were found

$$\{a1, m1, m2\}, \quad \{a1, a2, m1, m3\}.$$

On the basis of them, all the potential diagnoses can easily be found, that is,

$$D_1 = \{a1\}, \quad D_2 = \{m1\}, \\ D_3 = \{a2, m2\}, \quad D_4 = \{m2, m3\}.$$

Let us notice that only minimal diagnoses are found (i. e., if some set is a diagnosis, then any of its supersets will not be generated as a diagnosis) and that Reiter's theory allows for the generation of both single-element diagnoses (single faults) and multielement ones (multiple faults).

## 20.6 Causal Graphs

In *model-based diagnosis*, modeling of causal relationships plays a very important role. It makes possible pointing to the dependencies of potential faults of the elements of the system under consideration on its observed behavior, which is the result of the faults. The knowledge about causal dependencies allows for efficient diagnostic reasoning based on the direct use of a causal model or some rules generated on the basis of that model.

Let  $d$  denote any fault of some element of the diagnosed system. In the most simple case, it is assumed that the fault can occur or not; from a logical point of view,  $d$  may be considered to denote an *atomic formula* of *propositional logic*. For the purpose of diagnosis,  $d$  will be referred to as an *elementary diagnosis*, and as a logical formula, it will be assigned logical value *true* (if the fault occurs) or *false* (in case the fault is not observed).

Analogously, let  $m$  denote a visible result of some fault  $d$ ;  $m$  can be observed in a direct way or can be detected with the use of appropriate tests or measurements. In the most simple case, manifestation  $m$  may be just observed or not, so as before from a logical point of

view,  $m$  can be considered to denote an atomic formula of the propositional logic which can be assigned a logical value: *true* or *false*. For the purpose of diagnosis,  $m$  will be referred to as a *diagnostic signal* or a *manifestation* or just a symptom of a failure.

If there exists a causal relationship between  $d$  and  $m$  it means that  $d$ , is a cause of  $m$  and  $m$  is an effect of  $d$ . Let  $t_p$  denote the time instant when some symptom  $p$  occurred. For the existence of a causal relationship between symptoms  $d$  and  $m$ , it is necessary that the following conditions are valid:

- $d \models m$ , that is,  $m$  is a logical consequence of  $d$
- $t_d < t_m$ , that is, a cause precedes its result in time
- There exists a flow of a physical signal from symptom  $d$  to symptom  $m$ .

The first condition – the one of logical consequence – means that whenever  $d$  takes the logical value of *true*,  $m$  must also take the logical value *true*. So, this condition means that the existence of causal relationship also requires the existence of logical consequence. (Existence of logical consequence of the form  $d \models m$

does not mean that there exists also causal relationship, for example, the occurrence of  $d$  and  $m$  may be observed as some independent results of some other, external common cause.) This allows for the application of logical inference models for the simulation of systems behavior as well as for reasoning about possible causes of failure.

The second condition, that is, the one of precedence in time means that the cause must occur *before* its result, and that the result occurs *after* the occurrence of its cause. This implies some obvious consequences for modeling of the behavior of dynamic systems in the case of a failure.

The last condition means that there must exist a way for transferring the dependency (a signal channel enabling the flow of the physical signal); lack of such connection indicates that two symptoms are independent, that is, there is no cause–effect relationship among them. A more detailed analysis of theoretical foundations of the causal relationship phenomenon from the point of view of diagnosis can be found in [20.23, 25] or [20.3].

The above presented model of the causal relationship is, in fact, a simplest kind of the so-called *strong causal relationship*; by relaxing the condition of logical implication *potential* relationship can be obtained (in such a case occurrence of  $d$  may, but need not necessarily, mean the occurrence of  $m$ ), including a causal relationship of probabilistic nature (characterized by some quantitative or qualitative probability). For simplicity, such extensions are not considered here. Another extension may consist in the causal relationship between several cause symptoms and several result symptoms described with some functional dependencies; as this case is important for technical diagnosis, it will be considered in brief.

Let  $V$  denote some set of symptoms

$$V = \{v_1, v_2, \dots, v_k\}.$$

The discussion here is restricted to logical symptoms taking the value of *true* or *false*. In some cases, it may be observed that there exists a causal relationship between the symptoms of  $V$  constituting a common cause for some symptom  $v$  and this symptom. In particular, the following two cases are of special interest

$$v_1 \vee v_2 \vee \dots \vee v_k \models v, \quad (20.8)$$

and

$$v_1 \wedge v_2 \wedge \dots \wedge v_k \models v. \quad (20.9)$$

In the first case, occurrence of at least one symptom from  $V$  causes the occurrence of  $v$ ; it is said that there

exists a disjunctive relationship and the symptom  $v$  is of *OR* type. By using an arrow to represent the causal relationship, a dependency of disjunctive type will be denoted as  $v_1 | v_2 | \dots | v_k \longrightarrow v$ .

In the latter case, it is said that the relationship is a conjunctive one – for the occurrence of  $v$ , it is necessary that all the symptoms of  $V$  must occur; it is said that the symptom  $v$  is of *AND* type. The conjunctive relationship is denoted as  $[v_1, v_2, \dots, v_k] \longrightarrow v$ .

Furthermore in some cases, it may happen that the occurrence of some symptom causes another symptom to disappear and vice versa; in such a case, it is said that the relationship is of *NOT* type, that is

$$u \models \bar{v} \quad \text{and} \quad \bar{u} \models v. \quad (20.10)$$

In such a case, the causal relationship is denoted as  $u \succ v$ .

The above-presented causal relationship applies to symptoms having the character of propositional logic variables, that is, to formulas taking the value *true* or *false*. Such symptoms, apart from denoting the occurrence of a discrete event (e.g., tank overflow, signal is on, etc.) may also denote that certain continuous variables take some predefined values or achieve certain levels, that is, de facto they can encode some formulas of the form  $X = w$  or  $X \in W$ , where  $X$  is some process variable and  $w$  is its value, and  $W$  is some set (interval) of values. In such a case, qualitative reasoning and qualitative modeling of the causal relationship at the level of propositional logic only may turn out to be insufficient.

A more general notation for the representation of the causal relationship in case when values of certain variables influence the values taken by other variable may take the following form

$$v_1, v_2, \dots, v_k \longrightarrow_{\psi} v, \quad (20.11)$$

or in the form of an equation

$$\psi(v_1, v_2, \dots, v_k) = v. \quad (20.12)$$

Note that, in this case, it is important that variables  $v_1, v_2, \dots, v_k$  influence variable  $v$ , and the quantitative (or qualitative) characteristics of this influence are expressed with the appropriate equation. In practice, such characteristics can be expressed with a look-up table specifying the values of  $v$  for different combinations of values of the input variables.

Now, let us pass to more general case, that is, modeling the causal relationship among variables taking discrete, continuous, qualitative, or even symbolic values. This will be done with the use of *causal graphs* (CGs).

Consider two system variables, say  $X$  and  $Y$ . Then, if  $X$  influences  $Y$ , we speak about *causal dependency*.

Note that causality assumes at least the following three phenomena:

- Logical implication: a certain change of  $X$  implies a certain change of  $Y$ .
- Directed flow of a physical signal; if  $X$  influences  $Y$ , then there must be some way a physical signal flows from  $X$  to  $Y$ .
- Temporal precedence – the change of  $X$  must happen prior to the change of  $Y$ .

In the following, the definition of a CG is formally introduced.

**Definition 20.5**

A CG is a set of nodes representing system variables and a set of edges or links describing mutual influences among these variables. The edges of the graph are assigned equations describing the influences in a quantitative way, and the variables are assigned some domains.

Let us introduce the following notation:

- $A, B, C, \dots$  – measurable variables of the system
- $[U], [V], [W]$  – immeasurable variables (*internal* or *hidden* ones)
- $X^*$  – conflicting variable, that is, one taking the value *inconsistent* with the *model-based prediction*.

And let ( $\longrightarrow$ ) denote the existence of causal influence between two variables. Any such influence is assigned an expression of the form

$$i = ([X_1, X_2, \dots, X_k], f, Y, [c_1, c_2, \dots, c_k, c_Y]) \tag{20.13}$$

where  $X_1, X_2, \dots, X_k$  are the input variables,  $f$  is a function defining the dependency in quantitative terms,  $Y$  is an output variable and  $c_1, c_2, \dots, c_k$  are the system components responsible for the correct work of the subsystems generating the output values;  $c_Y$  is the component responsible for the value of the output variable  $Y$ .

### 20.7 Potential Conflict Structures

In general case, search for conflicts is not an easy task. In the original work of Reiter [20.22] no efficient method for conflict generation was given. To make things worse, in the general case it is necessary to use an automated theorem prover for proving inconsistency of the set  $SD \cup OBS \cup \{\neg AB(c) \mid c \in COMP\}$  in order to find all the refutations of it;

**Fig. 20.4** A complete CG for the multiplier–adder system

For example, a CG for the previously analyzed arithmetical unit has the structure, as shown in Fig. 20.4. Recall that variable  $F$  took an incorrect value; according to the accepted notation, in Fig. 20.4, it is marked with an asterisk.

The core idea of using the CG for search of conflicts is based on the following observations and assumptions:

- Existence of all the conflicts is indicated by misbehavior of some variables (behavior different from the predicted one).
- In order to state that a conflict exists in the current value of it (observed or measured) must be different from the one predicted with the use of the model.
- The conflict set will be composed of the components responsible for the correct value of the misbehaving variable.

So, in case the CG for the analyzed system is defined, the detection of all the conflicts requires the detection of all the misbehaving variables and next – search of the graph in order to find all the sets of components responsible for the observed misbehavior.

It seems helpful for the discussion to introduce the idea of a *potential conflict structure* (PCS) [20.24, 30].

for any such case the instances of predicates  $AB(\cdot)$  used in refutation should be collected because they form the conflict sets. Of course, the applied theorem prover should be consistent and complete. In conclusion, in the general case the task of finding all minimal conflicts is hard to accomplish and computationally complex.

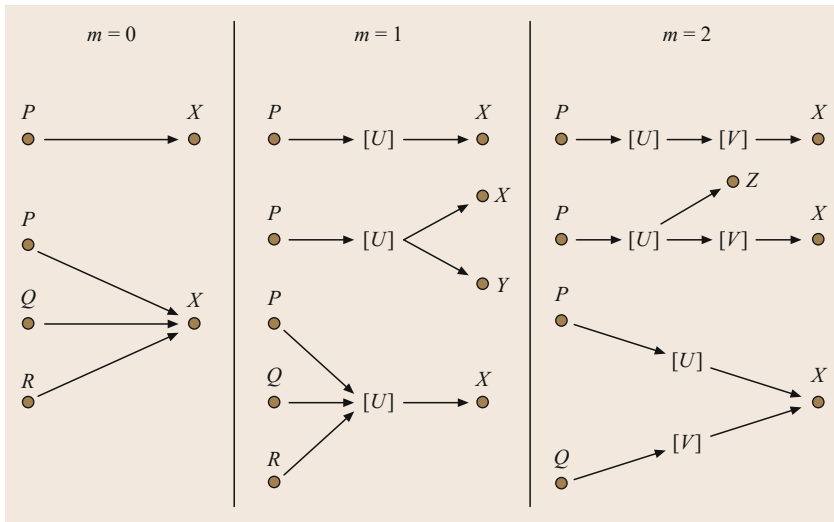

Fig. 20.5 Examples of a simple PCS (after [20.24])

A *potential conflict structure* is a subgraph of the CG sufficient for conflict generation; this idea was first introduced in [20.24]; then it was discussed and developed in [20.26, 27, 30] and [20.29]; an attempt at defining an approach to the automated search of conflict sets for a wide class of dynamic systems which is based on the use of CG representing the flow of signals in the analyzed system was undertaken. The use of such a graph simplifies the procedure of conflict generation and allows for relatively efficient search for all potential minimal conflicts.

Similar concept named *possible conflict* has also been described then in [20.31, 32].

Next, as a result of computational verification of potential conflicts, those which are not real ones are eliminated.

**Definition 20.6**

A PCS structure defined for variable  $X$  on  $m$  hidden variables is any subgraph of the CG, such that:

- It contains exactly  $m$  hidden variables (including  $X$ ).
- The values of all incorporated variables are measured or calculated (they are well defined).
- The value of variable  $X$  is double-defined (e.g., measured and calculated with the use of values of the other variables).
- In the considered PCS, all the values of the  $m$  variables are necessary for  $X$  in order to be double-defined.

A structure just defined allows for potential conflict generation. Some examples of PCS for  $m$  hidden variables are shown in Fig. 20.5.

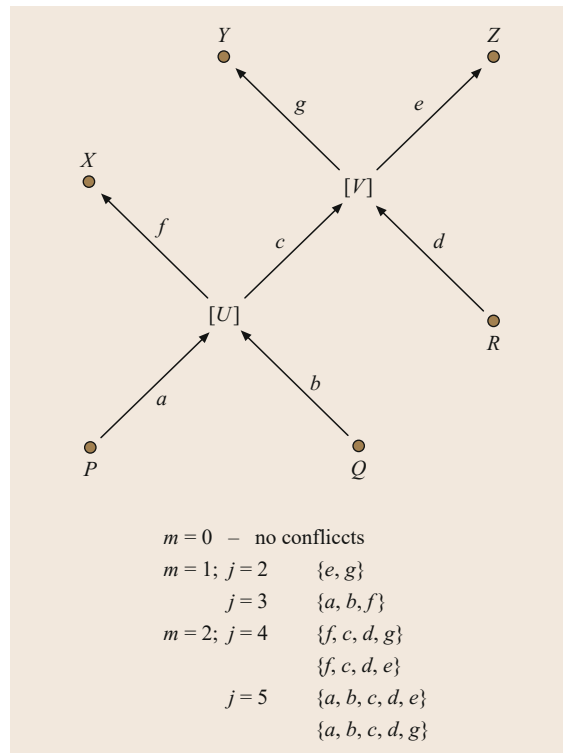

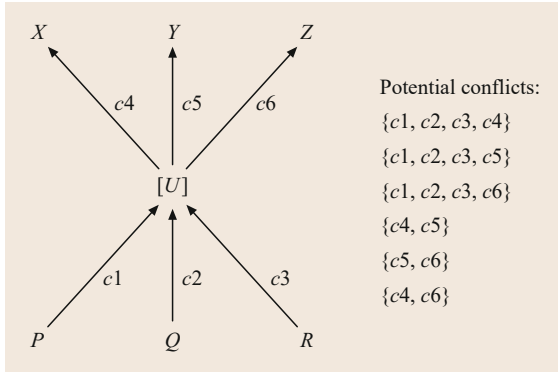

Fig. 20.6 Example conflict structures;  $j$  is the number of links used (after [20.24])

In Fig. 20.6, we show how the number of conflicts and their structure changes with  $m = 0, 1, 2$  for a simple CG of two hidden variables.

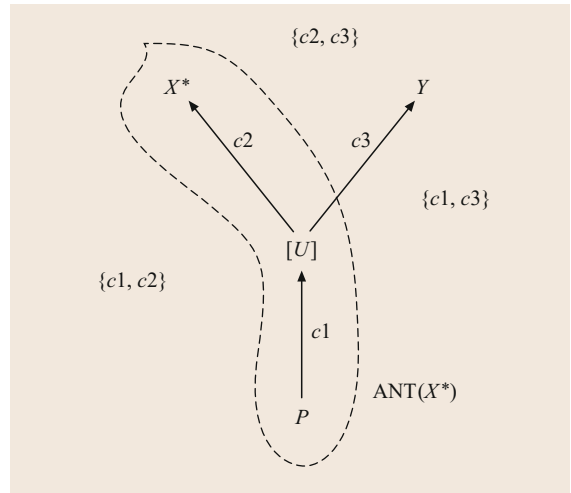

In Fig. 20.7, some further examples for a simple CG with a single immeasurable variable are shown.

**Fig. 20.7** A number of PCSs for a simple CG (after [20.24])

Finally, consider the graph presented in Fig. 20.8.

Since variable  $X$  takes a wrong value, certainly there exists a conflict of the form  $\{c_1, c_2\}$ . But if  $c_1$  were faulty, then  $Y$  should show an incorrect value, and it is not the case. But there is another conflict set  $\{c_2, c_3\}$  – since  $Y$  takes the correct value,  $U$  must be correct, and  $c_2$  must be wrong. Hence, the most obvious diagnosis is  $\{c_2\}$ ; it explains the misbehavior of  $X$  and is consistent with the observation of the correct value at  $Y$ .

**Fig. 20.8** An illustration to the compensation phenomenon (after [20.24])

On the other hand, a *legal* explanation is also diagnosis  $\{c_1, c_3\}$ . Here,  $c_1$  explains the wrong behavior of  $X$  (with  $c_2$  being OK), and faulty component  $c_3$  compensates the error caused by  $c_1$ , so that  $Y$  is observed to have the correct value.

## 20.8 Example Revisited. A Complete Diagnostic Procedure

Let us come back to the multiplier–adder example presented in Sect. 20.4. A detailed analysis of the observed failure is presented in the following. Moreover, an analysis of all potentially observed faults is provided.

Consider once again the multiplier–adder system as presented in Fig. 20.2. Assume that, as before  $F = 10$  and  $G = 12$ , that is, an incorrect output is observed at  $F$ . The current state of the system is that the inputs are:  $A = 3, B = 2, C = 2, D = 3$ , and  $E = 3$ . Having in mind the *model* of the system, it is easy to check that – if the system works correctly – the outputs should be  $F = 12$  and  $G = 12$ . Since the current value of  $F$  is incorrect, namely  $F = 10$ , a fault has been detected. At least one of its components must be faulty.

For simplifying further analysis, consider the CG for the multiplier–adder presented in Fig. 20.2. The graph itself is presented in Fig. 20.4. The CG represents a simplified model of the original system, at the level of detail satisfactory for automated diagnosis.

In order to perform diagnostic reasoning, let us start with *abduction*. We shall try to build a rule specifying hypothetical faulty elements. Note that the value of  $F$  is influenced by the inputs (observed) and the work of elements  $m_1, m_2$ , and  $a_1$ . If all the three elements work

correctly, then the output would be correct. Since it is not, we can conclude that a conflict (or *disjunctive conceptual fault* [20.29])  $DCF_1$  is observed: at least one of the elements  $\{m_1, m_2, a_1\}$  must be faulty. Hence, a rule of the form

$$\text{rule}_{1\_or} : m_1 \vee m_2 \vee a_1 \longrightarrow DCF_1 \quad (20.14)$$

can be stated.

The situation is illustrated in Fig. 20.9.

A further analysis leads to the detection of conflict  $DCF_2$ : under the assumed manifestations, one of the elements  $\{m_1, a_1, a_2, m_3\}$  must also be faulty. This is so

**Fig. 20.9** First conflict detected for the multiplier–adder example

since if all of them were correct, then  $Z = C \times E$  calculated by  $m3$  must be equal to 6, and since  $G$  is observed to be 12,  $Y$  (calculated backward and under the assumption that  $a2$  works correct) must also equal 6; hence, if  $m1$  is correct, then  $X$  must be 6 as well, and if  $a1$  is correct,  $F$  would be equal to 12. Since it is not the case, at least one of the used components must be faulty. So we have the following rule

$$\text{rule}_{2\_or} : m1 \vee m3 \vee a1 \vee a2 \longrightarrow \text{DCF}_2 . \quad (20.15)$$

The situation is illustrated in Fig. 20.10.

Note that if  $F$  would be correct and  $G$  would be faulty, for example,  $F = 12$  and  $G = 10$ , then another observed conflict would be  $\text{DCF}_3 = \{m2, m3, a2\}$  and so we would have a third OR rule of the form

$$\text{rule}_{3\_or} : m2 \vee m3 \vee a2 \longrightarrow \text{DCF}_3 . \quad (20.16)$$

Moreover,  $\text{DCF}_2$  equivalent to a fault in  $\{m1, m3, a1, a2\}$  would occur as well.

If both the outputs were incorrect (e.g.,  $F = 10$  and  $G = 14$ ), then, in general case, one can observe  $\text{DCF}_1$ ,  $\text{DCF}_2$ , and  $\text{DCF}_3$ . Note, however, that whether  $\text{DCF}_2$  is a valid conflict may depend on the observed outputs. For example, if  $F = 10$  and  $G = 10$  (both outputs are incorrect but equal), then the structure and equations describing the work of the system do not lead to a conceptual fault [20.16, 17].

Note that any DCF is modeled with some PCS. Depending on the current manifestations, a DCF can be observed (be active), that is, a real conflict exists or it may be a potential conflict only (be inactive). For effective diagnosis, one needs only the specification of active DCFs.

The diagnoses are calculated as reduced elements of the Cartesian product of the conflict sets associated with the active DCFs. The reduction consists in the elimination of duplicates.

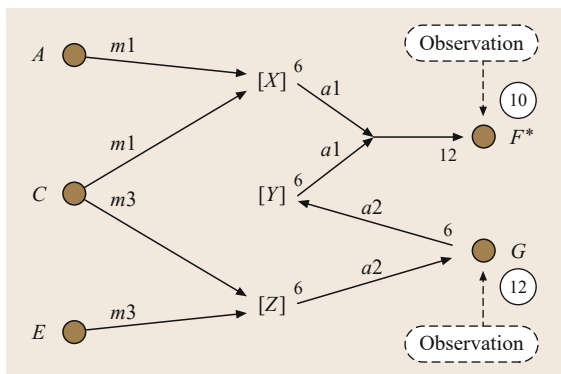

Fig. 20.10 Second conflict detected for the multiplier-adder example

The OR matrix for the diagnosed system is presented in Table 20.1.

The AND matrix defining the relationship between the DCFs (active in the case of  $F$  being incorrect and  $G$  correct) and the manifestations is presented in Table 20.2.

In Table 20.2,  $F^*$ ,  $G^*$ , etc., mean that the output is incorrect, while  $F$ ,  $G$ , etc. denote the correct output observed at the variable.

In the analyzed case, that is  $F$  being faulty and  $G$  correct, the final diagnoses for the considered case are calculated as reduced elements of the Cartesian product of  $\text{DCF}_1 = \{m1, m2, a1\}$  and  $\text{DCF}_2 = \{m1, m3, a1, a2\}$ . There are the following potential diagnoses:  $D_1 = \{m1\}$ ,  $D_2 = \{a1\}$ ,  $D_3 = \{a2, m2\}$ , and  $D_4 = \{m2, m3\}$ . They all are shown in Fig. 20.11.

The potentially possible final diagnoses in general case are presented in Table 20.3.

The calculation of diagnoses can be easily interpreted by using AND/OR CGs [20.25, 28]. An appropriate AND/OR graph is presented in Fig. 20.12. The active links are represented with continuous lines, while the potential ones are represented with dashed lines. Active DCFs are marked with bold circles and the current diagnostic problem (manifestations) are also represented with a bold-line circle.

The final diagnoses are calculated as the minimal sets of the lowest level elements which are necessary to satisfy the currently observed set of manifestations. The intermediate nodes representing the DCFs are OR

Table 20.1 An OR binary diagnostic matrix for the adder system (the lower level)

DCF	m1	m2	m3	a1	a2

$F, G^*, (F - G)^*$		1	1
$F^*, G^*, (F - G)$	1		1
$F^*, G^*, (F - G)^*$	1	1	1

Fig. 20.11 Generation of potential diagnoses

Fig. 20.12 An AND/OR CG for the example multiplier-adder system

Table 20.3 Final possible diagnoses

Observations	Diagnoses
$F^*, G, (F-G)^*$	$\{a1\}, \{m1\},$ $\{a2, m2\}, \{m2, m3\}$
$F, G^*, (F-G)^*$	$\{a2\}, \{m3\},$ $\{a3, m2\}, \{m1, m2\},$
$F^*, G^*, (F-G)$	$\{m2\},$ $\{a1, a2\}, \{a1, m3\},$ $\{a2, m1\}, \{m1, m3\}$
$F^*, G^*, (F-G)^*$	$\{a1, a2\}, \{a1, m2\},$ $\{a1, m3\}, \{a2, m1\},$ $\{a2, m2\}, \{m1, m2\},$ $\{m2, m3\}, \{m1, m3\}$

nodes, while the top-level nodes representing current manifestations are AND nodes.

The presented graphical interpretation can be considered as the effect of *knowledge compilation* for building an efficient diagnostic procedure. In fact, the graph covers all the possible potential failures. In order to build an automated diagnostic system, it would be enough to apply a simple, three-stage procedure:

- Decide which of the top-level nodes describe the current diagnostic situation.
- Find all the real conflicts corresponding to the unique top-level node.
- Generate all the minimal hitting sets.

The resulting diagnoses will be formed by minimal sets of the lowest level nodes, such that a combination of them *supports* the identified conflicts.

## 20.9 Refinement: Qualitative Diagnoses

### 20.9.1 Qualitative Evaluation of Faults

A most popular classification of faults is the binary one. An element can be just faulty ( $f = 1$ ) or not ( $f = 0$ ). This kind of classification is prevailing in technological systems, sometimes extended to several degrees or a fuzzy fault description.

Note, however, that in some particular cases, the fault can be interpreted as a significant deviation from some expected status or value, and the deviation has not only an amplitude but also a direction or sign as well. In this case, the fault can be said to be *negative* or *positive* one, and a classification described with three values  $\{-, 0, +\}$  can be established. This kind of knowl-

edge can be used for further refinement of diagnoses without taking extraordinary measurements, tests, or observations. Furthermore, the same classification can also be assigned to manifestations, that is, values of certain variables can be normal (0), below the norm (-) or above it (+). The presentation in the following is mostly based on [20.29].

### 20.9.2 Elimination of Spurious Diagnoses

The idea is that in numerous cases the influence of faults on the manifestations can be analyzed in a qualitative way using the three-valued approach. Two key observations may be useful: (1) that certain faults can be only

negative or only positive and (2) that the defined sign of deviation of a fault defines also the sign of deviation of the influenced manifestation.

For example, the voltage of a battery can only be normal (0, no fault) or low (−, below normal). The level of liquid in a tank can be normal (0), low (−), or high (+). The clock can be exact, but when faulty it can slow down (−) or advance (+).

The influence of a fault on manifestation can be denoted using the sign. For example, low battery (*battery\_fault*) causes low light (*light\_fault*), that is,  $\text{battery\_fault}(-) \longrightarrow \text{light\_fault}(-)$ .

Let  $V$  denote a set of variables. For diagnostic purposes, we shall assume that  $V = O \cup H \cup C$ , and these sets are pairwise disjoint.  $O$  is the set of observable (measurable) system variables,  $H$  is the set of hidden variables, and  $C$  is the set of diagnostic variables aimed at describing different faulty modes of diagnosed components.

In the case of the multiplier–adder example system, we have

$$\begin{aligned} O &= \{A, B, C, D, E, F, G\}, \\ H &= \{X, Y, Z\}, \text{ and} \\ C &= \{m1, m2, m3, a1, a2\}. \end{aligned}$$

Variables of  $O$  and  $H$  take the values of the real numbers (or integers) restricted to some reasonable intervals, while variables of  $C$  are restricted to some of the possible modes of misbehavior. In our case, the values are restricted to  $\{-, 0, +\}$  with the obvious meaning of lowering the output value, producing correct output and producing the output higher than expected.

For enhancing diagnostic reasoning, however, we shall assume that all the variables can take three qualitative logical values  $\{-, 0, +\}$ . For any variable  $V \in V$ , we can interpret these values as follows:

- $V(0)$  – the proposition that *the value of  $V$  is correct* holds
- $V(+)$  – the proposition that *the value of  $V$  is incorrect; deviation is positive* holds
- $V(-)$  – the proposition that *the value of  $V$  is incorrect; deviation is negative* holds.

In other words, the first statement can be interpreted as a *kind of true*, while the last two statements can be interpreted as some *two different types of negation*.

We shall extend the knowledge about the models of the system over incorrect behavior. In order to do that we shall define some qualitative inference rules. Let  $R$  be a set of rules defining all the accessible knowledge about the behavior of faulty components depending on the faulty mode. Note that, in fact, there are three generic forms of such rules, that is those:

- describing the faulty behavior of elements in the case of normal inputs
- describing the normal behavior in the case of deviated inputs
- describing faulty behavior in the case of deviated inputs.

Let  $c$  denote a single component and  $X$  a variable. By  $c(v)$ , where  $v \in \{-, 0, +\}$ , we shall denote the type of failure; if undefined, we shall write  $c(?)$ . For partial definition, we can use a set of values. The same applies to variables. Now, more detailed characteristics of the diagnoses can be found. Let us introduce a definition of *qualitative diagnosis* taking into account the deviation sign of a fault.

#### Definition 20.7

A *qualitative diagnosis*

$$D = \{d_1(\#), d_2(\#), \dots, d_k(\#)\}$$

is a diagnosis fully explaining the observed misbehavior and covering the knowledge of the deviation sign for any fault (if accessible). Here,  $\#$  is  $+$  if the deviation sign is positive,  $-$  if the deviation sign is negative, and  $?$  if the deviation sign is unknown (any, undetermined).

In the following, three types of causal rules describing the qualitative behavior are discussed in detail.

A generic form of the first type of rules is as follows

$$c(v) \longrightarrow \text{Out}(w)$$

where  $c$  denotes one of the five components of the system, and  $v$  is one of the logical values defining the operating mode,  $v \in \{-, 0, +\}$  and  $\text{Out}$  is its output,  $w \in \{-, 0, +\}$ . For example, a faulty  $m1$  lowering its output signal is described with the rule  $c(-) \longrightarrow \text{Out}(-)$  with the obvious meaning. In the case of the example system, we have as much as 10 such rules (two for each of the five components) defining particular lowering or increasing of the output values when in the faulty state.

A generic form of the second type of rules is as follows

$$\text{In}_1(v_1) \wedge \text{In}_2(v_2) \longrightarrow \text{Out}(w)$$

where  $\text{In}_1$  and  $\text{In}_2$  denote the inputs of a component and  $\text{Out}$  is its output,  $v_1, v_2, w \in \{-, 0, +\}$ .

A generic form of the third type of rules is as follows

$$\text{In}_1(v_1) \wedge \text{In}_2(v_2) \wedge c(v) \longrightarrow \text{Out}(w)$$

where  $In_1$  and  $In_2$  denote the inputs of a component  $c$  and Out is its output,  $v, v_1, v_2, w \in \{-, 0, +\}$ .

The rules of the second type (normal behavior, deviated inputs) are summarized in Table 20.4.

For example, a faulty component  $a1$  showing a lower value of its output signal (but assumed to be correct) and taking one input signal lower and one normal can produce a lower output value. Such a behavior is described with the rule

$$X(-) \wedge Y(0) \longrightarrow F(-)$$

The rules of the third type (abnormal behavior, deviated inputs) are summarized in decision Table 20.5.

For all other 10 combinations of input signals and component mode, the output is undefined. For example, a faulty component  $a2$  increasing its output signal and taking one input signal higher than normal and one normal produces a higher output value. Such a behavior is described with the rule

$$Y(0) \wedge Z(+) \wedge a2(+) \longrightarrow G(+)$$

### 20.9.3 Deduction for Enhanced Diagnoses

The analysis of potential qualitative diagnoses is performed by the propagation of values over the CGs forward, that is, deduction with the rules defined above. This is performed for all qualitative diagnoses. Whenever an inconsistency of the expected and observed values is encountered, the candidate diagnosis is eliminated.

**Table 20.4** Behavior of the correct component with deviated inputs

Inputs	-	0	+
-	-	-	?
0	-	0	+
+	?	+	+

**Table 20.5** Behavior of the incorrect component with deviated inputs

Input1	Input2	Component mode	Output
-	-	-	-
-	0	-	-
0	-	-	-
0	0	-	-
+	+	+	+
+	0	+	+
0	+	+	+
0	0	+	+

### 20.9.4 Analysis of Diagnoses

Let us analyze, in turn, all the four potential diagnoses and their potential qualitative forms. The analysis is aimed at finding all *admissible qualitative diagnoses*.

#### Case of $m1$

There are two false values for  $m1$ , that is,  $m1(-)$  and  $m1(+)$ .

Consider  $m1(-)$  first. Using an appropriate deduction rule of the form

$$m1(-) \longrightarrow X(-),$$

we have  $X(-)$ . Since  $a1$  is correct, but one of its inputs is false (lower), we can use another rule of the form

$$X(-) \wedge Y(0) \longrightarrow F(-)$$

and so we have  $F(-)$ . This is consistent with observations since  $F = 10$ , and the reference value was 12.

Now, consider  $m1(+)$ . Using an appropriate deduction rule of the form

$$m1(+) \longrightarrow X(+),$$

we have  $X(+)$ . Since  $a1$  is correct, but one of its inputs is false (upper), we can use another rule of the form

$$X(+) \wedge Y(0) \longrightarrow F(+)$$

and so we have  $F(+)$ . This is inconsistent with observations since  $F = 10$ , and the reference value is 12. Hence, the diagnosis  $m1(+)$  is inadmissible.

#### Case of $a1$

There are two modes of faulty operation of  $a1$ , that is,  $a1(-)$  and  $a1(+)$ .

Consider  $a1(-)$  first. The appropriate rule is of the form

$$a1(-) \longrightarrow F(-)$$

and so we have  $F(-)$ . This is consistent with observations since  $F = 10$ , which is lower than 12. Finally, diagnosis  $a1(-)$  is admissible.

On the other hand, consider  $a1(+)$ . The appropriate rule is of the form

$$a1(+) \longrightarrow F(+)$$

and so we have  $F(+)$ . This, however, is inconsistent with observations since  $F = 10$ , and the reference value is 12 and should be even higher. Hence, the diagnosis  $a1(+)$  is inadmissible.

**Case of  $\{a2, m2\}$** 

There are four combined potential faulty modes for diagnosis  $\{a2, m2\}$ , that is,  $\{a2(-), m2(-)\}$ ,  $\{a2(-), m2(+)\}$ ,  $\{a2(+), m2(-)\}$ ,  $\{a2(+), m2(+)\}$ . Let us analyze them in turn. For simplicity, we shall only show the applied rules and conclusions.

Case:  $\{a2(-), m2(-)\}$ . Rule to be used

$$m2(-) \longrightarrow Y(-)$$

Conclusion:  $Y(-)$ . Next rule to be applied

$$Y(-) \wedge Z(0) \wedge a2(-) \longrightarrow G(-)$$

Conclusion:  $G(-)$  is inconsistent with observations. Finally, diagnosis  $\{a2(-), m2(-)\}$  is eliminated as inconsistent with observations.

Case:  $\{a2(-), m2(+)\}$ . Rule to be used

$$m2(+) \longrightarrow Y(+)$$

Conclusion:  $Y(+)$ . Next rule to be applied

$$X(0) \wedge Y(+) \longrightarrow F(+)$$

Conclusion:  $F(+)$  is inconsistent with observations. Finally, diagnosis  $\{a2(-), m2(+)\}$  is eliminated as inconsistent with observations.

Case:  $\{a2(+), m2(-)\}$ . Rule to be used

$$m2(-) \longrightarrow Y(-)$$

Conclusion:  $Y(-)$ . Next rule to be applied

$$X(0) \wedge Y(-) \longrightarrow F(-)$$

Conclusion:  $F(-)$  is consistent with observations. We can proceed. Next rule to be applied

$$Y(-) \wedge Z(0) \wedge a2(+) \longrightarrow G(?)$$

Conclusion:  $G(?)$  may be consistent with observations. Finally, diagnosis  $\{a2(+), m2(-)\}$  is a potentially admissible one.

Case:  $\{a2(+), m2(+)\}$ . Rule to be used

$$m2(+) \longrightarrow Y(+)$$

Conclusion:  $Y(+)$ . Next rule to be applied

$$X(0) \wedge Y(+) \longrightarrow F(+)$$

Conclusion:  $F(+)$  is inconsistent with observations. Finally, diagnosis  $\{a2(+), m2(+)\}$  must be rejected.

**Case of  $\{m2, m3\}$** 

There are four combined potential faulty modes for diagnosis  $\{m2, m3\}$ , that is,  $\{m2(-), m3(-)\}$ ,  $\{m2(-), m3(+)\}$ ,  $\{m2(+), m3(-)\}$ ,  $\{m2(+), m3(+)\}$ . Let us analyze them in turn.

Case:  $\{m2(-), m3(-)\}$ . Rule to be used

$$m2(-) \longrightarrow Y(-)$$

Conclusion:  $Y(-)$ . Next rule to be applied

$$m3(-) \longrightarrow Z(-)$$

Conclusion:  $Z(-)$ . Next rule to be applied

$$Y(-) \wedge Z(-) \longrightarrow G(-)$$

Conclusion:  $G(-)$  is inconsistent with observations. Finally, diagnosis  $\{m2(-), m3(-)\}$  is eliminated as inconsistent with observations.

Case:  $\{m2(-), m3(+)\}$ . Rule to be used

$$m2(-) \longrightarrow Y(-)$$

Conclusion:  $Y(-)$ . Next rule to be applied

$$X(0) \wedge Y(-) \longrightarrow F(-)$$

Conclusion:  $F(-)$  is consistent with observations. We can proceed. Next rule to be applied

$$m3(+) \longrightarrow Z(+)$$

Conclusion:  $Z(+)$ . Next rule to be applied

$$Y(-) \wedge Z(+) \longrightarrow G(?)$$

Conclusion:  $G(?)$  may be consistent with observations. Finally, diagnosis  $\{m2(-), m3(+)\}$  may be considered admissible.

Case:  $\{m2(+), m3(-)\}$ . Rule to be used

$$m2(+) \longrightarrow Y(+)$$

Conclusion:  $Y(+)$ . Next rule to be applied

$$X(0) \wedge Y(+) \longrightarrow F(+)$$

Conclusion:  $F(+)$  is inconsistent with observations. Diagnosis  $\{m2(+), m3(-)\}$  must be eliminated.

Case:  $\{m2(+), m3(+)\}$ . Rule to be used

$$m2(+) \longrightarrow Y(+)$$

Conclusion:  $Y(+)$ . Next rule to be applied

$$X(0) \wedge Y(+) \longrightarrow F(+)$$

Conclusion:  $F(+)$  is inconsistent with observations. Diagnosis  $\{m2(+), m3(+)\}$  must be eliminated.

### 20.10 Dynamic Systems Diagnosis: The Three-Tank Case

As another example, let us consider the model of a widely used dynamic system composed of three interconnected tanks [20.3, 27, 30]. The schematic diagram of the system is presented in Fig. 20.13.

The components of the system selected for diagnostic purposes are specified by COMP = {k1, k12, k23, k3, z1, z2, z3}; they are the channels (responsible for flow) and tanks (responsible for the volume of the liquid). The signals to be observed are  $L_1, L_2,$  and  $L_3,$  and they describe the level of the liquid in the consecutive tanks and the signals controlling the input valve  $U$ . The model of the system is specified with the following set of differential equations

$$f(U) = F \tag{20.17}$$

$$A_1 \frac{dL_1}{dt} = F - F_{12} \tag{20.18}$$

$$A_2 \frac{dL_2}{dt} = F_{12} - F_{23} \tag{20.19}$$

$$A_3 \frac{dL_3}{dt} = F_{23} - F_3 \tag{20.20}$$

where  $F_{ij} = \alpha_{ij} C_{ij} \sqrt{2g(L_i - L_j)}, F_3 = \alpha_3 C_3 \sqrt{2gL_3}, A_i$  denote the cross-sectional areas of the tanks for  $i = 1, 2, 3,$  and  $C_{ij}, C_3$  denote the cross-sectional areas of the channels connecting the tanks for  $ij = 12, 23.$  Note that in the case of this system even a superfluous anal-

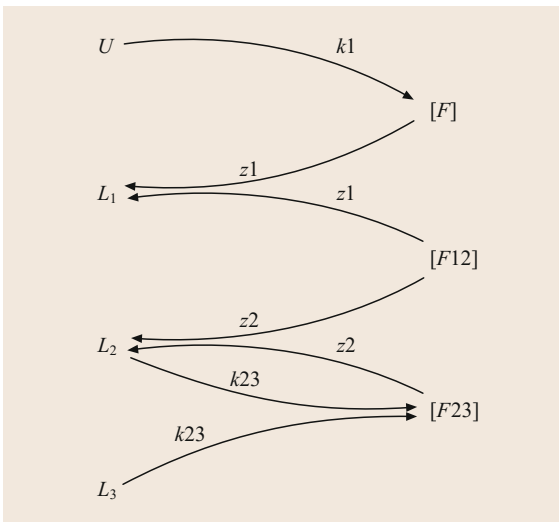

Fig. 20.17 Conflict set  $\{z1, k1, z2, k23\}$

Fig. 20.19 Conflict set  $\{k12, z2, k23\}$

ysis becomes a nontrivial task; this is the consequence of the fact that this time the system under analysis is a highly interconnected dynamic one, it is described with nonlinear equations and there exists strong feedback in the system.

The Matlab/Simulink model of this system is shown in Fig. 20.14. Using Matlab/Simulink, one can simulate the expected correct behavior of the system. If some calculated variables are different from the measured values, an inconsistency is observed and the diagnostic procedure should be activated.

The CG for the example system is shown in Fig. 20.15. The CG can be generated automatically from the Matlab/Simulink model of the system with conflict generator application developed for experimental use. The application is described in more detail in Sect. 20.12.

After defining which of variables are measured ones, the program can generate PCSs. All poten-

Fig. 20.20 Conflict set  $\{k12, z2, z3, k3\}$

tial conflicts for the three-tank system, that is,  $\{z1, k1, k12\}$ ,  $\{z1, k1, z2, k23\}$ ,  $\{z1, k1, z2, z3, k3\}$ ,  $\{k12, z2, k23\}$ ,  $\{k12, z2, z3, k3\}$ ,  $\{k23, z3, k3\}$  calculated by a conflict generator are shown in Fig. 20.22, and in the graphic way in Figs. 20.16–20.21. Notice that all PCSs can be calculated off-line. As the system is composed of strongly coupled subsystems (there are indirect feedback loops from  $L_2$  to  $L_1$  as well as from  $L_3$  to  $L_2$ ) the generated conflict sets are relatively complex. Assuming that the diagnostic system detected that real conflicts are:  $\{z1, k1, k12\}$ ,  $\{z1, k1, z2, k23\}$ ,  $\{z1, k1, z2, z3, k3\}$  based on Reiter’s theory, the following diagnoses may be calculated:  $\{z1\}$ ,  $\{k1\}$ ,  $\{k12, z2\}$ ,  $\{k12, k23, z3\}$ ,  $\{k12, k23, k3\}$ , so damaged is element  $z1$  or element  $k1$  or at the same time el-

ements  $k12$  and  $z2$  or at the same time elements  $k12, k23, z3$ , or at the same time elements  $k12, k23, k3$  (Fig. 20.24).

### 20.11 Incremental Diagnosis

The algorithm of calculating diagnoses from conflict sets given by Reiter [20.22] requires rather complicated data structures, such as hitting sets (HSs) tree, and is quite difficult to implement. Now, a theorem, that allows us to calculate diagnoses for some of conflicts when there are known diagnoses for those conflict sets will be proposed. This theorem may be used, for instance, in the case when diagnoses are generated simultaneously for some subsystems of one system; in such a case, it can be used for combining together the separately generated sets of diagnoses. It can also be used for incremental generation of diagnoses for one set of conflict sets, and especially when one generates conflicts and diagnoses simultaneously.

Before the theorem is formulated, it is necessary to put forward the following definition.

**Definition 20.8**

Let  $\mathbf{A}$  is set of nonempty sets. The reduced set  $[\mathbf{A}]$  for  $\mathbf{A}$  is the set containing this elements from  $\mathbf{A}$  which are not supersets for other elements.

**Example 20.1**

Let  $\mathbf{A} = \{\{a, b\}, \{a, b, c\}\}$ . We have  $[\mathbf{A}] = \{\{a, b\}\}$ . Let  $\mathbf{B} = \{\{a\}, \{a, b\}, \{a, b, c\}\}$ . Then  $[\mathbf{B}] = \{\{a\}\}$ . Finally, let  $\mathbf{C} = \{\{a\}, \{a, b\}, \{a, b, c\}, \{b, c\}, \{d, e\}\}$ . In this case,  $[\mathbf{C}] = \{\{a\}, \{b, c\}, \{d, e\}\}$ .

Now, a special operator for combining diagnoses will be defined. The operator as its arguments takes the diagnoses for two different families of conflict sets.

**Definition 20.9**

Let  $\mathbf{C}_i$  denote sets of conflict sets,  $\mathbf{D}_i$  sets of diagnoses calculable from  $\mathbf{C}_i$ , and  $\mathbf{H}_i$  sets of all hitting sets for  $\mathbf{C}_i$ ,  $i = 1, 2$ . Let  $D_1 \in \mathbf{D}_1$ ,  $D_2 \in \mathbf{D}_2$ . The operator  $\oplus$  is defined as follows

$$D_1 \oplus D_2 = \begin{cases} \{D_1, D_2\} & D_1 \in \mathbf{H}_2 \text{ and } D_2 \in \mathbf{H}_1 \\ \{D_1\} & D_1 \in \mathbf{H}_2 \text{ and } D_2 \notin \mathbf{H}_1 \\ \{D_2\} & D_1 \notin \mathbf{H}_2 \text{ and } D_2 \in \mathbf{H}_1 \\ \{D_1 \cup D_2\} & D_1 \notin \mathbf{H}_2 \text{ and } D_2 \notin \mathbf{H}_1 \end{cases}$$

Note that the result of operation  $\oplus$  is a family of sets, which may contain one or two sets and each of these sets is a hitting set for  $\mathbf{C}_i$ ,  $i = 1, 2$ .

**Example 20.2**

Let us consider the following sets of conflict sets

$$\begin{aligned} \mathbf{C}_1 &= \{\{a, b, c\}, \{a, d\}\} \\ \mathbf{C}_2 &= \{\{a, c, d\}, \{b, e\}\} . \end{aligned}$$

The sets of diagnoses that can be generated are, respectively,

$$\begin{aligned} \mathbf{D}_1 &= \{\{a\}, \{b, d\}, \{c, d\}\}, \text{ and} \\ \mathbf{D}_2 &= \{\{a, b\}, \{a, e\}, \{b, c\}, \{c, e\}, \{b, d\}, \{d, e\}\} . \end{aligned}$$

We have

$$\begin{aligned} \{b, d\} \oplus \{a, b\} &= \{\{b, d\}, \{a, b\}\} , \\ \{a\} \oplus \{a, b\} &= \{\{a, b\}\} , \\ \{a\} \oplus \{b, c\} &= \{\{a, b, c\}\} . \end{aligned}$$

Now, let us define another operator that constitutes a kind of extension of the previous one.

**Definition 20.10**

Let  $\mathbf{C}_i$  denote sets of conflict sets, and  $\mathbf{D}_1 = \{D_1^1, D_1^2, \dots, D_1^m\}$ ,  $\mathbf{D}_2 = \{D_2^1, D_2^2, \dots, D_2^n\}$  be the sets of diagnoses calculable from  $\mathbf{C}_i$ ,  $i = 1, 2$ . We define operator  $\oplus$  as follows

$$\mathbf{D}_1 \oplus \mathbf{D}_2 = \bigcup_{\substack{i=m, j=n \\ i=1, j=1}} \{D_1^i \oplus D_2^j\}$$

In other words, by using  $\oplus$ , one makes a union of results of operations with  $\oplus$  for each diagnosis from  $\mathbf{D}_1$  with each diagnosis from  $\mathbf{D}_2$ .

Finally, the main theorem of this algebraic approach will be presented. The theorem is named a *composition theorem* since it allows for combining partial results (ones obtained separately or in turn) into the final set of diagnoses (proof in [20.30]):

**Theorem 20.2 (Composition theorem)**

Let  $\mathbf{C}_i$  denote sets of conflict sets and  $\mathbf{D}_i$  sets of diagnoses calculable from  $\mathbf{C}_i$ ,  $i = 1, 2, 3$ . If  $\mathbf{C}_3 = \mathbf{C}_1 \cup \mathbf{C}_2$ , then  $\mathbf{D}_3 = \lfloor \mathbf{D}_1 \oplus \mathbf{D}_2 \rfloor$ .

**Example 20.3**

Let

$$\mathbf{C}_1 = \{\{a, b, c\}, \{a, d\}\} \quad \mathbf{C}_2 = \{\{a, c, d\}, \{b, e\}\}.$$

The sets of diagnoses are

$$\begin{aligned} \mathbf{D}_1 &= \{\{a\}, \{b, d\}, \{c, d\}\}, \text{ and} \\ \mathbf{D}_2 &= \{\{a, b\}, \{a, e\}, \{b, c\}, \{c, e\}, \{b, d\}, \{d, e\}\}. \end{aligned}$$

Consider the combined set of conflict sets

$$\mathbf{C}_3 = \mathbf{C}_1 \cup \mathbf{C}_2 = \{\{a, b, c\}, \{a, d\}, \{a, c, d\}, \{b, e\}\}.$$

The set of diagnoses in this case is as follows

$$\mathbf{D}_3 = \{\{a, b\}, \{a, e\}, \{b, d\}, \{c, d, e\}\}.$$

Now, let us calculate the combination of diagnoses as

$$\begin{aligned} \mathbf{D}_1 \oplus \mathbf{D}_2 &= \{\{a, b\}, \{a, e\}, \{a, b, c\}, \\ &\{a, c, e\}, \{b, d\}, \{a, d, e\}, \{b, c, d\}, \{c, d, e\}\}. \end{aligned}$$

Let us reduce the combined set of diagnoses; then we obtain

$$\lfloor \mathbf{D}_1 \oplus \mathbf{D}_2 \rfloor = \{\{a, b\}, \{a, e\}, \{b, d\}, \{c, d, e\}\}.$$

It is easy to see that  $\mathbf{D}_3 = \lfloor \mathbf{D}_1 \oplus \mathbf{D}_2 \rfloor$ .

The composition theorem allows for calculating diagnoses for the sum of two families of conflict sets in the case where there are known diagnoses for each of these sets of conflicts. One does not need start generation of diagnoses from the beginning, that is, without using the known diagnoses for each individual family of conflicts. The application of this theorem may, therefore, significantly increase the efficiency of a procedure for the calculation of diagnoses.

The composition theorem may be easily generalized to the following theorem (proof in [20.30]):

**Theorem 20.3 (Generalized composition theorem)**

Let  $\mathbf{C}_i$  denote sets of conflict sets and  $\mathbf{D}_i$  sets of diagnoses calculable from  $\mathbf{C}_i$ ,  $i = 1, 2, \dots, n, n + 1$ . If

$$\mathbf{C}_{n+1} = \mathbf{C}_1 \cup \mathbf{C}_2 \cup \dots \cup \mathbf{C}_n,$$

then

$$\mathbf{D}_{n+1} = \lfloor \lfloor \lfloor \mathbf{D}_1 \oplus \mathbf{D}_2 \rfloor \oplus \mathbf{D}_3 \rfloor \oplus \dots \rfloor \oplus \mathbf{D}_n \rfloor.$$

## 20.12 Practical Example and Tools

For modeling dynamical systems, Matlab/Simulink was chosen as a pretty good standard. A diagnostic system was designed and implemented, which uses the presented theory. The system is a consistency-based diagnostic module and may be used to diagnose the class of the systems modeled with CGs. In particular, it needs a model of the diagnosed system made with Matlab/Simulink. The system is composed of two separate modules:

- Conflict generator
- Diagnostic module.

A conflict generator is an application implemented in C/C++. The main window of the system is shown in Fig. 20.22.

The conflict generator performs two main tasks, that is, the generation of CG from the model developed by using the Matlab/Simulink application and generation of all minimal, potential conflicts for such a graph. Con-

flict generation is done by the identification of all PCS in the given structure according to the previous considerations. The potential conflicts generated with the use of the conflict generator are then used by the diagnostic module.

The diagnostic module has been implemented in the Matlab/Simulink environment. It consists of three parts, which are in Matlab/Simulink as masked subsystems:

- A fault detector that has as input the values of measured variables of the diagnosed system and the corresponding values obtained from the model. The task of the fault detection subsystem is to detect inconsistency.
- A conflict verifier that takes potential conflicts as its input. Its task is to determine which of the conflicts are real ones.
- Diagnoses generator that calculates diagnoses in the form of minimal hitting sets for all real conflict sets. Its algorithm is based on Theorem 20.3.

A diagram of the diagnostic module is shown in Fig. 20.23.

Output of the system (main window) is shown in Fig. 20.24. One can see there:

- List of potential conflicts (in case there is fault detected real conflicts are marked)
- List of generated diagnoses
- Graphical visualization of the state of the system.

The graphical interface is quite important part of the application which supports monitoring of the diagnosed system and course of the diagnostic process. It can also be useful in teaching about diagnosis of static and dynamic systems, especially about MBR.

## 20.13 Concluding Remarks

In this chapter, selected methods of knowledge engineering in application for the diagnosis of technical systems were presented in brief. These methods belong to the category of *model-based reasoning* since the analysis is performed with by using the system model. Contrary to the so-called *expert systems*, especially ones using the so-called *shallow knowledge* of expert being the result of experience and useful for diagnosis, and methods based on using model of the system do not require expert knowledge, experience, evidence, etc., but only the model of correct system behavior.

A classical example of the use of model-based diagnosis with the illustrative example of the multiplier–adder system is presented in detail. The methods used are based on *consistency-based reasoning* and *abductive inference*. Both the paradigms use models of the system. A typical example for consistency-based reasoning is Reiter’s theory. Abductive inference may use a model in the form of a CG. A detailed analysis of an example CG by abductive reasoning was shown. The produced results are consistency-based reasonings with the use of a system model.

The main idea for the search of *conflicts* which form *disjunctive conceptual faults* is the one of potential conflict structures; it was shown that PCS can be used to find all DCFs in an efficient way, and even to compile the diagnostic knowledge.

An elaborated analysis of *qualitative diagnoses* was presented in detail. Such an analysis yields more

detailed specification of diagnoses, and, simultaneously, may serve for the elimination of spurious behavior.

An example of the application of the theory to a dynamic system of three tanks was also presented in detail. In the case of dynamic systems, the on-line generation of conflicts may be necessary. As new information becomes accessible, the DCFs can be recalculated, thanks to the provided theorems. A note on practical diagnostic experiments and tools was provided as well.

The presented groups of methods have well-defined theoretical foundations. However, for efficient application, they require adjustment to the specific type of the diagnosed system. Moreover, new approaches to problem statement and new tools may open new diagnostic possibilities; those include embedding the diagnostic process within the framework of constraint programming and compilation of diagnostic knowledge [20.33, 34]. These methods may serve as a core of advanced diagnostic system, but in order to improve efficiency, they should be equipped with specific domain knowledge and heuristic knowledge. They may be also complementary to one another, and it seems reasonable to join expert knowledge based on experience with knowledge about the system model. It should allow for the diagnosis of new, unknown before failures, while the expert component should allow for improving reasoning efficiency.

## 21. Thought Experiments in Model-Based Reasoning

Margherita Arcangeli

Thought experimentation is at least as old as Western philosophy. Scholars have made much use of it in many disciplines. For instance, philosophical discussions on ethics, morality, knowledge, and language abound with thought experiments. Likewise, great scientific developments, such as in physics and mathematics, have been achieved via thought experimentation. This is true even long before the introduction of the term, between the late seventeenth and nineteenth centuries. But what is a thought experiment? Although giving a clear answer to this question is a very complicated task, it is quite common to consider thought experiments as pieces of reasoning about imaginary cases mainly performed with the aim of increasing our knowledge or understanding of the world. In this chapter, I review the lively debate on thought experiments. First, I introduce some famous examples and detail six of them (Sect. 21.1). Second, I give some historical background (Sect. 21.2). Then, I focus on three of the main questions asked in the literature, namely: What is a thought experiment? (Sect. 21.3), What is the function of thought experiments? (Sect. 21.4), How do thought experiments achieve their function? (Sect. 21.5). These issues will lead to tackle other important points, such as the relationship between real and thought experimentation, the differences between philosophical and scientific thought experimentation, the role played by intuitions and imagination in thought experimentation.

## 21.1 Overview

Thought experiments (TEs) have a rather curious history. Although thought experimentation is as old as philosophy, both the introduction of the term and the philosophical interest in thought experiments as such have a much more recent history. Since the beginning of Western philosophy, many famous thought experiments have been proposed and discussed, including *Plato's* ring of Gyges [21.1, 358a–360d], *Hilary Putnam's* brain in the vat [21.2], *John Locke's* inverted spectrum [21.3, II, Ch. 32, §15], *Galileo Galilei's* thought experiment on free-fall [21.4], *Étienne Bonnot de Condillac's* statue [21.5], *Immanuel Kant's* on handedness [21.6], *Charles Darwin's* thought experiment on the evolution of the eye [21.7], *Henri Poincaré's* disk world [21.8], *Albert Einstein's* lift [21.9], *Werner Heisenberg's*  $\gamma$ -ray microscope [21.10], *Tyler Burge's* arthritis [21.11], and *John Searle's* Chinese room [21.12]. These examples are only a sample of a vast production that spans a huge amount of time and issues (for other surveys and in-depth analyses see contributions in *Horowitz and Massey* [21.13]; *Casati et al.* [21.14]; *Ierodiakonou and Roux* [21.15]; *Frappier et al.* [21.16], and in the special issues of *Philosophica* – 72, 2003 – and that of *Perspectives on Science* – 2/22, 2014). But what is a thought experiment? After a brief historical introduction (Sect. 21.2), this chapter focuses on philosophical answers to this question (Sect. 21.3) and on other issues concerning thought experimentation, namely on the issues about the function of thought experiments (Sect. 21.4) and how thought experiments achieve their function (Sect. 21.5). Before turning to these questions, it is worth having a precise idea of what is under discussion by looking at some concrete examples. The remainder of the section will be devoted to the introduction of six thought experiments that can be seen as a good sample of the most quoted and discussed thought experiments in the literature.

### 21.1.1 Galileo on Falling Bodies

Galileo was a great thought experimenter. Via his thought experiments he forcefully undermined Aristotelian physics. One among them is widely quoted in the literature, namely the thought experiment against the Aristotelian idea that the speed of a body's free fall increases proportionally to its weight. As Galileo put it in his *Discorsi e dimostrazioni matematiche intorno a due nuove scienze* (*Discourses and Mathematical Demonstrations Relating to Two New Sciences*), the supposition that [21.4, p. 62]

“bodies differing in heaviness [*gravità*] are moved in the same medium with unequal speeds, which maintain to one another the same ratio as their weights [*gravità*].”

Galileo thought that this supposition was false and maintained that a heavy cannon ball of 100 or more pounds will not anticipate a half-pound musket ball both dropped from a height of 200 *arms*. In order to make his point, Galileo put forward a thought experiment and observed that the Aristotelian idea leads to a contradiction. His thought experiment runs as follows (Fig. 21.1).

Imagine two bodies (e.g., stones) that have unequal weights, and so speeds (e.g., the heavy stone falls with a rate of 8 and the light stone with a rate of 4). Suppose that these bodies are linked together (e.g., with a weightless chain) and, then, that one drops them from a certain height (e.g., the top of the Tower of Pisa). The Aristotelian thesis would entail that the velocity of the composite body will have: a) an intermediate value between the two, since the lighter body delays the heavier, and b) a higher value than the two, since both bodies are lighter than their union.

Galileo's conclusion is that large and small bodies fall with the same speed [21.4, p. 65]. He stresses that the slight differences we experience are due to external factors, such as the air resistance. Arguably, “in the vacuum their velocities would be completely identical” [21.4, p. 73].

Interestingly, it turns out that this hypothesis holds also for bodies made of different materials, for example, a hammer and a feather, as the well-known recreation of the experiment by Apollo 15 astronaut David Scott

Fig. 21.1 Two bodies falling from the Tower of Pisa

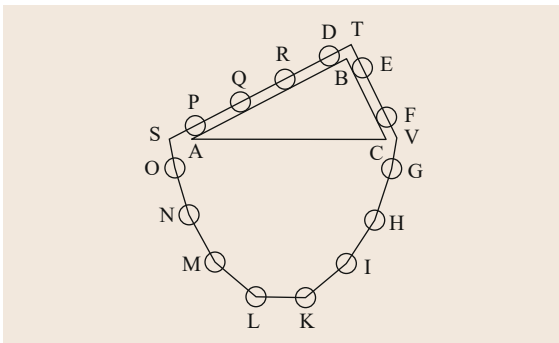

on the Moon showed. An Italian team of scientists has since conducted an atomistic version of Galileo's experiment, in which atoms of different weights fall in the vacuum at the same speed [21.17]. How could Galileo have seen so far using only his imagination?

### 21.1.2 Stevin's Chain Thought Experiment

In *De statica*, the fourth tome of Simon Stevin's *Hypomnemata mathematica*, Stevin was dealing with the force needed to keep an object on an inclined plane from sliding down, and he concluded that the force required is inversely proportional to the length of the plane. In order to demonstrate his result, he proposed the following thought experiment.

Imagine a triangular prism ABC (depicted in section in Fig. 21.2) whose basis (AC) is horizontal and the left side (AB) is twice the length of the right side (BC). A wreath of 14 balls of equal weight and size is draped over the prism, so that four balls are on AB (D, R, Q, P), two on BC (E, F), and the remaining eight beneath the base (G, H, I, K, L, M, N, O). The spheres are linked by a thread passing through their centers, so that they can move, but they must remain equally spaced. Moreover, the sides are frictionless, and S, T, and V are fixed points on which the thread can slide freely.

Stevin claimed that if D, R, Q, and P were not balanced by E and F, one of the two groups of spheres would pull the other. What would happen if this was so? Let us suppose that the block with eight balls (D, R, Q, P, O, N, M, and L) generates more force than the one with six balls (E, F, K, I, H, and G) and D, R, Q, and P slide down the left side. Thus, D will go down where O is and E, F, G, and H will take the place of P, Q, R, and D, while I and K, will take the place of E and

**Fig. 21.2** Stevin's chain: ABC is the section of the prism, whose basis (AC) is horizontal and the left side (AB) is twice the length of the right side (BC). Fourteen balls (D–R) compose the chain draped over the prism. S, T and V are fixed points on which the chain can slide freely

F. Nevertheless, as Stevin remarked, we are now facing the same setup of the beginning and for the same reason the four balls on the left side will slide down the left side and be replaced by other four balls, and so on and so forth. “These spheres will produce by themselves a continuum and eternal motion [*continuum et aeternum motum*], which is false” [21.18, p. 35]. Given the fact that a perpetual motion is absurd, we are led to conclude that the block with eight spheres and the one with six balance each other. Moreover, since the spheres beneath the basis are symmetrically arranged and pull equally in both directions, we can imagine cutting the string at the two lower corners without disturbing the equilibrium. Hence, two spheres (E, F) offset four spheres (D, R, Q, and P). From that Stevin concluded that the force required to keep an object from sliding down on an inclined plane varies inversely with the length of the plane and derived his law of the inclined plane: The ratio of the force to the weight is equal to the ratio of the height to the length of the plane.

### 21.1.3 Newton's Bucket Thought Experiment

When we are sitting in a train and realize that the train on the next platform changes its spatial relationship with our train, without any other external cue we are not immediately able to say which train is *really* moving. However, when a motion changes in speed or direction (i. e., accelerates), it is directly detectable, apparently without reference to any other object. Are accelerated motions a special type of motion or even in such cases is there an implicit contrast between relative and absolute motion? In his *Principia Mathematica* Isaac Newton [21.19] put forward a thought experiment in order to ascertain whether absolute and relative motions differ as regards their effects in the context of accelerated motions, more precisely whether only the former would involve centrifugal force. Let me explain step by step the thought experiment.

Imagine a bucket containing water, which hangs on a rope that is twisted as much as possible, and then released. We can distinguish four phases (Fig. 21.3): (a) both the water and the bucket are stationary, (b) only the bucket begins to move, (c) the water and the bucket are both moving, (d) the bucket stops, but the water keeps moving. According to Newton, the existence of relative motion between the water contained in the bucket and the bucket itself is not able to explain the changes in the surface shape of the water, when the water is rotating. Indeed, in both the first and the third phases, the water and the bucket are stationary relative to one another. Yet while in (a) the water's surface is flat, in (c) it is concave. Likewise, in both the second and the

**Fig. 21.3** Newton's bucket experiment: (a) both the water and the bucket are stationary, (b) only the bucket begins to move, (c) the water and the bucket are both moving, (d) the bucket stops, but the water keeps moving

fourth phases, the bucket is in motion from the point of view of the water and vice versa, but the water's surface is flat in (b) and concave in (d). Moreover, Newton suggests that the same would hold even in infinite empty space, where there is no object external to the device. This last remark gives to the thought experiment its unperformable flavor. In fact, although in the literature the bucket experiment has been mostly discussed as a thought experiment, Newton affirmed to have done it (clearly not in the empty space!).

According to the standard interpretation of the bucket experiment (be it a real or a thought experiment), the Newtonian theory could explain the phenomenon: Absolute space is what discriminates between absolute and relative motions, that is, between real and illusory motions. Absolute space would be the system with respect to which it is possible to understand that in the first and in the second phase the water surface is flat, because the water does not *really* move, whereas it does in the third and the fourth phases, thus climbing the bucket's wall.

#### 21.1.4 Gettier's Thought Experiment

In his article, *Is Justified True Belief Knowledge?*, Edmund Gettier [21.20] seriously undermined the classic definition of knowledge via thought experimentation. Almost from Plato to 1963, knowledge was considered

true and justified belief. A subject (S) knows the content of a proposition ( $p$ ) if and only if: (a)  $p$  is true, (b) S believes that  $p$ , and (c) S is justified in believing that  $p$ . Via his thought experiments Gettier pointed out how a justification may be flawed, thus implying that we can have true and justified beliefs that seem not to be states of knowledge (it should be noted that Bertrand Russell, in his *Human Knowledge: Its Scope and Its Limits*, anticipated this kind of example; see [21.21, pp. 170–171]). Many attempts have been made in order to account for Gettier's insight. Although none of these has been widely accepted, the overall debate has helped to clarify the concepts of knowledge and justification. Here is one of Gettier's original examples: Suppose that Smith has applied for a job, as well as Jones. Actually, the person in charge of hiring tells Smith that Jones will get the job. Moreover, Smith has just counted the number of coins in Jones' pocket, which is ten. Having such strong evidence, Smith believes that Jones is the man who will get the job and Jones has 10 coins in his pocket. Suppose that Smith infers from his belief another belief, namely the belief that the man who will get the job has 10 coins in his pocket. The same evidence grounds both beliefs.

But imagine that Smith gets the job, not Jones, and that by sheer chance, Smith unknowingly has 10 coins in his pocket. Although his belief that the man who will get the job has 10 coins in his pocket is both justified and true, Smith does not appear to know that the man who will get the job has 10 coins in his pocket.

After Gettier's original examples, a variety of cases à la Gettier have been proposed. A quite popular Gettier case is worth mentioning, namely the cow in the field problem [21.22]. Briefly, this example sets up an imaginary scenario in which a farmer is worried about his cow Daisy and gets relaxed when he sees her black and white shape in the field. It happens that Daisy was safely in the field, but hidden in a hollow. What the farmer mistook for his cow was a large sheet of black and white paper. Like Smith, the farmer has a justified, true belief which seems not straightforwardly to count as knowledge.

#### 21.1.5 Twin Earth

Among philosophers, a famous thought experiment is that of Twin Earth. Putnam [21.23, 24] proposed a thought experiment in order to show that psychological states conceived in a narrow (i. e., intensional) sense do not determine the references (i. e., extensions) of natural kind terms.

Suppose that somewhere in the Universe there is Twin Earth, which is a planet exactly like Earth, with

the exception that the chemical composition of what is called *water* on Twin Earth is not  $H_2O$ , but a very long and complicated formula that can be abbreviated as *XYZ*. Nevertheless, water and twin water (i. e., what is called *water* on Twin Earth) have the same visual appearance, flavor, odor, etc. Thus, if Earthlings ever visit Twin Earth, at first they will believe that the term *water* has the same meaning on both planets. But they will suitably revise their belief after discovering that *water* on Twin Earth refers to *XYZ*. And it would be the same for Twin Earthlings, if they ever visited Earth and discovered that *water* on Earth refers to  $H_2O$ .

Oscar-te is the Doppelgänger on Twin Earth of Oscar, a typical inhabitant of Earth, and we can suppose that both persons are perfect duplicates. Going back to 1750 (about 50 years before the discovery of the chemical composition of water on Earth and, by hypothesis, also of what is called *water* on Twin Earth), neither Oscar, nor Oscar-te had beliefs about the chemical elements of what they call *water*. Yet the term *water* referred to  $H_2O$  on Earth and to *XYZ* on Twin Earth, respectively, in 1750 as much as nowadays (i. e., the extension of the term did not change). Although by hypothesis Oscar and Oscar-te had all the same beliefs, and enjoyed the exact same psychological states with respect to the word *water*, they did not mean the same thing by *water*, because each use referred to a different substance. Therefore, Putnam argues that meanings of words are not in our heads.

## 21.2 Historical Background

Schematically, it is possible to divide the long debate on thought experiments into two phases, which we could call *classical* and *contemporary* (see [21.27] for a more fine-grained division in four stages). Thomas S. Kuhn, in his 1964 paper, *A Function for Thought Experiments*, marks the division between the two phases. Kuhn has the merit of having highlighted an epistemological problem hitherto underestimated. His essay opened a new way of viewing thought experiments as puzzles, by asking: How might a mere thought experiment yield new knowledge, without the input of new data? It should be noted that Kuhn's paper is mostly known in its 1977 version. This is the reason why some of his contemporaries (e.g., Carl Hempel) can be considered as belonging to the classical phase, even if their writings are posterior to Kuhn's essay.

The contemporary phase can, therefore, be separated quite sharply from the classical phase along two criteria:

1. A greater awareness of the problematic aspect of thought experiments tied to their epistemic function

### 21.1.6 Mary the Super-Scientist

Frank Jackson [21.25] proposed a famous thought experiment (also known as the knowledge argument) aimed at showing that physicalism (i. e., the view that everything can be physically explained) cannot account for our knowledge about what it feels like to be in a certain mental state. The thought experiment runs as follows.

Suppose that Mary is a brilliant neuroscientist who knows all physical facts about chromatic vision. For instance, she knows precisely which combinations of wavelengths from a tomato stimulate the retina, and “exactly how this produces via the central nervous system the contraction of the vocal chords and expulsion of air from the lungs” [21.25, p. 130], which results in the utterance of the judgment *the tomato is red*. Although she possesses all physical information concerning what happens when, for example, we see the redness of a tomato and use terms like *red*, she has never had the experience of seeing any color, because she has spent all her life in a black and white room. Now imagine that Mary could see a tomato, because either she is released from her room or provided with a color television monitor. Would she learn something or not? The intuitive answer seems to be *yes*. But does she really learn a new fact? These questions have sparked a lively debate [21.26], which led Jackson himself to revise his position and claim that, after all, Mary is not discovering a new fact, but rather a new way to represent it.

2. The extension of the analysis to thought experiments outside the realm of science (mainly physics), in particular to philosophical thought experimentation.

In this section, I shall review the most important steps of the history of thought experimentation. I begin with the origin of the term (Sect. 21.2.1). Then I briefly describe the two historical phases and finally introduce the main actors of each phase (Sect. 21.2.2 and Sect. 21.2.3, respectively).

#### 21.2.1 The Rise of the Term

At the end of the nineteenth century, the Austrian physicist and philosopher Ernst Mach wrote a paper entitled *Über Gedankenexperimente* [21.28], which popularized the German term *Gedankenexperiment* (thought experiment) and sparked a methodological debate on thought experiments, specifically in the scientific domain – physics in particular.

However, the authorship of the German term goes to the Danish physicist *Hans Ørsted* [21.29] and, perhaps, even before him to the German physicist and aphorist Georg Christoph Lichtenberg, who wrote about experimenting with thoughts [21.30, 31]. Actually, the very starting point of the philosophical interest about thought experimenting can be found in Immanuel Kant's philosophy [21.31], which is explicitly present in Ørsted's work [21.32], but also inspired Lichtenberg and many other philosophers [21.33].

Despite the controversy about who coined the term (on the topic see, for example, [21.31–37]), what is striking is that thought experimentation has a much older history – in philosophy, as well as in natural sciences. According to Nicholas Rescher, Pre-Socratics “invented thought-experimentation as a cognitive procedure and [...] practiced it with great dedication and versatility” ([21.38, p. 31] – see also [21.39, 40], for a critique of Rescher's view; on the topic of ancient thought experiment; see [21.41] and several contributions in [21.15]). Likewise, *Imre Lakatos* [21.42] located in Ancient Greece the beginning of thought experimentation, specifically in formal Euclidean mathematics [21.43]. Afterward the practice of thought experimentation continued (see [21.44–46] for discussions on thought experiments during Middle Ages) and flourished, mainly thanks to exceptional thought experimenters, such as Galileo, René Descartes, Locke, Newton and Gottfried Leibniz (on thought experimentation between Middle Ages and the introduction of the term, see contributions in *Horowitz and Massey* [21.13], *Casati et al.* [21.14], and *Ierodiakonou and Roux* [21.15]; on historical perspectives about Galileo's thought experimentation, see also *Prudovsky* [21.47], *Atkinson and Peijnenburg* [21.48], and *Palmieri* [21.49]).

### 21.2.2 The Classical Phase

In the classical phase, the first reflections on thought experiments are due to Lichtenberg and Ørsted (also Novalis, according to *Daiber* [21.50] and *Fehige* [21.51]; see also *Fehige* and *Stuart* [21.33] for an in-depth discussion of Lichtenberg's, Novalis', and Kant's analyses of thought experimentation). It is worth noting that former analyses mainly focused on thought experimentation in the scientific domain. Curiously, though, milestone scientific thought experiments in the history of physics, such as Galileo's on free-fall (Sect. 21.1.1) or Newton's bucket (Sect. 21.1.3), are rarely mentioned. Ørsted, for instance, mainly addresses thought experimentation in geometry and, when it comes to physics, only Kant's philosophy is mentioned.

One might resist counting Mach among the *classical* authors, given his systematic analysis of thought ex-

perimentation, which seems to go beyond the scientific domain. Indeed, when he lists thought experimenters, he speaks of dreamers and novelists – whilst not of philosophers [21.28, p. 451 of the 1973 English translation]). He also wrote that “Experimenting in thought is extremely important for cognitive development” and that “the thought experiment not only is of importance in the field of physics, but on the contrary, in all fields of knowledge” [21.28, pp. 455–456]. Still he analyses only thought experiments in physics and mathematics.

Moreover, in Mach's work we can find two traits typical of the classical phase: (i) it is not always clear how to distinguish between genuine thought experimenting and merely imagining about real experiments (REs) [21.52, p. 74]; and (ii) Mach does not worry about the distinct sphere of autonomy of thought experiments as such, and eventually he brings back the latter to real experiments. This is not intended to underestimate in any way the great significance played by Mach's analysis of thought experiments on the subsequent debate. Indeed, credit is due to his examination of the features proper to thought experiments (as well as to real experiments) and inquiry on how they function, even from a psychological point of view (Sect. 21.5).

*Alexius Meinong* first noticed the quite broad notion of thought experiment introduced by Mach. In his discussion of thought experiment [21.53], he addresses the distinction between experiments carried out *on* thoughts (i. e., psychological experiments based on the subjects' thoughts) and *within* thought (e. g., mathematical thought experiments). But he himself did not acknowledge that thought experiments should also be differentiated from imaginings about real experiments. The same can be said about another stakeholder of this stage, namely Pierre Duhem.

Scepticism about the epistemic value of thought experiments is common to Meinong and *Duhem* [21.54]. Duhem is known to have been a strenuous critic of the idea that thought experiments could play a legitimate role in the development of scientific thinking [21.34, 55, 56]. However, Duhem's thesis is not to reject thought experiments in toto [21.36, 57], but a certain use of them: Thought experiments should not be used as if they were real experiments just in order to conceal hypotheses arisen from pure supposition and abstraction.

Scepticism about thought experimentation is also present in both Karl Popper's and Hempel's inquiries, but it is accompanied by the acknowledgement of the positive uses of thought experiments. Their analyses have led these authors to suggest useful taxonomies of thought experiments [21.58, 59] (see Sect. 21.4.1). By contrast *Alexandre Koyré*, more in line with Lichtenberg, Ørsted and Mach, focused almost exclusively on the positive role played by thought experiments in sci-

entific inquiry (only in an appendix, he considers their misuse – see [21.60]).

### 21.2.3 The Contemporary Phase

In his milestone 1964 paper, *Kuhn* raised three questions that set the subsequent debate on thought experiments:

1. To what extent must the imagined situation be one that can be (or has been) found in nature, that is, what conditions of verisimilitude are thought experiments subject to?
2. How, “relying exclusively upon familiar data, can a thought experiment lead to new knowledge or to new understanding of nature?” [21.61, p. 241].
3. What, if any, kind of knowledge do thought experiments produce?

The authors of the classical phase have analyzed only thought experiments within the scientific domain, physics in particular. Although *Kuhn* is no exception, the many attempts that have been made to answer his questions have extended the enquiry to thought experiments in philosophy.

The contemporary phase is characterized by both a proliferation of works on thought experiments, due to the impact of *Kuhn*'s paper, and a very considerable production of thought experiments. Philosophy was the main protagonist of this new season of thought experimentation. Just to give some examples, between the 1970s and the 1980s: *Judith Thomson* [21.62] questioned on the concept of the right to life and how it differs from the concept of the right to what is needed to sustain life, through a bizarre kidnapping of a violinist by the Society of Music Lovers; *Put-*

*nam* wondered what would happen to the meaning of the word *water* in a twin Earth where what is called *water* has a different chemical composition from H<sub>2</sub>O (Sect. 21.1.5); *Searle* [21.12] attempted to refute the idea that the mind is a suitably programmed computer, by imagining himself in a room that receives and returns input in Chinese; *Derek Parfit* [21.63] *racked his brain* on personal identity and tried to show that the concept of identity is less important than that of survival by imagining a person splitting like an amoeba (for concise but exhaustive descriptions of *Thomson*'s, *Searle*'s and *Parfit*'s thought experiments, see [21.64]). As hinted earlier (Sect. 21.2.1), there have been philosophical thought experiments long before, but much of contemporary philosophy makes heavy use of thought experiments and it would be severely impoverished without them.

However, not all contemporary analyses of thought experiments deal with both scientific and philosophical examples (Sect. 21.4.3). As underlined by *Rachel Cooper*, although many authors have restricted their study to scientific thought experiments, a fine-grained theory of thought experimentation should cover both the sciences and the humanities [21.65–67].

Different answers to *Kuhn*'s questions have emerged in a stream of literature since the 1990s, with two polar positions: *James R. Brown* and *John D. Norton*. “The views of *Brown* and *Norton* represent the extremes of platonic rationalism and classic empiricism, respectively” [21.34, p. 69]. The best way to get into this still flourishing debate is by tackling three of the main issues which the contemporary phase has sought to clarify further: What is a thought experiment? What is the function of thought experiments? How do thought experiments achieve their function?

## 21.3 What Is a Thought Experiment?

The aforementioned examples give an idea of what a thought experiment is, but is it possible to offer a precise and comprehensive definition? The lively debate among contemporary philosophers has not led to a unanimous definition. Indeed, thought experiments are characterized variously as sometimes being arguments [21.68], specific ordered pairs [21.69], glimpses into a Platonic world [21.55, 70–72], experiments whose aim can be achieved without the benefit of execution [21.52], forms of “simulative model-based reasoning” [21.73], icons [21.74], abstract entities that are not particularly experimental, but rather an exploration and a refinement of theoretical models [21.75], guided contemplations [21.76] and pieces of counterfactual reasoning with experiment-like features [21.77].

Thus, it is a hard task to give a clear definition of thought experiment that does not widen the concept so as to make it practically useless. Too broad a definition would capture phenomena that intuitively are not thought experiments [21.78]. It has been claimed that we do not need a definition after all [21.55, 79]. *Geordie McComb* [21.80] suggests to see thought experiment as a cluster concept.

At a closer look, we can impose some order into the spectrum of definitions, which ranges from definitions that classify thought experiments as belonging to the theoretical realm, to those placing thought experiments within the experimental realm. In this section, I shall, first, review what has been said about the experimental side of thought experimentation (Sect. 21.3.1)

and, then, turn to the opposite end, namely the arguments given in favor of the theoretical nature of thought experimentation (Sect. 21.3.2). Finally, I shall dwell on the main features that should make thought experiments easily identifiable (Sect. 21.3.3).

### 21.3.1 Thought Experiments and the Experimental Realm

The issue about the relationship between thought and real experiments is a much discussed topic in the debate. The trend, as shown in Table 21.1, has been to underline a continuity between thought experiments and real experiments.

However, very often the experimental side of thought experimentation has not been evaluated per se: Thought experiments have been judged from the standards of real experiments, rather than on the basis of a broad definition of experiment that can include both types of experimentation. According to many scholars, thought experiments are not kinds of experiment, but tend to proceed as if they were.

The analysis of the experimental side of thought experiments seems to be influenced by a widespread

**Table 21.1** Simplified overview of some of the positions in the debate on the continuity or discontinuity between TE and RE. Strong continuists are authors who explicitly and extensively talk about the common features between the two types of experimentations. Even though Paul Humphreys admits a parallelism between thought and real experiments, he is considered as a strong discontinuist, because he sharply distinguishes between the theoretical realm of the former and the empirical realm of the latter [21.75, pp. 218–219]. In italics are highlighted philosophers who can be classified in the classical phase of the analysis of thought experiments. More will be said in the following about both Duhem and Marco Buzzoni

Status	Degree	
	Weak	Strong
Continuity between TE and RE	<i>Ørsted</i> [21.29] <i>Popper</i> [21.58] <i>Hempel</i> [21.59] Kuhn [21.61] Brown [21.55, 70] Szabó Gendler [21.81] Bokulich [21.56] Peijnenburg and Atkinson [21.79] Buzzoni [21.57] Brendel [21.82]	<i>Mach</i> [21.28, 83] <i>Koyré</i> [21.60] Sorensen [21.52] Nersessian [21.84] Gooding [21.85] Häggqvist [21.86] Wilkes [21.87] Bishop [21.88] Cohen [21.64]
Discontinuity between TE and RE	<i>Duhem</i> [21.54]	Hull [21.89, 90] Norton [21.68] Humphreys [21.75] Hacking [21.74]

preconception about the intrinsic epistemological superiority of real experiments. By following this preconception, we risk focusing on the features proper to *true* experiments (i. e., real experiments) that thought experiments lack. For instance, a typical plea for real experimentation would stress that, insofar as thought experimentation does not directly examine nature, it is less reliable and lacks justificatory power (Sect. 21.4.3). The upshot of this line of reasoning is that thought experiments should be employed only when real experiments are not available, otherwise they are useless.

Following *Roy Sorensen* [21.52], we might say that the problem is rooted in how the adjective *thought* should be interpreted in the expression *thought experiment*. A terminological attitude that can fall prey to the aforementioned preconception is to consider thought experiments as mere imaginary visualizations of experiments. In the works of many philosophers (particularly belonging to the classical phase), the expression *imaginary experiment* is frequently used as a synonym for thought experiment. However, substituting *thought* with *imaginary* can be misleading (see also *Krimsky* [21.91], who claims that all imaginary experiments are thought experiments but not vice versa, and *Wilkes* [21.87]). The imaginary unit and the imaginary number for mathematicians, as well as the social imaginary and the child imaginary for psychologists, are not degraded entities. Still *imaginary* is commonly used as an adjective that falsifies or somehow discredits the phenomenon to which it refers. An imaginary friend, imaginary worlds, imaginary fears and beliefs are understood as fictional entities. The emphasis is on the negative aspects, on what they lack in order to be real friends, worlds, fears or beliefs.

It is no coincidence that Duhem called thought experiments *expériences fictives* (fictitious experiments), given his harsh critique of thought experiments used as if they were real experiments. Similarly, albeit not motivated by the same causticity, Hempel spoke of imaginative experiments and seemed to complain about the fact that thought experiments tend to be merely heuristic, instead of providing purported evidence to be further validated. Hempel had been influenced, more or less explicitly, by the neo-positivist distinction between *context of discovery* and *context of justification* [21.55, p. 89]; for the relevant distinction, see *Hans Reichenbach* [21.92]). Contrary to real experimentation, thought experimentation would be confined to the domain of discovery, that is, the processes through which a hypothesis has been formulated, rather than how such hypothesis could be controlled and confirmed. The dichotomy between the context of discovery and that of justification seems to have influenced much of the analysis on thought exper-

iments belonging to the classical phase, but also some reflections of the contemporary phase, such as that of Norton (according to *Brown* [21.55]) and of David Hull (Sect. 21.4.3).

In his *Plea for real examples* [21.89, 90], Hull puts forward a critique of thought experimentation even harsher than that of Duhem. As suggested before (Sect. 21.2.2), Duhem's criticism should not be seen as a total rejection of thought experimentation. Although Duhem is commonly presented in the literature as a detractor of the role of thought experiments in scientific practice (thus, as a discontinuist – see Table 21.1), his remarks should lead us to re-evaluate (but not dismiss) thought experimentation (also suggested in *Daly* [21.93, p. 114]). He criticized a naive view of real experimentation and put forward very innovative ideas about it (e.g., real experiments are not a matter of mere observation without theory; they are subject to underdetermination in the choice of a theory, that is, they cannot test isolated hypotheses). Duhem focused his attention on the negative aspects of thought experimentation that convey such a naive view without realizing that thought experimentation itself can be seen in a less simplistic way and be subject to the same conceptual revision he was advancing for real experimentation. Most likely Duhem is a continuist, who undermined a naive view of experimentation as a whole, including thought experimentation.

Hull is more likely to be considered as a discontinuist. According to him, thought experiments are mostly useless, and real experiments should be preferred to them (on real examples that go beyond our imaginative ability; see [21.89, p. 312] and [21.90, p. 435]; on Hull's view see also Sect. 21.4.3). In fact, Hull seems to admit that thought experiments can have scientific value, but only if they involve an imaginary situation which is as plausible and detailed as possible (on the importance of a detailed scenario see also *Brendel* [21.82] and *Häggqvist* [21.86], which ties with issues discussed in Sects. 21.3.3 and 21.4.3). Moreover, he seems to take for granted that thought experiments must become, sooner or later, real experiments (on the issue about whether real experiments can resolve thought experiments, see *Arthur* [21.94]; Sect. 21.3.3). However, *Hull* is not willing to concede that thought experiments can be of value in all scientific fields, but only for those which are “well-articulated” ([21.90, p. 431], where he quotes other detractors of thought experimentation such as *Wilkes* [21.87], and *Fodor* [21.95]; other sceptics are in line with Hull's view – for example, *Feyerabend* [21.96], *Quine* [21.97] and *Thagard* [21.98, 99]). For example, he argues that in biology thought experiments cannot play any role; rather they risk to create only confusion (for a critique of this position,

see [21.100]; for an analysis of thought experiments in biology, see [21.101, 102]; see also [21.103], for a discussion on artificial life and thought experimentation in biology, and [21.104], for a recent discussion on the relationship between real and thought experimentation in biology).

Recalling what was said earlier with respect to how adjectives can transform the value of the name they modify, it is interesting to notice that Hull mostly calls thought experiments *fictitious examples*, but when he emphasizes their positive aspect, he employs the expression *hypothetical examples*. *Hypothetical* does not convey a negative value as *imaginary* does. Still it is more cautious than *thought*. For example, a hypothetical buyer is not really a buyer, she may become a buyer, but at that point she will be a *real* buyer and not anymore hypothetical. Thus, Hull's view on thought experiments is nicely exemplified by his use of the adjective *hypothetical* as a synonym for *thought*.

It should be noted that positive continuist views also oversimplify thought experimentation when they anchor it to real experimentation. For instance, it has been stressed that Mach talks about thought experiments as if they always lose to real experiments [21.52, p. 74]. *Mach* acknowledged that the outcome of some thought experiments, such as Galileo's thought experiment on falling bodies (Sect. 21.1.1), is strictly determined, so that the thought experimenter is led to consider superfluous “any further test by means of a physical experiment, whether rightly or wrongly” [21.28, p. 452]. However, he seems to complain about thought experimenters that avoid further real experimentation and take the result of thought experiments as conclusive. In this regard, Mach's critique of Newton's bucket thought experiment (Sect. 21.1.3) is a good example. According to Mach, Newton violated his rule of *hypotheses non fingere* (to feign no hypotheses), since he used the bucket thought experiment in order to show what was actually presupposed by the thought experiment itself (i. e., the existence of absolute space).

Similarly, even *Koyré's* analysis [21.60] might seem driven by considering real experimentation as the benchmark: Thought experiments are positive, since they accentuate positive features of real experiments. In this respect, *Koyré's* and *Duhem's* approaches can even be seen as complementary, more than opposed.

More recent views have tried to investigate thought experimentation as a genuine experimental practice on a par with real experimentation. At least two analyses are worth mentioning. *Sorensen* argues that thought experiments are a limiting case of real experiments. Both types of experimentation have very similar purposes and also share methods for assessing such purposes (Sect. 21.3.3 and 21.4). Clearly, they differ insofar as

thought experimentation emphasizes the design aspect at the expense of the execution aspect (other scholars have followed Sorensen on this point – for example [21.82, 85, 105]). Sorensen goes further and argues that, although historically thought experiments have become autonomous, their origin has to be individuated in the mental component of real experimentation. They should be seen as the result of an evolutionary process: a “selective pressure” would have deprived real experimentation of the execution aspect, emphasizing the design aspect ([21.52, pp. 186 and 212], [21.106] for a critique of Sorensen’s evolutionary explanation; on Sorensen’s view, see also contributions in the special issue of *Informal Logic* [21.107–110]).

Marco Buzzoni argues that Sorensen underestimates “the technological-operational dimension of the scientific experiment” and supports a concept of real experiment as a mathematical function ([21.57, p. 175]; see also [21.36]). Buzzoni [21.36, 57, 111] develops a Kantian framework according to which from an empirical point of view (i. e., exactly with respect to the *technological–operational* dimension) real and thought experimentations coincide, but they are complementary from a transcendental point of view. Thus, one type of experimentation without the other is unproductive for scientific purposes (see [21.112, 113] for objections to Buzzoni’s account and Buzzoni’s reply in [21.114]). Many other scholars have underlined that thought experimentation shows an action-practical component (e.g., [21.85, 101]; see Sect. 21.3.2 and 21.5). Moreover, this component has been adduced as one of the main arguments against views that confine thought experiments into the theoretical realm.

### 21.3.2 Thought Experiments and the Theoretical Realm

Instead of considering thought experiments either as rough copies of real experiments or as peculiar experiments, it might be claimed that they do not belong at all to the experimental realm. There are two major proponents of this point of view: Norton and Humphreys (Ian Hacking’s view might also belong to this interpretative current, since he sharply distinguishes thought from real experiments and considers the former as *static* entities. However, he seems to concede that the embodiment aspect is important for thought experimentation [21.74]; Sect. 21.5).

Norton argues that thought experimentation cannot be a type of experimentation, because it lacks the essential element proper to the latter, namely interaction with the natural world [21.115]. According to Norton,

thought experiments are disguised arguments [21.68, 115–117]: a good thought experiment should be a sound argument that increases our knowledge. In other words, without epistemic loss a thought experiment can be reconstructed (translated, or reduced) into an argument – i. e., a list of propositions, of premises and assumptions, leading to a conclusion via (inductive or deductive) inferences. Thought experiments are often rhetorically embellished and frequently they do not make explicit all the assumptions on which they rely: these features conceal their argumentative nature. Along with this *reconstruction thesis*, Norton suggests an *elimination thesis*: Thought experimentation is a dispensable epistemic tool (see Gendler Szabó [21.76, 118] for a fine-grained analysis of Norton’s elimination thesis; see also Timothy Williamson’s view [21.119] – which seems in line with Norton’s view, except for the role granted to imagination – Sect. 21.5).

Humphreys claims that thought experiments “lie much closer to theory than to the world” [21.75, p. 218]. He admits that they can be assimilated to that type of real experiments that isolate “those features of the world that are represented in a theoretical model” and approximate “the idealizations that are employed therein” [21.75, p. 218]. But nowadays, according to him, this function is fulfilled by theories. In support of his argument, he compares thought experiments to computer simulations (or numerical experiments). Both methods involve refinements of theories, adjustments to conform conditions, parameters, approximations and idealizations to empirical data, and can deliberately alter parameters in order to produce laws different from those of our world.

Actually, the parallelism between thought and numerical experiments can show that the issue of the experimental nature of thought experiments is still open. Indeed, a lively debate among philosophers of science on the status of computer simulations has led to considerations very similar to those discussed earlier (Sect. 21.3.1) about thought experiments. For instance, some (e.g., [21.120]) argue that real experiments and numerical experiments could not possibly differ from each other more and that the latter can be seen as arguments [21.121]; while others regard numerical experiments as a genuine experimental practice (e.g., [21.122, 123]), whose analysis has been often influenced by a bias for real experiments [21.124, 125].

Several parallelisms between thought experiments and numerical experiments can be drawn and a comparative analysis can shed light on both topics at once. Even though some authors have suggested that numerical experiments can be seen as type of thought experiments ([21.126]; see also [21.103], for a specific

biological case, and [21.127], for a provocative view according to which computer modeling will replace thought experimentation), the *trading zone* between thought experiments and numerical experiments has been sparsely considered by current works on either thought or numerical experiments. These works have primarily focused their attention on the links between these two scientific tools and real experiments (in-depth analysis can be found in [21.128–131]; in passing other authors have commented on the parallelism between thought experimentation and numerical experimentation – for example, [21.36, 43, 52, 57, 64, 65, 73, 101, 132]; see also the related topic of video games as executable thought experiments [21.133]).

Much criticism has been raised against theoretical views about thought experimentation, especially against Norton’s argument view. Although some have found the latter too liberal (e.g., [21.134]), most philosophers have found it too restrictive and have offered four main objections. First, Norton’s translation of thought experiments into arguments would lose some important aspects proper to thought experimentation (e.g., [21.71–73, 82, 101, 135–138]), such as its nonpropositional dimension or an action-practical component. These aspects should not be neglected, for they play an epistemic role, rather than being merely picturesque. *Tamar Gendler Szabó* [21.76, 118], for instance, maintains that Galileo’s thought experiments on falling bodies (Sect. 21.1.1) cannot be fully reconstructed into arguments (see also [21.71, 72, 139] for other examples; see [21.140] for a reconstruction of Galileo’s thought experiment within a nonclassical logical framework). It has been pointed out that the same holds for thought experiments that rely heavily on sensory imagination or spatial reasoning (e.g., [21.65]).

A second related objection concerns the cognitive underpinnings of thought experimentation. The same conclusions can be drawn from a thought experiment and from a logical argument, but constructing and performing the former are different from producing and carrying out the latter. This is so even if we take for granted that all thought experiments are translatable into arguments and that such a translation procedure is epistemically advantageous (Sect. 21.5).

Third, it has been pointed out that thought experiments may feature in the argumentation steps, but this does not mean that they are arguments. Likewise for real experiments. Real experiments can play a role in or be rephrased as arguments, but typically they are not considered as arguments and it is unlikely that someone would claim that they are dispensable. We should not confuse an experiment of whatever kind with its published description [21.86, 101].

Finally, *Michael Bishop* ([21.88]; see also [21.141]) has offered a counterexample to Norton’s view: The same thought experiment can be reconstructed in two different arguments. Often this is the case when scholars disagree about the upshot of a thought experiment; otherwise it would be impossible to compare their views and determine who is right. The main example given by Bishop is the debate between Einstein and Niels Bohr on an Einsteinian thought experiment, namely the clock-in-the-box thought experiment (see the volume dedicated to Einstein of *The Library of Living Philosophers*, edited by Arthur Schlipp, for a complete description of this thought experiment and also for Bohr’s objections and Einstein’s reply [21.142]).

Nevertheless, one might think that Norton’s argumentative reconstruction thesis is valuable, while maintaining that thought experiments are not arguments and/or rejecting the elimination thesis. Once translated into arguments, thought experiments can make explicit their implicit assumptions. As pointed out by *Richard Arthur*, “the reformulation of thought experiments as arguments is a vital part of the scientific process” ([21.136, p. 228]; see also [21.101]; see [21.143] for a proposal which takes into account both the experimental and the argumentative sides of thought experimentation).

### 21.3.3 Thought Experiments and Their Features

Despite the fact that there is not a unanimous definition of thought experiment and different views push thought experimentation toward either the empirical or the theoretical realms, there are some features common to most thought experiments. It should be noted that, although discussions about these features often lead to draw several parallelisms between thought and real experimentations, they are not committed to the experimental nature of thought experimentation. After all it might be profitable to study thought experiments as if they were experiments, even if they are not [21.52, 132].

In what follows I shall focus, on three features common to both thought and real experimentation:

1. *The method of variation* (i. e., isolation of variables, *manipulation* and *observation*)
2. Fallibility and
3. Theoretical underdetermination.

I shall then turn to the main feature proper to thought experimentation only (i. e., the mental nature of its laboratory) and some connected features.

### The Method of Variation, Fallibility, and Theoretical Underdetermination

Mach [21.28] maintained that the leading principles of real experimentation must hold for thought experimentation as well. According to Mach, the experimental practice in toto is based on the *method of variation*. He wrote that [21.28, p. 452]

“It can be seen that the basic method of the thought experiment is just like that of a physical experiment, namely, the method of variation. By varying circumstances (continuously, if possible) the range of validity of an idea (expectation) related to these circumstances is increased.”

Many philosophers agree with Mach and have stressed that the method of variation is a core feature of thought experimentation [21.36, 57, 75, 82, 86, 87, 132]. It has been pointed out that such a method is common also to numerical experimentation [21.128].

The method of variation can be seen as a three-step procedure describing what in general a thought experimenter has to do: (i) select and isolate the features which act as variables, (ii) *manipulate* these variables, that is, make them interact, and (iii) finally observe what consequently happens.

The first step leads to the question: *what are the variables involved?* Here answers diverge, since they are hostage to the held view about the nature of thought experimentation (Sects. 21.3.1 and 21.3.2). Can thought experimentation examine nature or does it merely explore theoretical models? Anyway, it seems that thought experimentation deals more with abstract representations [21.128] or suppositions ([21.52]; see also Goffi and Roux [21.144], who speak of beliefs) than natural circumstances and concrete entities.

As far as the second step is concerned, one might be uneasy with the fact that in thought experimentation an experimenter is not literally *manipulating* the variables in question. Despite philology, however, manipulating is not merely influencing manually. Things can be rotated and moved also in our imagination. Expert chess players or Rubik’s Cube solvers do perform such kind of mental manipulation [21.52, 145]. This consideration leads us to the third step of the method of variation, namely the observation of the interactions among the variables ([21.64, 73, 85, 146–148] have particularly stressed both (ii) and (iii)).

Observation or visualization has seemed to many a necessary condition of thought experimentation, as well as of real experimentation [21.36, 57, 71, 72, 85, 147, 149, 150]. The problem is that it is not clear whether observation means the same thing in both contexts. In thought experimentation, observation seems

not to be grounded in perceptual experiences as in real experimentation. Often enough authors speaking of observation in thought experimentation seem to refer to a representation of the described situation in the mind’s eye and to imagination as a vehicle for quasi-observation [21.64, 90, 103, 145, 150]. Making observations, however, can be interpreted in a less perceptual sense. John Gilbert and Miriam Reiner [21.148], for instance, take thought experimental observations as outcomes produced by logical laws, without denying that in a thought experiment a world containing objects is imagined (this issue relates to that of the underpinnings of thought experimentation, see Sect. 21.5).

Other features of thought experimentation have been pointed out. Two of them are worth mentioning, which are still common to thought and real experimentation, namely fallibility and theoretical underdetermination.

Like real experiments, thought experiments can fail. Alan Janis [21.151] has underlined three different ways in which real and thought experimentation may fail. First, an experiment can fail because of its incompleteness, due to inadequacy of the equipment, or to external factors (see also [21.64, 65]). It is difficult to give examples of this category, because usually they are not published. Second, an experiment can fail when its results are incorrect (e.g., Einstein’s clock-in-the-box, according to Janis). Third, an experiment can yield correct results, but ones that elude the question which motivated the experiment in the first place (Janis gives as example the Einstein–Podolsky–Rosen (EPR) thought experiment – see next paragraph). Arguably, thought experimenters, similarly to real experimenters, need to engage in error management in order to improve their results (e.g., the thought experimental debate between Einstein and Bohr, as well as that between Darwin and Fleeming Jenkin – as for the latter, see [21.100, 101]).

Alisa Bokulich [21.56] has suggested that thought experiments can show theoretical underdetermination in that they cannot discriminate between different theoretical frameworks (see also [21.86, particularly ch. 6], [21.152] and [21.153]). EPR, a thought experiment by Einstein et al. [21.154], is an example of a thought experiment that can be *rethought* from the perspective of different and incompatible theories [21.56, p. 299]. Sidestepping the technical details of such thought experiment, what is important to keep in mind is that its upshot is a *dangerous* correlation between two physical quantities (position and momentum), which would undermine quantum mechanics (QM) (in its Copenhagen version). Commonly EPR has been interpreted as a failed demonstration of the incompleteness of QM and as an argument in embryo form for a determinis-

tic completion of QM, which is indeterministic. Indeed, precisely on the basis of EPR, David Bohm developed the most famous deterministic version of QM. However, per se EPR is not a crucial thought experiment that can help us to decide between QM and its deterministic rivals (EPR is widely discussed in the literature on thought experiments – for example, see the debate between *Atkinson*, [21.155], and *Stöltzner*, [21.43]). This feature of thought experiments undermines the idea that they do not have a life of their own [21.74], that is the ability to evolve and be adapted to different theories and ends (also philosophical thought experiments seem to have a life of their own – for example, see *Twin Earth* chronicles in [21.156]).

### The Laboratory of the Mind

The most striking feature of thought experiments is that they are conducted in the “laboratory of the mind” [21.55, 70]. Thought experimentation seems to be grounded in imagination (Sect. 21.5). The fact that we can *experiment* within our mind has its advantages. As remarked by *Mach*, “Our own ideas are more easily and readily at our disposal than physical facts. We experiment with thought, so to say, at little expense” ([21.28, p. 452]; see also [21.52] for a discussion of the advantages of thought experimentation over real experimentation). However, the fact that thought experiments are not in direct contact with natural phenomena and are merely a product of our imagination has its shortcomings (Sects. 21.3.1 and 21.4.3).

Two other features are tied to the mental nature of thought experimentation. First, thought experimentation seems not able to give quantitative outcomes, since it does not involve instrumental apparatus. However, at least scientific thought experiments can give quantitative results (e.g., Ronald Fisher’s thought experiments that explained the influence of natural selection on sex ratio – [21.52, p. 250]; Sect. 21.4.3). Still, the outcomes of real experimentation seem to be fixed and possible to be determined in a way that the outcomes of thought experimentation cannot ([21.157]; see also [21.52, p. 247], on the unavoidable incompleteness of thought experimentation, which ties with the issue about philosophical thought experimentation heavily relying on unclear background assumptions – Sect. 21.4.3).

Second, it has been argued that a genuine thought experiment should not require a concrete implementation, which can even be impossible for practical or ethical–political reasons. *Sorensen* [21.52], for instance, conceives thought experiments as experiments in which the design aspect is accentuated at the expense of the execution aspect (Sect. 21.3.1). Furthermore, he has identified three reasons (impossibility, unimprovableness, unaffordability) that explain why thought experiments need not to be concretely performed (see the previous discussions on this issue in [21.54, 83]). *Sorensen*’s view can be summed up by means of a spectrum: There would be nonimplementation, on one extreme, due to the maximization of benefits and, on the other, due to containment of losses.

To put it in another way, even when possible, a real performance of a thought experiment would be irrelevant to the purpose of the thought experiment [21.72]. This does not mean that thought experimentation cannot lead to real experimentation. Arguably, a thought experiment can open new lines of inquiry, which can be explored by means of real experiments. Still the resulting real experiment should not be seen as the realization of the initial thought experiment.

Some authors disagree and claim that, at least some, thought experiments can be concretely implemented and that, more generally, thought experimentation should be resolved into real experimentation [21.78, 79, 89, 90, 155, 158]. A classical example given in favor of this view is *Alan Aspect* and colleagues’ real experiments, whose results have been published in a paper titled *Experimental Realization of Einstein–Podolsky–Rosen–Bohm Gedanken Experiment: A New Violation of Bell’s Inequality* [21.159]. However it is possible to contend this interpretation of EPR. Despite part of the title of Aspect and colleagues’ paper, the real experiment they conducted can be considered as an empirical test of a hypothesis suggested by John Stuart Bell, who found it by studying Bohm’s version of EPR ([21.152]; see also [21.43, 160–162] for similar views on EPR).

On a moderate view, some thought experiments can be concretely performed, without denying a genuine status to thought experimentation (on this topic see recent discussions in [21.16]; Sect. 21.3.1).

## 21.4 What Is the Function of Thought Experiments?

Independent of the adequate definition of thought experiment, scholars widely agree on what it should do: to increase our knowledge. Thought experiments have generated a lot of epistemological interest, mainly

sparked by Kuhn’s inquiry (see Sect. 21.2.2). The main epistemological questions addressed in the literature are the following: What kind of knowledge do thought experiments really produce? To what ex-

tent are thought experiments a reliable source of information? What role do thought experiments play in processes of rational choice? The last question is strongly connected to the issue about how to classify thought experiments according to their epistemic functions. I shall begin by presenting some proposed taxonomies (Sect. 21.4.1), then I shall turn to the questions about the type of knowledge (if any) produced by thought experimentation (Sect. 21.4.2) and about its status (Sect. 21.4.3).

### 21.4.1 Sorting Thought Experiments

It might be useful to have an efficient classificatory scheme of immediate understanding, in order to put some order in the domain of thought experimentation and to try to understand it better. However, this is not an easy task. Thought experiments are employed in so many disciplines. Moreover, their interpretation can depend on historical factors ([21.163]; see also [21.164]) and on the intention of the thought experimenter, indeed they can even be rethought for different purposes ([21.56]; Sect. 21.3.3).

Thought experiments can be classified along several dimensions (e.g., by domains such as science vs philosophy, by type of reasoning such as inductive vs deductive). However, most taxonomies classify thought experiments according to their functions with respect to a group of hypotheses or a theory (several taxonomies are put forward by different scholars in [21.13]). None of these taxonomies seems to be definitive, but one has become quite popular, namely the taxonomy proposed by Brown ([21.81]; see [21.165] for a critique of this taxonomy).

Brown firstly divides thought experiments into two general types, destructive and constructive. A thought experiment falling within the former category is “a picturesque *reductio ad absurdum*” ([21.55, p. 34]; see also [21.70, p. 123]) devised in order to reject, or at least seriously undermine, some hypotheses or a theory. Here Brown rejoins Popper’s taxonomy and his critical use of thought experiment [21.58], which in turn is analogous to Hempel’s *theoretical* thought experiments – although the latter category goes beyond thought experiments against theories and encompasses all thought experiments that explicitly make fruitful predictions [21.59].

There are different ways of undermining a theory, thus suggesting different subcategories of destructive thought experiments. At least two subcategories can be offered. First, a thought experiment can show a problem *internal* to a given theoretical framework. This is the case, for instance, in Galileo’s falling bodies thought experiment (Sect. 21.1.1), since it shows an inconsis-

tency within Aristotle’s account of motion (due to the Aristotelian hypothesis that speed is proportional to weight).

Second, a thought experiment can show a problem *external* to a given theoretical framework, that is, between the latter and other assumptions or theoretical frameworks. Erwin Schrödinger’s cat thought experiment is such an example, since it underlined how QM (in its Copenhagen interpretation) was in conflict with our beliefs about the macroscopic level.

According to the Copenhagen interpretation of QM, a physical system can be in a very special state which actually is a simultaneous superimposition of different states. Once observed or measured, the physical system collapses into one of the superimposed states. This physical phenomenon occurs only at the quantum or microscopic level, but the problem is precisely where to draw the divide between the latter and the macroscopic level (i. e., the object of study of classical physics). As pointed out by Schrödinger, macroscopic objects like cats are not likely to be at the same time dead and alive (Fig. 21.4).

Following Brown and Fehige [21.27], a third subcategory might be added, namely “counter thought experiments” [21.166] or “thought-experiment/anti-thought-experiment pairs” [21.115, 117]. Counter or anti-thought experiments target thought experiments, more than theoretical frameworks. Examples of this category are Lucretius’ thought experiment (originally introduced by the Pythagorean Archytas; see [21.115, 167]), meant to undermine an Aristotelian thought experiment on finiteness of space, and Mach’s version of Newton’s bucket (Sect. 21.1.3) aimed at showing that centrifugal forces are due to the rotatory motion relative to the terrestrial mass and other celestial bodies ([21.168]; on this topic see, for example, [21.31, 116, 169]). Popper stressed that counter-thought experiments run the risk to be unacceptable, because unfair with respect to the opponent’s position [21.58, p. 466]. This is the apologetic use condemned by Popper (on the latter and Popper’s critical use, see [21.170]).

Fig. 21.4 Schrödinger’s cat thought experiment

Constructive thought experiments aim to support a theory or theoretical hypothesis, but they can do so in very different ways. Thus, Brown divides this category into three further types, namely mediative, conjectural, and direct. Mediative thought experiments have a pedagogic or illustrative role (generally on the pedagogical role played by thought experiments see, for example, [21.148, 171–176]). Indeed, they help us to better understand the conclusions that can be drawn from a specific theory. Brown gives as an example James Clerk Maxwell’s demon thought experiment. According to the kinetic theory of Maxwell, there is a probability, albeit very small, that heat moves from a cold body to a hot one. The second law of thermodynamics, however, implies the impossibility of such an event. To show the logical possibility of violating classical thermodynamics, *Maxwell* proposed his thought experiment of the demon [21.177].

Imagine two interconnected boxes; one filled with cold gas (C) and the other with hot gas (H). A very small door controlled by a demon is in between the two boxes (Fig. 21.5). The demon lets fast molecules go from C to H, and slows molecules go from H to C. In this way, while the average speed of the molecules in H would increase, the average speed of the molecules in C would decrease. Since according to Maxwell’s theory, heat is nothing more than the average speed of the molecules, the thought experiment shows the possibility of the flow of heat moving from a cold body to a hot body.

Given their illustrative and expository role, Brown’s mediative thought experiments recall *Popper’s heuristic* use of thought experiment [21.58] – a category profoundly similar to *Hempel’s inductive* thought experiments [21.59]. According to Brown, however, positive thought experiments can do more than merely illustrate a theory; they can help in constructing a theory. This is precisely what both conjectural and direct thought experiments aim to do. Contrary to mediative thought experiments, they do not start from a specific theory, but they end with one. What distinguishes conjectural from direct thought experiments is that they make up conjectured phenomena and put forward theories in order to explain them. Brown gives Newton’s bucket experiment (Sect. 21.1.3) as an example of con-

Fig. 21.5 Maxwell’s demon

jectural thought experiment, since it advanced a problem (i. e., things being equal from a relative point of view, there can be different effects on the surface of some water contained in a rotating bucket) and its solution (i. e., we should distinguish between relative and absolute motions, where the latter refer to the absolute space). It should be noted that Mach would have disagreed with such an interpretation of Newton’s bucket thought experiment, which will turn to be a mediative more than a conjectural thought experiment. According to *Mach* [21.168], from the thought experiment, we can reach the conclusion that absolute motions and space do exist, only if we accept from the beginning the existence of absolute space and the distinction between absolute and relative motions. Moreover, if we consider Newton’s bucket as a thought experiment run against relativist theories of motion (such as Descartes’s and Leibniz’s ones), it can also be seen as a destructive thought experiment.

Direct thought experiments establish new theories starting with unproblematic phenomena. An example of this category is Stevin’s chain thought experiment, since it introduced Stevin’s law of the inclined plane – i. e., the force to the weight is equal to the ratio of the height to the length of the plane (Sect. 21.1.2; this thought experiment can be seen also as destructive [21.153]).

Finally, according to *Brown* some thought experiments are both destructive and direct-constructive, these are platonic thought experiments [21.55, 70–72]. An example of this category is Galileo’s thought experiment on falling bodies (Sect. 21.1.1), since at the same time it undermined the Aristotelian theory of motion and put forward a new theoretical framework. As *Koyré* [21.60] remarked, such a thought experiment seems an example of good physics made a priori. This is precisely what characterises platonic thought experiments; they are vehicles of a priori knowledge (Sect. 21.4.2).

The following schema (Fig. 21.6) sums up Brown’s taxonomy.

Although Brown applies his taxonomy only to scientific thought experiments, it might be extended to

Fig. 21.6 Brown’s taxonomy of thought experiments (after [21.55])

encompass philosophical thought experiments too (as suggested in [21.27]). For example, Twin Earth thought experiment (Sect. 21.1.5) may count as internal-destructive, since it targets a hypothesis assumed by internalist theories of meaning (i. e., identical psychological states imply identical references). The same thought experiment can also be seen as a conjectural-constructive one, since it highlights a problematic phenomenon (i. e., the situation in which identical psychological states imply different references) and suggests a solution (i. e., meanings are constrained by natural kinds). The fact that a thought experiment can be difficult to classify is specific neither to philosophical thought experiments (see what was said earlier about Newton’s bucket), nor to Brown’s taxonomy (as will become clearer in the following). This is nothing but a symptom of how sorting thought experiments is difficult in itself.

Two more taxonomies are worth mentioning, which have sought to integrate also philosophical thought experiments. *Sorensen* has proposed a taxonomy of thought experiments driven by the idea that thought experiments are “stylized” paradoxes [21.52, p. 165], which serve as “alethic refuters” [21.52, p. 135]. In other words, thought experiments can be seen as “expeditions to possible worlds,” whose mission is “to refute a source statement that has an implication about the constituents of these worlds” [21.52, p. 135]. In analogy with the two alethic modalities, *Sorensen* divides thought experiments into two categories: refuters of possibility and refuters of necessity. Both argue against a theory or theoretical framework: the former by pointing out inauthentic possibilities wrongly considered as authentic, the latter by revealing neglected genuine possibilities. *Sorensen* gives many examples, for instance, while *Gettier*’s thought experiments (Sect. 21.1.4) and *Maxwell*’s demon are necessity refuters, *Schrödinger*’s cat and *Mark Johnston*’s [21.178] thought experiment against views on personal identity that make the latter dependent on future events are possibility refuters (see [21.86] for a critique of *Sorensen*’ logical regimentation, which is at the bottom of his taxonomy; it might be interesting to explore the link between *Sorensen*’s taxonomy and the one proposed in [21.179], pivoting on the idea that while some thought experiments enlarge the domain of properties pertaining to the actual world, others restrict such a domain).

*Gendler* [21.118] proposes a tripartite taxonomy of thought experiments pivoting on three different questions that can arise from a thought experiment. First, one may wonder what would happen if the imaginary scenario take place. This is what factive thought experiments ask. Second, there are conceptual thought experiments that pose the question of how what takes

place in the imaginary scenario should be described. Finally, valuational thought experiments assess the appropriate, moral, or aesthetic, evaluation of the envisaged situation. However, this taxonomy can be reduced to two broad categories. *Gendler* takes thought experiments as contemplations of imaginary cases that force us to account for the represented exceptional episodes and identifies two strategies for doing that, namely exception-driven and norm-driven. On the one hand, the exception helps us to establish the norms of a theory (e.g., *Galileo* on falling bodies – Sect. 21.1.1) and, on the other hand, norms guide us in evaluating the exception (e.g., the thought experiment of the ship of *Theseus*, which questions criteria for identity). While factive thought experiments typically fall within the former strategy, conceptual and valuational thought experiments fall within the latter.

Note that some authors might complain that all these taxonomies neglect to consider other specific types of thought experiment. First, some thought experiments seem neither to refute, nor to support a theory, but rather to be part of the theory itself. These thought experiments have been called *functional*, precisely because they have “a specific function within a theory” [21.180, p. 384]. In psychological testing, for instance, thought experiments advancing brainwashing procedure made possible to apply a frequentist conception of probability [21.180, p. 384]. It has been pointed out that functional thought experiments can also be found in modern physics [21.43].

Second, some thought experiments can start by clarifying conceptual issues and then turning to provide the basis for normative judgments. This seems to be the case with respect to the concept of money in economics. *Julian Reiss* has labeled such thought experiments “genealogical” ([21.181]; see also [21.182] for parallels between thought experiments in physics and in politics – on political thought experimentation, see also [21.183]).

Third, by analyzing thought experimentation in quantum gravity, *Mark Shumelda* [21.184] stresses that thought experiments can also be used in order to impose logical constraints on future scientific theories.

### 21.4.2 Thought Experiments and Kinds of Knowledge

A good thought experiment should be conducive to a new justified belief about the world or, at least, our interpretation of the latter. For instance, thanks to *Galileo*’s thought experiment on free fall (Sect. 21.1.1), we know that speed is not proportional to weight. Hence, we have, on the one hand, reasons against the Aristotelian theory of motion and, on the other hand, ev-

*idence* in favor of Galileo's theory, according to which speed is proportional to time.

Nevertheless, the fact that thought experimentation can produce knowledge is not a simple issue, and it turns out to be more complicated than in the case of real experimentation. Leaving aside arguments to the effect that thought experiments do not at all increase our knowledge, disagreements arise when philosophers want to specify the kind of knowledge that we gain through thought experimentation. This is easily seen with the problem of informativeness raised by Kuhn (Sect. 21.2.2): How can a thought experiment yield new empirical knowledge without the input of new data? This question has a paradoxical flavor due to the fact that only real experimentation is in direct contact with the world, from which it directly derives new materials. By contrast, thought experimentation is bound to use only old data, stored in the mind of the thought experimenter. How, therefore, can thought experiments provide us with new knowledge or understanding of nature? And what kind of *new* knowledge would they produce?

Very different stances have emerged in the many attempts to answer this epistemological question since the 1990s. Two among them can be seen as the polar positions of the relevant logical space: Brown and Norton, respectively, claiming that there is, and that there is not, new knowledge.

Following Koyré, Brown identifies a set of a priori thought experiments. These are, in Brown's terminology, Platonic thought experiments (Sect. 21.4.1), since they are neither based on new empirical data, nor simply inferred from old ones [21.55, 70–72]. These thought experiments are to be considered constitutively a priori and a source of knowledge independent of experience. How are we to explain, for example, the transition from the Aristotelian theory to the Galilean theory of motion? The right answer cannot be new sensory data, since none has been added. According to Brown, it is not even possible either to invoke any logical truth, that allows us to infer that all bodies fall at the same speed, or to appeal to other criteria, such as aesthetic ones (e.g., that of simplicity). Platonic thought experiments allow us to *see* the laws of nature. Many authors have criticized Brown's aprioristic account, above all his risked extension of Platonism from mathematics to physics [21.65, 75, 136].

According to Norton, pure thought is totally unable to generate any kind of knowledge, except from logical truths, and can only transform what the subject already possesses [21.115, p. 49]. Moreover, he criticizes a fundamental assumption in Brown's account:

the parallelism between visual and platonic perception [21.116]. Norton highlights that we have good criteria for assessing the unreliability of the former, but the same does not hold for the latter, which relies on both imagination and intuition [21.71, 72, 150]. Finally, since he argues that thought experiments can be reconstructed into arguments without epistemic loss (see Sect. 21.3.2), Norton denies that thought experimentation has a distinguishing kind of epistemic force. Thus, thought experiments can increase our knowledge, but only in the way logically sound arguments can do.

Between these two extremes, many scholars agree in thinking that new knowledge can be gained via thought experimentation. For example, *Humphreys* [21.75] maintains that thought experimentation provides a better understanding of the conditions needed for a theoretical model to hold. By contrast, *Gendler* [21.118, 145] claims that via thought experiments, we can get either new justified beliefs about contingent aspects of the natural world or new justifications for old beliefs. Gendler's reflections are clearly influenced by Kuhn, who already emphasized the importance of thought experiments in conceptual reconfiguration. Moreover, like others (e.g., [21.73, 82]), she also follows some insights of *Mach*, who argued that thought experiments make explicit a kind of inarticulate knowledge, not yet organized in theoretical frameworks, though stored in memory [21.28, 83]). In line with Mach's view, it has been claimed that successful thought experiments transform ability knowledge into propositional knowledge [21.185].

As far as the kind of knowledge is concerned, while some authors have maintained that thought experimentation involves both a priori and a posteriori knowledge (e.g., [21.186]; see also [21.136] for an aprioristic account of thought experiments), others have strongly criticized any aprioristic account of thought experimentation. For instance, although *Rodney Snooks* [21.78] agrees with Brown in thinking that thought experiments are a direct vehicle for the laws of nature, he argues that they do not give us access to a priori truths (see also *Hopp* [21.138], where a phenomenological approach is defended according to which thought experimentation can lead us to intuit universals and relations among them).

The debate has tackled also other kinds of knowledge, for instance, both modal and counterfactual knowledge [21.119, 187].

The issue about the kind of knowledge (e.g., new/old, a priori/a posteriori, universal/contingent, conceptual/empirical) gained via thought experiments is not the only thorny problem. Also, the issue about the status of such knowledge remains open.

### 21.4.3 The Epistemological Status of Thought Experiments

Is the knowledge gained via thought experimentation valid or reliable? And more generally we may ask: Are thought experiments indispensable epistemic tools? These questions, on the one hand, take us back to the comparison between real and thought experimentation (Sect. 21.3.1) and, on the other hand, open the issue about thought experiments in philosophy. In what follows, I shall address these issues respectively and devote a final subsection to the topic of intuitions.

#### The Proper Functions of Thought Experimentation

As we have seen (Sect. 21.3.1), thought experimentation is often considered as being of a rank lower than real experimentation, as if they were competing strategies. That is, the two types of experimentations perform the same function and the real type is to be preferred when possible (Sect. 21.3.3). And indeed, real and thought experimentations seem to play very similar roles in the evaluation of theories: Both test hypotheses, help to refine theories and similarly may fail in achieving these goals. However, one might ask whether there is a functional difference between thought and real experiments.

Some authors argue that, in fact, contrary to real experiments, thought experiments cannot have a justificatory role, but only an illustrative or explanatory role [21.89, 90, 98, 99]. However, this position does not do justice to both types of experimentations. After all, even real experiments are not only means of theoretical justification. Moreover, reasoning along this line tends to focus only on the justificatory inadequacy and to see it as the major limit and deficiency of thought experimentation. Once again the running idea seems to be that thought experimentation has no role to play within the context of justification and should be confined to the context of discovery (see Sect. 21.3.1). Once again we run the risk of underestimating the peculiarities of both types of experimentation. What, then, is the proper function of thought experiments, which sets them apart from real ones and is also what motivates us to use them instead of the latter?

In the literature, answers given to this question are not crystal clear. Let us mention some of them. It has been emphasized that thought experimentation provides us with idealization and modeling of reality to a higher degree compared to real experiments (e.g., *Koyré* [21.60]); idealization can also be a source of unreliability, for a discussion on this topic, see *Sorensen* [21.188]). However, it is questionable whether this really answers the above question, or merely

changes the focus to *how* thought experimentation functions (Sect. 21.5). *Gendler* [21.118] has proposed to see the functional difference in the type of results. Both thought experiments (at least scientific ones) and real experiments tell us about the real physical world, but via the former we obtain *intuitions*, whereas via the latter *data* (Sect. 21.3.3). A question arises: Do we really make use of thought experiments because we are in search of intuition rather than data?

Inspired by Kuhn, *Bokulich* [21.56] has suggested that thought experimentation tests the nonempirical virtues of theories, such as (internal or external) coherence, simplicity, and fruitfulness (for the notion of nonempirical virtues, see [21.189]; similar notions can be found in [21.190, 191]). On this view, Galileo's thought experiments showed an incoherence internal to Aristotle's theory of motion, stemming from an ambiguous use of the concepts of *speed* and *weight*. He also dared to go beyond the impasse, and to propose a new theoretical framework within which he could account for the phenomena. Bokulich's conclusion on thought experimentation in physics finds a parallel in the work of *James Lennox* [21.101, 102] on Darwin's thought experiments (see also the claim that thought experiments in science test how unified a theory is in [21.132]). Indeed, Lennox argues that thought experiments are functionally experiments, but we appeal to them under special conditions: "thought experiments are especially important when the issue at hand is the theory's *potential* to explain *as*, and *what*, it claims it will" [21.101, p. 236]. It has been proposed to extend a similar approach to philosophical thought experiments [21.152].

It should be noted that most authors who challenge the epistemic validity of thought experimentation do not object to scientific thought experiments. *George Bealer* [21.192] has proposed to formalize this view terminologically. According to him, the expression *thought experiment* should refer only to those hypothetical situations designed to generate intuitions about the natural world, in other words to scientific thought experiments. Likewise, others, among the fiercest critics of the epistemological role of thought experiments, have always rescued scientific thought experiments, specifically within physics. For example, both *Hull* [21.90] and *Snooks* [21.78] limit the power of thought experiments to well-articulated scientific fields, that is physics. Generally, there is a sharp scepticism about philosophical thought experiments.

#### The Status of Philosophical Thought Experimentation

*Rachel B. Cooper* [21.65] has pointed out that much of the analysis on thought experimentation is restricted to

scientific thought experiments, probably due to a strategy of caution (Sect. 21.2.3). In the last decade, the number of analyses considering only philosophical thought experiments has also grown – mainly due to the debate about the role of intuition in philosophy (see in the following). Although *Brown* does not deal with examples of philosophical thought experimentation, he is aware of this shortcoming and wonders whether scientific and philosophical thought experiment can be accommodated by a single theory [21.55, p. 28–31]. He also claims that perhaps this kind of conceptual analysis reveals a core common to philosophy and physics. If we were able to know more about such a common core, we would probably learn more about physics and philosophy, as well as thought experimentation (it is worth underlining that also in mathematics thought experimentation seems an important, and perhaps the only, form of experimentation; on the topic see, for example, [21.42], contributions in [21.13, 193–195]).

*Cooper* claims that often what distinguishes scientific from philosophical works are only the journals in which they are published. But papers on scientific thought experiments, such as Schrödinger's cat (Sect. 21.4.1), can be found both in scientific and philosophical journals. Similarly, a philosophical thought experiment such as Searle's Chinese room (Sect. 21.2.3) is tackled by philosophers, as well as by psychologists. "It is hard to distinguish science from philosophy and even harder to distinguish philosophical from scientific thought experiments" [21.65, p. 329]. *Cooper* suggests that a comprehensive analysis of thought experimentation cannot avoid to give an account of both philosophical and scientific thought experiments.

Besides *Cooper*, other scholars have tried, more or less extensively, to analyze both scientific and philosophical thought experiments, without raising a barrier between them [21.52, 64, 79, 82, 118, 141, 152, 161].

Arguably science and philosophy are intertwined, but one might think that the latter is more hostage to speculation and boundless imagination than the former. Precisely, for this reason, *Kathleen Wilkes* maintains that a good thought experimenter should envisage a scenario not too far from reality and specify all conditions relevant to its understanding ([21.87, p. 9]; see also [21.28]). Thus, she considers thought experimentation fruitful only in the scientific domain, because the latter, contrary to the philosophical domain, cannot deviate too much from reality and must invoke a type of thought experimentation more akin to real experimentation (this point brings us back to the issue about the biased continuity between real and thought experimentation see Sect. 21.3.1; see recent discussion in [21.196] about the idea that also thought experimentation in science is weakened by being dependent on imagination –

Sect. 21.5). According to *Wilkes*, there are two conditions for any experimenter (thought or real): first, to aim at testing a theory by varying key parameters and maintaining constant other relevant parameters (Sect. 21.3.3) and, second, not to violate natural laws. This second condition should further distinguish scientific from philosophical thought experiments. On this condition, however, the philosophical thought experiment of the brain in the vat [21.2] would be acceptable, since it is not obviously nomologically impossible, whereas the thought experiment of Einstein chasing a light beam would not be (see [21.164] for an in-depth analysis of this thought experiment). Moreover, as rightly stressed by *Brown* [21.55, p. 30–31]

"Too often thought experiments are used to find the laws of nature themselves; they are tools for unearthing the theoretically or nomologically possible. Stipulating the laws in advance and requiring thought experiments not to violate them would simply undermine their use as powerful tools for the investigation of nature"

See also what will be said about *Cooper* on this point Sect. 21.5.2).

Philosophical thought experiments are generally pictured by their detractors as fairy tales, which do not deserve to be taken seriously. The underlining idea seems to be that philosophy is too much prone to conceptual ruminations, involving idealization and approximation, and based on a methodology less strict than the scientific one. Philosophical thought experimentation would be paradigmatic of these flaws. Following *Hull's* discussions ([21.89, 90]; Sect. 21.3.1), which sum up criticisms against philosophical thought experiments very well, there are four negative aspects, which make philosophical thought experimentation less effective than scientific thought experimentation.

First, philosophical thought experiments lack well-defined theoretical frameworks. According to *Hull* [21.90, pp. 432, 434 and 438] this is the fundamental difference between philosophical and scientific thought experiments and, probably, the reason for the disparity (at the time of his writings) between many excellent analyses of scientific thought experiments and poor accounts of philosophical thought experiments. *Hull* thinks that thought experiments made within analytic philosophy well exemplify the lack of a theoretical framework that allows us to set up the imagined scenario. Provocatively, he writes: "If no such context exists, philosophers need to construct one. [...] If Jane Austen can do it, so can Hilary Putnam" [21.90, p. 434]. If a theoretical and technical background is missing, as much as one tries to refine the details of the given thought experiment, it will remain hopelessly incom-

plete (Sect. 21.3.3) and of poor cognitive value. Furthermore, without a reliable theoretical background, the usefulness of philosophical thought experimentation is also undermined, in so far as thought experimentation cannot exploit a fruitful interdependence between observations and theories [21.89, p. 311].

Second, philosophical thought experiments are used in order to justify or provide evidence in favor of theoretical hypotheses, though they should be used only for descriptive purposes ([21.89, pp. 315–316]; see also [21.90, p. 438 and p. 453]). According to Hull, the fact that philosophical thought experimentation relies more on common sense than on scientific data weakens its justificatory power and is also the reason why they cannot offer the same degree of technical specificity as scientific thought experimentation and real experimentation.

Third, Hull maintains that, contrary to real experimentation, thought experimentation requires a theory of conceivability as a vehicle for possibility. Thus, thought experimentation should adopt a strong standard of conceivability. Unfortunately, “Too often, the decisions that philosophers make rest heavily on intuitions about what sounds right” [21.90, p. 435]. In a nutshell, we settle for weak requirements for assessing the plausibility of the conclusions reached via thought experimentation (there is a vast philosophical literature on the link between conceivability and possibility; see, for example, contributions in [21.197], which also touch upon the issue about thought experimentation; see also [21.198]).

Finally, misleading intuitions seriously undermine the efficacy of thought experimentation. These intuitions are culturally variable, being dependent on our cultural beliefs. The latter can help us in exploring possible worlds, but also be narrow-minded and inhibit innovation [21.90, p. 431 and p. 446]. It does emerge, from the catastrophic picture of the critics about philosophical thought experiments, that the latter are a source of, in Hull words, “conceptual morass” [21.89, p. 315], rather than a prelude to its remediation.

The lack of a strong standard of conceivability, the contextual vagueness, and the consequent paucity of interrelation between empirical and theoretical data are errors that can be traced to a single source: misleading intuitions. Hence, criticisms against philosophical thought experimentation can be reduced to 2. Philosophical thought experimentation, on the one hand, relies on questionable intuitions and, on the other hand, purports to bring evidence in defence of a philosophical claim or theory. Without calling into question, the plausibility of such a view, a further difficulty arises from the fact that the meaning of the term *intuition* is not crystal clear. There is not a consensus either on what intuitions are or on what we can reasonably ex-

pect from them. This is so not only in the debate on thought experimentation, but also in the specific debate about the nature of intuitions (a good starting point on the topic are the contributions in [21.199]; see also Cappelen [21.200], Chudnoff [21.201] and Booth and Rowbottom [21.202]).

### Intuitions and Thought Experimentation

Intuitions seem to be an integral part in the processes of rational choice. Psychology and related disciplines have been investigating the formation and variation of our daily choices for a long time [21.203]. The picture that has emerged is that our decisions are highly sensitive to many elements which, at first sight, appear irrelevant, such as the framing of the context. Similar considerations seem to apply to intuitions as well. This line of research is a warning to a standard philosophical practice that uses intuitions generated in response to thought experiments as evidence in the assessment of a philosophical thesis (e.g., in ethics – see, [21.204–206]). The lesson would be that a more rigorous program, whose goal is to observe responses obtained via thought experiments and to study the nature of the intuitions involved, is needed. A new philosophical movement known as *Experimental Philosophy* (or *X-Phi*) aims precisely at meeting this challenge, by making use of the critical methods proper to social experimental psychology (for an introduction to X-phi, see [21.207] and contributions in [21.208]).

Note that the methodology of the experimental philosophers has been highly criticized (e.g., [21.209] and [21.210]), *Williamson* is also sceptical about the role of intuitions in thought experimentation – [21.119, 211, 212] – without being sceptical about thought experimentation itself like [21.213]). Leaving aside such critiques, X-Phi studies have shown that some philosophical thought experiments typically considered as universally acceptable (e.g., Gettier’s cases, *Keith Lehrer’s* Mr. Truetemp thought experiment [21.214], Putnam’s brain in a vat, *Saul Kripke’s* thought experiment on Gödel and Schmidt – [21.215]) evoke variable intuitions both *inter-* and *intra-*subjectively [21.216, 217]. The fact that thought experiments produce unstable intuitions makes thought experimentation itself shaky. However, thought experimentation in the scientific domain is commonly considered efficient. Therefore, it is legitimate to ask whether only philosophical thought experiments evoke poor intuitions and, if not, whether scientific thought experiments have other resources in order to make their intuitions more useful.

Some contemporary philosophers have explicitly pointed out that all thought experiments, both philosophical and scientific, evoke and make use of intuitions. In *Brown’s* account, for example, the state of

seeing the laws of nature is interpreted in terms of having intuitions [21.55, 72]. On this view, in Galileo's thought experiment (Sect. 21.1.1) the desired scientific conclusion comes as a result of our having the intuition that the two bodies fall at the same speed. However, it seems that in the scientific domain as well, thought experimentation can elicit misleading and unreliable intuitions (e.g., in EPR thought experiment, which is generally interpreted as a failed thought experiment – Sect. 21.3.3). Still it is an open question whether and how these intuitions can be properly used in the scientific domain.

One way to answer this question is to argue that philosophical and scientific thought experiments do not involve the same type of intuitions. Bealer [21.192] seems to hold this view. He distinguishes between rational and physical intuitions. The former would be *sui generis* intellectual seemings and would arise when considering the (logical or metaphysical) possibility of an imagined scenario or the applicability of a given concept to such a scenario. The author gives as an example of this type of intuition Gettier's cases (Sect. 21.1.4), which trigger two rational intuitions: A first intuition confirms that the case is possible, while a second intuition that we cannot ascribe to the imagined subject a state of knowledge. Physical intuitions deal with what would happen if the given imagined scenario were actual, rather than with its plausibility. Newton's rotating bucket thought experiment (Sect. 21.1.3) would exemplify this type of intuition, since in this case a physical intuition has to answer the question: "Would water creep up the side of the bucket (assuming that the physical laws remained unchanged)?" [21.192, p. 207]. According to Bealer, another feature distinguishes rational from physical intuitions: only the former present themselves as necessary. As Bealer would say, necessarily if a subject S intuits that the given imagined scenario is not a case of knowledge, it seems to S that the given imagined scenario is not a case of knowledge and also that necessarily the given imagined scenario is not a case of knowledge. By contrast, it does not seem that the water must crawl up the side of the bucket, though it is possible. Finally, Bealer claims that the expression *thought experiment* should be used to refer only to hypothetical situations that generate physical intuitions – i. e., to scientific thought experiments (mathematics and logic excluded).

Beyond the plausibility of a distinction between physical and rational intuitions drawn on the distinction between possibility and necessity, its relevance for a corresponding distinction between scientific

and philosophical thought experiments is questionable, since the alleged self-evidence of intuitions produced by philosophical thought experimentation has been seriously challenged.

Daniel Dennett [21.218] defined thought experiments as *intuition pumps*. Generally, in the literature on thought experiments, this expression is interpreted in a negative sense. Indeed, Dennett does not consider (at least philosophical) thought experiments highly. However, the philosopher seems to acknowledge that thought experiments can be useful when he writes that [21.218, p. 18]

"Philosophy with intuition pumps is not science at all, but in its own informal way it is a valuable – even occasionally necessary – companion to science."

Following Peter Swirski [21.219], it can be argued that the fact that thought experiments, both scientific and philosophical, are intuition pumps, and that these intuitions are unstable, is not negative per se. The epistemic force of a thought experiment seems precisely to arise from the fact that it depicts an exceptional case and forces us to account for the latter. Perhaps, the problem lies in an overestimation of what "can reasonably be expected of such experiments" [21.219, p. 105]. For example, it might be an exaggeration to consider thought experimentation a canonical procedure of justification [21.192], as if a single thought experiment could lead us to accept or to reject a theory. After all, even real experiments seem not capable of doing so much.

It is also possible to argue that it is a mistake "to describe the sort of knowledge involved in these thought experiments as intuitions" [21.56, p. 300]. The idea would be that intuitions are a component in the cognitive process of thought experimenting, more than its upshot. It might be even argued that intuitions are dispensable in thought experimenting [21.31, 119, 211, 212, 220]. According to many authors [21.71, 72, 82, 137, 161, 204, 221], however, intuitions play a crucial role in thought experimenting. Through these intuitions, in conjunction with other components (e.g., theoretical assumptions, empirical data), thought experiments lead us to acquire knowledge. The power of thought experiments would rely on optimizing the combination between data, theories, and intuitions. It can be argued that scientific and philosophical thought experimentations are functionally similar: The latter have the same potential as the former in order to make interact data, theories, and intuitions [21.152].

## 21.5 How Do Thought Experiments Achieve Their Function?

The discussion on the intuitions involved and generated by thought experimentation (Sect. 21.4.3) highlights another important issue in the debate on thought experimentation, namely the question about how the latter obtains its results. This question is intimately connected to the cognitive side of thought experimentation. In what follows, first, I shall outline the motivation for a cognitive approach to thought experimentation and briefly review what has been said about the cognitive underpinnings of thought experimentation (Sect. 21.5.1). Second, I shall focus on the role played by imagination in thought experimentation, since almost all scholars agree in thinking that imaginative capacities are recruited by thought experimenters (Sect. 21.5.1). Third, I shall draw on issues connected to the latter, namely the narrative dimension of thought experimentation.

### 21.5.1 A Cognitive Approach to Thought Experimentation

Most analyses in the debate have been primarily concerned with epistemological issues that aim to analyze thought experiments with respect to their outputs, more than their cognitive underpinnings. A cognitive approach would, however, be worth pursuing, because we could consider not only the result of a thought experiment, but also what happens in the head of someone performing a thought experiment (on the advantages and disadvantages of the study of thought experimentation via cognitive sciences see the debate between *Stuart* [21.222] and *Thagard* [21.99]).

*Mason Myers* [21.185] complained about both the lack of a deep investigation of the basis of thought experimental reasoning and the epistemic aspects of (philosophical) thought experiments. However, an epistemological approach to thought experiments is not cognitive, or not necessarily so. The difference between these two ways of studying thought experiments lies in the specific issues addressed, as well as in the fact that while the epistemological approach is generally normative, the cognitive approach is more descriptive. A fine-grained and comprehensive analysis of thought experiments should acknowledge the differences between these two approaches and pursue them together insofar as they are complementary [21.223].

In the literature, there have been several attempts to describe the stages of a thought experiment or how it works. For instance, *Reiner* and *Gilbert* [21.148] argue that there are six stages to thought experimenting:

1. A problem or a hypothesis is stated
2. An imaginary world that contains objects and laws is made up
3. The thought experiment is designed
4. The thought experiment is run
5. *Observations* are made (i. e., an outcome produced with the use of the laws of logic) and
6. Conclusions are drawn (see also [21.52, 86] and more recent contributions in [21.15]).

However, it is not always clear if these analyses focus on what really happens in the heads of thought experimenters or if they are about the argumentative structure of thought experiments. Indeed, it seems that thought experiments are pieces of reasoning, so that it should be possible to organize them into a premise-conclusion structure, involving certain inferential rules (Sect. 21.3.2).

Anyway, the question of how thought experiments fulfil their functions has led many to tackle the issue about the kind of reasoning underlying thought experimentation. On this issue, authors disagree and have appealed to different, but sometimes compatible, kinds of reasoning: hypothetical [21.38], counterfactual [21.77, 119], deductive [21.115, 117, 134], inductive [21.115, 117], abductive [21.103], simulative model-based [21.73], propositional [21.119], nonpropositional [21.73, 136], and heuristic (e.g., *De Mey* [21.224], who pleads for an approach who integrates both the heuristic value and the demonstrative force of thought experiments).

A related debate concerns the role played by intuitions in thought experimentation (Sect. 21.4.3). *Jeanne Peijnenburg* and *David Atkinson* claimed that, although there is not a unanimous definition of what thought experiments are, there is unanimity about what they should do, that is to give “a sudden and exhilarating insight” ([21.79, p. 306]; see also the definition in the *Encyclopedia of Cognitive Science* – [21.81]). Indeed, many philosophers in the debate on thought experiments have claimed that intuitions are an important component of the thought experimental process, as well as the type of its outcome. However, the precise role played by intuitions in thought experimentation is an open question. As previously stressed, while some authors have argued that intuitions cannot explain by themselves the epistemic role of thought experiments [21.56], others have based their scepticism about the thought experimental practice precisely on the fact that they mainly involve (deceptive) intuitions [21.79, 89, 90, 99].

Despite this disagreement, almost all authors involved in the debate on thought experiments agree in considering thought experiments as epistemic tools, which involve imagination in order to provide insights on a certain hypothesis or theory (see the definition in the *Encyclopedia of Cognitive Science* [21.81]).

### 21.5.2 Imagination and Thought Experimentation

*Mach* [21.28, 83, 168] was the first to argue that imagination plays a pivotal role in thought experimentation. According to him, performing a thought experiment is to “combine circumstances” in imagination [21.28, p. 452]. Some passages of his writings have led authors to maintain that Mach conceived imagination as visualization. Among these authors is *Gendler* [21.145], who attributes to Mach the idea that it is visual imagery (i. e., visual imagination) that is primarily at work in thought experimenting (see also [21.52]; for a critique [21.223]). *Gendler* herself has tried to pursue Mach’s approach. She establishes a link between research of cognitive scientists and philosophers on visual imagery and the analysis of *Stevin’s* thought experiment on the inclined plan (Sect. 21.1.2), and finds that at least in some thought experiments the role of visual imagery is epistemically crucial (see also [21.105] on this point).

It is possible to consider the *model-based approach*, which calls on the literature of model-based reasoning in cognitive science, as belonging to the *Machian tradition* too, that is, they pursue Mach’s aim of analyzing thought experiments with the help of a psychological theory (for a detailed analysis, see [21.86, Chap. 4]). Among the authors advocating this approach [21.85, 132, 225, 226], three are to be considered as its main developers, namely *Miščević* [21.137, 149], *Nersessian* [21.73, 84, 135, 227] and *Cooper* [21.65]. These authors agree in maintaining that in thought experimentation we gain new knowledge through manipulating a model. They have, however, advanced different theses pivoting on different notions of model.

*Miščević* and *Nersessian* appeal to the cognitive literature concerning *mental modeling*, and more specifically to the notion of the mental model proposed by *Philip Johnson-Laird* [21.228, 229]. In a nutshell, a mental model is a structure stored in short or long term memory and it is defined by cognitive scientists as a third type of mental representation, half way between propositional and pictorial. Indeed, mental models are structurally analogous to that which they represent, but not all such models can be visualized. This is clearly seen in *Nersessian’s* account [21.86], whereas *Miščević* holds a more pictorialist view about mental models. Indeed, *Miščević* claims that the mental model

is a “quasi-spatial picture” and has a “concrete and quasi-spatial character” [21.149, p. 220].

By contrast, *Nersessian* argues that the mental model manipulated in thought experimentation is neither a picture in the head nor a linguistic representation. Following *Johnson-Laird*, she maintains that it is rather a structural analog of the situation depicted in the thought experimental narrative [21.73, p. 297]. Nevertheless, *Nersessian* highlights the role of nonpropositional representations much more than *Miščević*: In her view the reasoning proper to thought experiments is entirely rather than partially nonpropositional. For that reason, *Nersessian* maintains that deductive and inductive inferences do not have a central part in thought experimentation.

*Cooper* disagrees with both *Miščević* and *Nersessian* and holds a much more liberal view. On the one hand, she maintains that the hypothesis of mental models is debatable as it is based on contestable empirical data. On the other hand, she argues that [21.65, p. 341]

“whether the thought experimenter reasons through the situation via manipulating a set of propositions, or a mental picture, or even plasticine characters makes no difference.”

For *Cooper*, a thought experimenter can manipulate physical models in addition to mental representations, and she can carry out deductive or inductive inferences, as well as diagrammatical ones. Another point of disagreement is that for *Nersessian* and *Miščević*, “models are restricted to simulating the way in which phenomena would unfold in the real world”. *Cooper* replies that “the thought experimenter may model a world in which some laws of nature are suspended or altered” ([21.65, p. 341] – see what has been said about *Wilkes* on this point Sect. 21.4.3).

Two other views that fall within the mental-model approach are worth mentioning. First, by following *Nersessian’s* account, *Michael Bishop* [21.132] has put forward a very liberal view according to which mental models of actualized experiments and at least some computer simulations count as thought experiments (see what has been said about numerical experiments Sect. 21.3.2). Second, *David Gooding* [21.85, 147] was in line with *Nersessian’s* approach too. However, he did not rely on the notion of a mental model and developed an embodied view on thought experiments where the bodily and visual components play a central role (see [21.230] for a more phenomenological and less naturalistic embodied approach on thought experimentation).

According to the *Machian tradition*, thought experiments are species of simulative-based reasoning. This

idea is implicit in Gendler's analysis, but it is only in the model-based approach that it is made fully explicit and linked to the notion of a (physical or mental) model. *John Zeimbekis* [21.231] has criticized simulationist approaches to thought experiments by arguing that we should distinguish between two kinds of mental simulation: mental–mental simulation and mental–physical simulation (see also the similar distinction between recreative and icastic imagination drawn in [21.223]). He claims that while only the latter is captured by mental models, the former is a source of epistemic bias, at least, for moral thought experiments. Zeimbekis grounds his argumentation on the literature in philosophy of mind about simulation theory. However, it is not entirely clear, whether he is dealing with high-level or low-level mental simulations. While the former comes at the personal level and can be interpreted as conscious imagination, the latter comes at the subpersonal level and is realized by mirroring processes, for example, the activation of mirror neurons in the observation mode [21.232, 233].

Imagination is often cited by all these authors, but it is not crystal clear how imagination is defined and what the link is between mental or physical models and imagination. More generally, the role of imagination in thought experiment is a controversial topic (see [21.196]; on imagination and thought experiments see also [21.234, 235]). Indeed, some authors, like *Gendler* [21.145], give it a central role, while others, such as *Norton* [21.115], maintain that thought experimenters could and should do without it, imagination being here a source of error (see also [21.54]). Moreover, an additional complication arises once we acknowledge that accounts of imagination provided by the cognitive literature have pointed out that imagination comes in many varieties, for instance there would be sensory and nonsensory forms of imagination (e.g., [21.232]). A closer look at the expressions used in the literature to describe thought experimentation suggests that most authors think of imagination as the means by which the thought experimenter gains access to a scenario which is not directly accessible to her senses: in thought experimenting she *quasi-observes*. For instance, *Brown* [21.55, 70–72] speaks of *seeing* the laws of nature and he claims that the pictorial and sensory aspects are essential to thought experimentation (see also [21.136] on that point). *Nersessian* [21.73] stresses that when we perform a thought experiment, we feel ourselves as observers. *Martin Cohen* takes the second rule of good thought experimenting to be that the thought experiment must be imaginable, that is, “the clearer the picture, the stronger the image, the better the experiment” [21.64, p. 106]. *Gooding* [21.85] claims that visualization is a necessary and sufficient condition

to most if not all thought experiments. *Norton* [21.115] admits that thought experiments involve visualization, though he denies its epistemic role. Thought experimentation, thus, seems to involve a sensory – specifically, visual – variety of imagination. Although they are in the minority, other authors have suggested that non-sensory forms of imagination may be necessary to the thought experimenter, like supposition [21.236] or conceiving [21.237]. Indeed, Mach himself seems to have given to imagination in all its forms a role in thought experimenting [21.223].

### 21.5.3 The Narrative Dimension of Thought Experimentation

The model-based approach has underlined a rather neglected aspect of thought experimentation, namely its narrative dimension [21.73, 85]. Thought experiments are extremely important because they are intentional products related to the sharing and the spreading of knowledge. Moreover, they are publicly presented to different audiences through narratives [21.219]. In disagreement with Norton, *Nersessian* has stressed that the aesthetic details in thought experimental narratives are not simply rhetorical, but “serve to reinforce crucial aspects of the [thought] experiment” ([21.73, p. 296] – she also sees a parallel between thought and real experiments, since also the latter when published are presented in a narrative form). Still, according to *Lawrence Souder* [21.238], even in *Nersessian's* account the role played by the narrative aspect of thought experimentation is underestimated. The same holds for other views that deny to thought experimentation a life of its own (the reference is mainly to [21.74], as we have seen before Sect. 21.3.3).

The narrative dimension of thought experimentation has led some authors to conclude that the reasoning underlying thought experimentation is closely related to the one used in the consumption of fiction [21.73, 149, 186, 234]. Some have proposed to consider thought experiments as a genre, like science fiction [21.239]. This view is in line with *David Davies' one*. Indeed, he argues [21.240, 241] that both philosophical and scientific thought experimentation meet two necessary and sufficient conditions for the fictionality of a narrative. That is, first, they involve to make believe, rather than to believe, that the state of affairs described holds (this point brings us back to the issue about the role played by imagination in thought experimentation, since make-believing is a form of imagining, see [21.234, 242], Sect. 21.5.2); second, they involve a narrative constrained by some specific purpose “such as entertaining or perhaps instructing readers in certain specific ways” ([21.241]; in [21.240] he specifies that

the imaginary world should not be constrained by actual events).

If, on the one hand, we can put thought experimentation on the level of literary fiction, on the other hand, we can also do it the other way around and put the latter on the level of the former. Fictions themselves can be seen as thought experiments aiming at enriching the subject's knowledge via *journeys* in more or less far possible worlds [21.219, 243]. Precisely, on this basis, both Carroll [21.244] and Elgin [21.245, 246] have tried to defend literary cognitivism, that is, the view according to which fictional narratives can be a source

of knowledge or understanding of the real world (in [21.246], the author also argues that the process of *exemplification* is common to literary fiction, thought and real experimentation). Some caveats to this move have been raised by Davies ([21.241]; see also [21.80]), in particular when applied to films [21.247].

**Acknowledgments.** I am very grateful to Marco Buzoni, Jérôme Dokic, Yiftach Fehige, and Michael Stuart for helpful comments on earlier versions of this chapter. I would also like to thank the editor in charge of the part D, Nora Schwartz, for her support.

**25 Abduction and the Emergence  
of Necessary Mathematical Knowledge**

Ferdinand Rivera, San Jose, USA

The use of models in mathematics can broadly be distinguished as two categories. Most commonly, mathematical models are applied to the formal sciences and engineering, as well as to social sciences and other modes of quantitative reasoning. Secondly, models are also used within formal mathematics and in mathematical practice. This part of the book is mostly concerned with the latter use of models. In this sense, models are tools for reasoning in mathematics or teaching mathematics, and as a consequence also a means for understanding mathematical practice. The oldest and most common use of models in mathematical practice are applications of extended cognition. Chinese counting rods, the Roman abacus, medieval *jetons* or reckoning counters, or modern day computers are all material aids that allow us to delegate part of the cognitive load in performing complex calculations to the external environment. The operations that we carry out using these contrivances represent specific calculating procedures and in that sense they act as specific models of algorithms in arithmetic.

Diagrams are a more interesting application of extended cognition in mathematics. It is rather surprising that after more than 2000 years of practice with diagrams in mathematics, a study of their precise meaning, use, and function in mathematical reasoning has become a subject of serious study only during the past 20 years. **Chapter 22** by *Valeria Giardino* provides us with a comprehensive state of the art in recent research on mathematical diagrams. The new approach from the philosophy of mathematical practice – studying what mathematicians are actually doing when producing mathematics – has focused on the role of diagrams as a reasoning model rather than a visual representation of a mathematical object. Especially, the classic lettered diagram from Euclidean geometry has come under scrutiny, with the role of its constituent elements, their ontology, their epistemic functions, and their relation with the text and inherent ambiguities being inspected. It turns out that the diagram is not just a static object in a textbook, but as *Giardino* calls it, the diagram is *kinaesthetic*, as the text referring to it treats it as a constructed and manipulative object in which its inherent ambiguities become productive and open up modes of reasoning which are inhibited in more formal representations.

**Chapter 23** is a contribution by *John Mumma* that builds further on research from the philosophy on mathematical practice on Euclidean diagrams, in particular the work of *Ken Manders* (2008). *Mumma* presents a formalization of the model-based reasoning involved in mathematical diagrams, not only accounting for the

construction of the geometrical diagram but also its use in the demonstration.

A third application of extended cognition worth mentioning, while not treated as a dedicated subject below, are symbolic representations. It might be less obvious to view mathematical symbolism as a form of model-based reasoning, but recent research indicates that symbolism is not just a game of meaningless symbols and that modern symbolism, as it is taught and practiced today, relies on the visual processing of elements in a way that is similar to the interpretation of diagrams. Spatial organization, directionality, grouping, and mental operations like *picking up* and moving elements across symbolic expressions, appear to be crucial for our understanding of mathematical symbolism (*Heffer* 2014).

**Chapter 24** is the reflection of a joint project by two philosophers of mathematical practice, *Joachim Frans* and *Bart Van Kerkhove*, and the mathematician *Isar Goyvaerts*. This contribution provides a more general account of model-based reasoning in mathematical practice, concentrating on the processes that are required to arrive at higher levels of abstraction in mathematics. Three examples from different mathematical disciplines show how models facilitate additional layers of abstraction. The first one is from Euclidean geometry and deals with the abstraction from concrete shapes and measures to mathematical objects to which deductive reasoning can be applied. The second one is from approximation theory, in which functions can be modeled by other, more nicer and simpler functions. The third example is more technical and describes how the highest level of abstraction is achieved by the modeling of the inferences on certain algebraic objects by category theory.

**Chapter 25** deals with abduction, which is well suited for modeling mathematical inferences within the context of discovery. Abduction is the response to observations or findings which appear surprising or anomalous, and formulating hypotheses which allow us to evaluate their consequences. Abductive reasoning can thus lead to the emergence of new mathematical objects, ideas, or even theories. An earlier historical case study has shown how imaginary numbers appear from practice in Renaissance algebra (*Heffer* 2007). By means of empirical case studies, *Ferdie Rivera* shows how abductive processes are prominent within students' understanding of mathematics in the classroom, while previous studies have only focused on deductive or inductive reasoning. Four concrete suggestions are formulated to illustrate how abduction can be applied to mathematics education in a more systematic way.

## 22. Diagrammatic Reasoning in Mathematics

Valeria Giardino

The objective of the present chapter will be to review the most recent studies about diagrammatic reasoning in mathematics. Section 22.3 will focus on the very much discussed topic of the role and of the features of diagrams and diagrammatic reasoning in Euclidean geometry. Section 22.4 will be devoted to the proposal of considering diagrams as representations that are introduced in support of other symbolic practices and whose power resides in their ambiguity. In Sect. 22.5, the attention will turn toward studies discussing diagrammatic reasoning in contemporary mathematics. In Sect. 22.6, computational perspectives on how to implement diagrammatic reasoning in computer programs will be introduced, both for Euclidean geometry and theory of numbers. In Sect. 22.7, it will be discussed how the study of diagrammatic reasoning can shed light onto the nature of mathematical thinking in general. Finally, in Sect. 22.8, some brief conclusions about diagrammatic reasoning in mathematics will be drawn. The choice of reviewing the research about diagrammatic reasoning along these lines is of course at least in part arbitrary. The aim of such a regrouping is to provide the reader with a map that can be helpful for exploring the various and already copious literature that has been recently produced on the subject. The ambition is that such a map will be as extensive as possible.

### 22.1 Diagrams as Cognitive Tools

In his *Parallel Lives*, Plutarch famously reported the murder of Archimedes. He relates three different versions of the circumstances that brought about his death. According to the first one, Archimedes was so intent upon inspecting a diagram to work out some problem that he never noticed the incursion of the Romans, nor that the city was taken. His absorption in study and contemplation of the diagram was so deep that he declined to follow a soldier who had unexpectedly come up to him and commanded him to do so. Given his refusal, the soldier drew his sword and ran him through. In the

same spirit, in one of the most celebrated frescoes of the Italian Renaissance, *The School of Athens*, Raphael depicts a group of men attentively watching a scholar – most likely to be interpreted as Archimedes or Euclid – while he draws a geometrical figure on a clay tablet.

The mathematician is thus often portrayed as intently working on a diagram; this popular image attests to what extent the resource to diagrams, figures, or sketches – among other possible available instruments – is commonly considered as an outstanding element of the practice of mathematics. Is this picture true to the

facts? Are diagrams really part and parcel of the mathematical practice? And if it is so, what can be said about their features, use, and relations with other elements of the same practice? The objective of the present chapter is to introduce the most recent works on diagrammatic reasoning in mathematics and to review the answers that have been proposed so far for these questions. In this first section, the domain of inquiry – diagrammatic reasoning in mathematics – and the issues at stake in exploring it will be defined.

First of all, a clarification is needed on the meaning of the term *diagram* in diagrammatic reasoning, so as to avoid misinterpretations. Throughout the chapter – and possibly in contrast with other views – the term will be used in a very broad sense, that is, to include all cases of two-dimensional representations where their two dimensionality is relevant for the way in which information is displayed and read off from them. This seemingly too vague definition is actually appropriate to refer to many different phenomena that are found in mathematics. Moreover, diagrams will be intended here as *cognitive tools* that are meant to spatially display information in order to improve memory and promote inference, and not necessarily to depict mathematical objects. This will have two consequences: first, the focus of the analysis will be on diagrams and not on visualizations; second, lengthy discussions about the implications for the ontology of mathematics will be avoided. For these issues, one can refer among others to *Brown*, who claims that diagrams are not really pictures but rather “windows to Plato’s heaven” [22.1, p. 40], or to *Sherry*, who argues that some particular uses of diagrams make a realist view problematic [22.2].

Diagrammatic reasoning is surely relevant for human reasoning in general. As has been pointed out, human reasoning is *heterogeneous*: humans happen to rely on many different sorts of instruments with the aim of externalizing thought, diagrams being among them [22.3]. A common saying is that we are halfway to finding a solution to a problem when we are able to draw the right diagram for it. Nonetheless, in relation to mathematics, it is necessary to distinguish between mere sketches and diagrams. Sketches are certainly widespread and useful for the mathematician to reason about a problem or to communicate with one’s peers. However, they will not be the topic of this chapter, which will be devoted to diagrams as parts of a system of representation. Such diagrams obey some (more or less explicit) rules and their manipulation is controlled by the particular practice, in terms that will be defined later.

Not surprisingly, most analyses of diagrammatic reasoning in mathematics have dealt with Euclidean geometry, where the recourse to diagrams is so natural

and spontaneous that there is a tendency to take the presence and the effectiveness of diagrams for granted. Moreover, most diagrams in Euclidean geometry become part of our *visual repertoire* from a very early age at school. Think of the *Pythagorean theorem* and the impressive number of so-called *visual proofs* that have been given for it [22.4]. According to this theorem, the square of the hypotenuse ( $c$ ) of a right triangle equals the sum of the squares of its other two sides ( $a$  and  $b$ ). In letters,

$$a^2 + b^2 = c^2. \quad (22.1)$$

One of the possible visualizations for the Pythagorean theorem is offered in Fig. 22.1.

In Fig. 22.1a, four identical right triangles have been arranged into two rectangles. To obtain a square of side  $a + b$ , these two rectangles are added to two squares: one of side  $a$ , and the other of side  $b$ . In Fig. 22.1b, the same four triangles have been rearranged inside the square of side  $a + b$  and they now individuate another square of side  $c$ . By looking at the two diagrams together and by applying subtraction of the same objects – the four right triangles – to the same object – the square of side  $a + b$  – the Pythagorean theorem is obtained.

However, there are cases of diagrammatic reasoning that may be less obvious than in Euclidean geometry, for example, for statements about numerical properties. Consider the following *geometric series*

$$\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \dots = 1 \quad (22.2)$$

and its possible spatial arrangement in Fig. 22.2, in which each new rectangle or square drawn in the diagram – each new element added to the series – brings us closer to the square of area 1 (the example is taken from [22.1, pp. 36–38]).

As Brown points out, this *picture proof* should be contrasted with a traditional proof using  $\varepsilon$ - $\delta$  techniques. In such a proof, we first have to note that an infinite series converges to the sum  $S$  whenever the sequence of

Fig. 22.1a,b Pythagorean theorem

**Fig. 22.2** A geometric series

partial sums  $\{s_n\}$  converges to  $S$ . In this case, we have

$$\begin{aligned} s_1 &= \frac{1}{2}, & s_2 &= \frac{1}{2} + \frac{1}{4}, & s_3 &= \frac{1}{2} + \frac{1}{4} + \frac{1}{8}, \\ s_n &= \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \dots + \frac{1}{2^n}. \end{aligned} \quad (22.3)$$

The values of these partial sums are

$$\frac{1}{2}, \frac{3}{4}, \frac{7}{8}, \dots, \frac{2^n - 1}{2^n}. \quad (22.4)$$

This infinite sequence has the limit 1, provided that for any number  $\varepsilon > 0$ , no matter how small, there is a number  $N(\varepsilon)$ , such that whenever  $n > N$ , the difference between the general term of the sequence  $\frac{2^n - 1}{2^n}$  and 1 is less than  $\varepsilon$ .

In symbols,

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{2^n - 1}{2^n} &= 1 \\ \iff (\forall \varepsilon)(\exists N) n > N &\rightarrow \left| \frac{2^n - 1}{2^n} - 1 \right| < \varepsilon. \end{aligned} \quad (22.5)$$

By applying some algebra, one obtains

$$\left| \frac{2^n - 1}{2^n} - 1 \right| < \varepsilon \iff \left| \frac{-1}{2^n} \right| < \varepsilon \iff 2^n > \frac{1}{\varepsilon}$$

$$\iff \log_2 \frac{1}{\varepsilon} < n. \quad (22.6)$$

Let now  $N(\varepsilon) = \log_2 \frac{1}{\varepsilon}$ . As a consequence,

$$n > \log_2 \frac{1}{\varepsilon} \rightarrow \left| \frac{2^n - 1}{2^n} - 1 \right| < \varepsilon. \quad (22.7)$$

We have thus proven that the sum of the series is 1. Compare now the easiness of forming the belief that the sum of the series is 1 by looking at the diagram in Fig. 22.2 with the resources required to prove the same result in a traditional way. The topic of the chapter will thus not only be Euclidean geometry. Other studies will be presented that analyze the usefulness of diagrammatic reasoning also in other branches of mathematics.

For the sake of completeness, there exists also very interesting work on ancient mathematics other than in Greece, involving, in some cases, also visual tools [22.5, 6]. Nonetheless, for reasons of space and given the specificity of the research, these works will not be among the subjects of the present chapter. It must also be noted that analogous considerations about the importance of diagrammatic reasoning in mathematics can be made to logic. Many scholars have discussed diagrammatic reasoning in logic, in an interdisciplinary fashion. Some studies have focused on the cognitive impact of diagrams in reasoning [22.7] and others on the importance of heterogeneous reasoning in logical proofs [22.8] and on the characteristics of nonsymbolic, in particular diagrammatic, systems of representation [22.9]. Very recently, and coherently with what will be later said about diagrammatic reasoning in mathematics, it was claimed that different forms of representation in logic are complementary to one another, and that future research should look into more accurate road maps among various kinds of representation so that the appropriate one may be chosen for any given purpose [22.10]. However, for reasons of space and despite the numerous parallels with the case of mathematics, the use of diagrammatic reasoning in logic will not be a topic of the present chapter.

## 22.2 Diagrams and (the Philosophy of) Mathematical Practice

The subject of diagrammatic reasoning in mathematics has recently gained new attention in the philosophy of mathematics. By contrast, in the nineteenth and twentieth centuries, this topic was neglected and not considered to be of philosophical interest; the heuris-

tic power of diagrams in mathematics was never denied, but visual mathematical tools were commonly relegated to the domain of psychology or to the context of discovery – by referring to a distinction between the context of discovery and that of justification that was very pop-

ular and that has become more and more precarious in recent years.

Famously, among others, *Russell* criticized Euclidean geometry for not being rigorous enough from a logical point of view [22.11, p. 404ff]. Consider the very first proposition of the *Elements*, which corresponds to the diagram in Fig. 22.3. The proposition invites the reader to construct an equilateral triangle from a segment AB by tracing two circles with centers A and B, respectively, and then connecting the extremes of the segment with the point that is created at the intersection of the two circles. According to *Russell*, “There is no evidence whatever that the circles which we are told to construct intersect, and if they do not, the whole propositions fails” [22.11, p. 404]. The proposition does, in fact, contain an implicit assumption based on the diagram – the assumption that the circles drawn in the proposition will actually meet. From *Russell*’s and analogous points of view, diagrams do not entirely belong to the formal or logical level, and therefore they should be considered as epistemically fragile. If this is assumed, then a proof is valid only when it is shown to be independent from the corresponding diagram or figure. In order to save Euclidean geometry from the potential fallacies derived from the appeal of diagrams, such as the one just shown, some assumptions, sometimes called *Pasch axioms*, were introduced. For example, it is necessary to assume that *A line touching a triangle and passing inside it touches that triangle at two points*, so as to avoid the reference to the corresponding diagram and make it a logical truth. By contrast, prior to the nineteenth century, such assumptions were generally taken to be “diagrammatically obvious” [22.12, p. 46].

There were historical reasons for this kind of scepticism in relation to the use of visual tools in mathematics. At the end of the nineteenth century, due to progress in disciplines such as analysis and algebra on the one hand, and the development of non-Euclidean geometries on the other, the request for a foundation of

Fig. 22.3 Euclid, Proposition I.1

mathematics expressed a genuine mathematical need. Euclidean geometry was not the only logically possible geometry, and therefore it did not necessarily convey truth about the physical world: perception, motion, and superposition of figures had to be excluded as illegitimate procedures. In the course of the twentieth century, this *search for certainty* – as *Giaquinto* called it – became a sort of philosophical obsession [22.13]. Figures were considered as definitely unreliable, since they did not any more represent our knowledge of physical space. Moreover, they give rise to errors. Famously, *Klein* presented a case of a diagram that is apparently correct, but which in fact induces one to draw the – false – conclusion that all triangles are isosceles triangles [22.14, p. 202]. Paradigmatic in this sense was *Hilbert*’s program, who attempted to rewrite geometry without any unarticulated assumptions [22.15]. For such post-nineteenth century philosophy of mathematics, a proof should be followed, not *seen*.

However, some studies based on the scrutiny of the practice of mathematics have recently challenged this standard point of view. As editors of a book on visualization, explanation, and reasoning styles in mathematics, *Mancosu* et al. explained in 2005 how it was necessary to extend the range of questions to raise about mathematics besides the ones coming from the traditional foundational programs. The focus should be turned toward the consideration of “what mathematicians are actually doing when they produce mathematics” [22.16, p. 1]:

“Questions concerning concept-formation, understanding, heuristics, changes in style of reasoning, the role of analogies and diagrams etc. have become the subject of intense interest. [...] How are mathematical objects and concepts generated? How does the process tie up with justification? What role do visual images and diagrams play in mathematical activity?”

This invitation to widen the topics of philosophical inquiry about mathematics has developed into a sort of movement, the so-called *philosophy of mathematical practice*, which also criticizes the “single-minded focus on the problem of *access* to mathematical objects that has reduced the epistemology of mathematics to a *torso*” [22.16, p. 1]. Epistemology of mathematics can venture beyond the present confines and address epistemological issues that have to do with [22.16, p. 1]

“fruitfulness, evidence, visualization, diagrammatic reasoning, understanding, explanation and other aspects of mathematical epistemology which are

orthogonal to the problem of access to *abstract objects*.”

This approach would be more in line with what at least some of the very practitioners seem to think about the practice of mathematics. As *Jones*, a topologist and former Field medallist, summarizes, it is quite usual among mathematicians to have very little understanding of its philosophical underpinnings; in his view, for a mathematician, it is actually not at all difficult to live with worries such as Russell’s paradox while having complete confidence in one’s mathematics [22.17].

In this perspective, the study of diagrammatic reasoning in mathematics thus resumes its philosophical interest, by taking into account the appropriate areas of mathematics. Before presenting the different analyses that have been provided about diagrammatic reasoning in mathematics, three features of diagrammatic reasoning that will characterize most of the studies reviewed should be pointed out. First, diagrammatic reasoning in mathematics is not only *visual* reasoning. In fact, in most cases, a diagram comes with a *text*, and, as a consequence, any analysis of diagrammatic reasoning cannot disregard the role of the text accompanying diagrams. In two very fascinating volumes, *Nelsen* collected a series of proofs, taken from the *Mathematics Magazine*, that he calls “without words” [22.18, 19]. Nonetheless, these proofs are not exactly “without

words,” since to use a diagram is not only a matter of applying specific perceptual capacities but also of mastering the relevant background knowledge. In *Nelsen*’s proofs, diagrams refer to mathematical statements that can in some way be *found* in them. Diagrams and texts are, in fact, related: each practice will in turn define the terms of this relation. Second, there is another sense in which diagrammatic reasoning is not only visual. In most cases, diagrams are *kinaesthetic* objects, that is, they are intended to be changed and manipulated according to practice. A diagram can be conceived as an experimental ground, where mathematicians are qualified to apply *epistemic actions*, which are – following *Kirsch* and *Maglio*’s definition – “actions that are performed to uncover information that is hidden or hard to compute mentally” [22.20]. Third, as will be discussed in the Conclusions, the philosophical interest in studying diagrammatic reasoning is due to the cognitively hybrid status of diagrams. In fact, diagrams are certainly related to text, but at the same time, they are more than a mere visual translation of it; moreover, they are not only synoptic images, but also tools subject to manipulation; finally, they are not only part of the process of discovery, but in the appropriate context of use they are also able to constitute evidence for justification. The inquiry into diagrammatic reasoning in mathematics will in the end force us to blur the standard boundaries between the various elements of the mathematical practice.

## 22.3 The Euclidean Diagram

A review of the literature on diagrammatic reasoning in mathematics has to start from the research on Euclidean geometry. This section will be thus focused in particular on some of the most influential studies on the role and use of diagrams in the Euclidean system, both from a historical and a cognitive perspective. Given the complexity of such a discussion, details beyond the consideration of diagrammatic reasoning in mathematics will not be treated.

The reason for devoting one whole section of the chapter to Euclidean geometry is that the Euclidean diagram has always been considered as the paradigm of diagrammatic reasoning in mathematics. As *Ferreiros* has proposed, the mathematical practice of Greek geometers summarized in the *Elements* can be considered as a theoretical study of practical geometry [22.21, Chap. 5]. Its theoretical nature comes not only from the new goals and values that are identified as guiding the practice, but also from the idealizations introduced. This picture of Greek geometry contrasts with the ab-

stract tendency of reflections on the subject since Pasch and Hilbert. I have already pointed out in Sect. 22.1 that the post-nineteenth century approach tried to formalize mathematical proofs in such a way that diagrams are not part of them. One of the consequences of such an attitude was to consider diagrams as simple heuristic tools that are possibly useful in illustrating a result, but not constitutive of it. Therefore, there was an interest in translating Euclid’s *Elements* – maybe the most widely read text in the entire history of mathematics – into formal sentences of quantificational logic, so as to show that the reference to implicit assumptions based on the diagram could be avoided. A common feature of the studies that will be presented in this section will be precisely to point out that such a move would not represent Euclidean geometry as was originally conceived. If this is true, then it is necessary to provide a plausible explanation for the way in which information that is relevant for the proof can be read off from an Euclidean diagram. The post-nineteenth century philos-

ophy of mathematics gave foundations of logic for what was implicitly assumed in reference to a particular diagram. But what is *implicit* in a diagram? What cognitive abilities are needed to recognize this information and use it in a proof? Some proposals gave a Kantian reading of the *spatial intuition* that is involved in reasoning with a Euclidean diagram, as, for example, in the works of *Shabel* [22.22] and *Norman* [22.23]. According to these views, in Euclid's time, spatial and visual intuition was considered as mathematically reliable, and tacit assumptions were warranted on *the basis of spatial and visual information*. Nonetheless, these works have a wider scope than that of the present chapter, that is, they aim to give evidence in favor of the plausibility of a Kantian philosophy of mathematics, or at least of part of it. For this reason, they will not be discussed here.

Despite the specificity of the Euclidean case, in the remainder of the chapter, it will become evident how some of the characteristics of diagrammatic reasoning in Euclidean geometry can also be adapted to other mathematical practices involving diagrams. As already mentioned, the literature about diagrammatic reasoning in ancient Greek geometry is vast. The studies presented here are among the most influential ones. For other works, one can refer to the bibliography at the end of the chapter and to the references given in the single studies.

### 22.3.1 The (Greek) Lettered Diagram

The first analysis that will be introduced is the original and fascinating contribution on the shaping of Greek deduction provided by *Netz* [22.12]. *Netz*' aim is to reconstruct a *cognitive history* of the use of diagrams and text in Greek mathematics. According to his definition, cognitive history lies at the intersection of the history of science and cognitive science: it is analogous to the history of science, because it takes into account cultural artifacts, but it is also comparable to cognitive science because it approaches knowledge not through its specific propositional contents but by looking at its forms and practice. In *Netz*' words, such an intersection is "an interesting but dangerous place to be in" [22.12, p. 7]. In fact, his worry is that historians might see his research as over-theoretical and too open to generalization, while cognitive scientists might consider it as too "impressionistic" [22.12, p. 7].

*Netz*'s idea, in line with the philosophical approach described in Sect. 22.1, is to look at specific practices and consider the influence that they might have (or might have had) on the cognitive possibilities of science. His case study is Greek geometry. Note that *Netz*' analysis concerns Greek geometry in general and, differently from the studies that will be presented be-

low, does not focus on Euclid only. He starts from the observation that despite the already discussed post-nineteenth century criticisms, when doing Euclidean geometry, one would find it difficult [22.12, p. 23]

"to *unsee* the diagram, to teach oneself to disregard it and to imagine that the only information there is is that supplied by the text. Visual information is itself compelling in an unobtrusive way."

Euclidean diagrams seem to be part of the visual repertoire of shapes and figures that we are familiar with. If this is the case, then any analysis of Euclidean geometry must take this fact into account. One possible strategy would be to try to reconstruct the geometric practice of the time and focus on what *Netz* believes is the distinctive mark of Greek mathematics, something that has not been developed independently by any other culture: the *lettered diagram*.

Following *Netz*' definition, the lettered diagram is a combination of distinct elements that taken together make it possible to generalize an argument that is given in a single diagram having specific geometrical properties. The lettered diagram can thus be considered at different levels. At the logical level, it is composed, as the name suggests, by a combination of the continuous – the diagram – and the discrete – the letters added to it. At the cognitive level, it is a mixture of the visual resources that are triggered by it, and the finite manageable models that the letters made accessible. By following *Peirce*'s distinction among icons, indexes, and symbols [22.24], the lettered diagram associates, at the semiotic level, an icon – the diagram – with some indices – the letters. As will be shown in the next sections, *Peirce*'s distinction will be a reference also for other studies on diagrammatic reasoning in mathematics. It is interesting to point out from now that the *Peircean* terminology, despite being a common background for many of these authors, is applied in a variety of ways to different elements of diagrammatic reasoning in mathematics. The lettered diagram can be considered also from an historical point of view. Against this background, the same diagram is a combination of two elements. First, it refers to an art related to the construction of the diagram which, in *Netz*' analysis, is most likely a *banausic* art, that is, a practical art serving utilitarian purposes only. Second, it exploits a form of very sophisticated reflexivity, which is related to the use of the letters. The lettered diagram is an effective geometric tool precisely because of the richness of these different aspects characterizing it. In a lettered diagram, we see how almost antagonistic elements are integrated, so as to make it the appropriate instrument to promote and justify deduction [22.12, p. 67].

In Netz' reconstruction, Greek mathematics is constituted by a whole set of procedures for argumentation. These procedures are based on the diagram, which consequently serves as a source of evidence. Thanks to the procedure described in the text accompanying the lettered diagram in Fig. 22.3, one knows that the circles will actually meet at the intersection point. An interesting consequence of this reading is that the lettered diagram supplies a universe of discourse, without referring to any ontological principle. According to Netz, this would be a characteristic feature of Greek mathematics: the proof is done at an object level – the level of the lettered diagram – and no abstract objects corresponding to it need to be assumed. As he explains, in Greek practice [22.12, p. 57]:

“One went directly to diagrams, did the dirty work, and, when asked what the ontology behind it was, one mumbled something about the weather and went back to work. [...] There is a certain single-mindedness about Greek mathematics, a deliberate choice to do mathematics and nothing else. That this was at all possible is partly explicable through the role of the diagram, which acted, effectively, as a substitute for ontology.”

This point on the ontology of the Euclidean diagram is not uncontroversial. Other studies dealing with the Euclidean practice consider it necessary to take into account the abstract objects to which, in a way to define, the diagrams seem to refer. For example, *Azzouni* conjectures that the Greek geometers had to posit an ontology of geometrical objects, even if, in his stipulationist reading, this drive was not motivated by sensitivity to the presence of anything ontologically independent from us that mathematical terms refer to, but rather by geometers' need to prove things in a greater generality and to make applications easier [22.25]. We will see later how Panza introduces quasi-concrete geometrical objects (Sect. 22.3.4).

In this perspective, the paradox that Netz has to solve is how to explain that one proof – done by referring to a particular diagram, inevitably having specific properties – can be considered as a general result. In his interpretation, a proof in the Greek practice is an event occurring on a papyrus or in a given oral communication, and, despite this singularity, is something that is *felt* to be valid. Nonetheless, validity must be intended here in a different sense than the standard one. When looking at Greek mathematics, and contrary to the post-nineteenth century philosophy of mathematics, logic seems to collapse back into cognition.

In order to reply to this challenge, Netz first points out that generality in Greek mathematics exists only on a *global* plane: a theorem is proved having the global

system of Greek mathematics as a background. Thanks to this feature, the proof can be considered as invariant under the variability of the single action of drawing one diagram on the papyrus or of presenting the particular proof orally. Therefore, in Greek mathematics, what counts is the *repeatability* of the proof rather than the *generalizability* of the result (for details, see [22.12, Chap. 5]). According to Netz, to understand Greek geometry, a change of mentality is required: while we are used to generalizing a particular result, Greek mathematicians were used to extending the particular proof to other proofs using other and different objects that are nonetheless characterized by the same invariant elements. A particular construction, given by the lettered diagrams – the diagram plus the text accompanying it – can be repeated, and this is considered as certain.

The lettered diagram was a very powerful tool, because it allowed Greek mathematicians to automatize and elide many of the general cognitive processes that are implied in doing geometry. This was connected to expertise: the more expert a mathematician was, the more immediately he became aware of relations of form and the more readily he read off information from the diagram. Interestingly enough, such a feature of the practice with the Greek diagrams seems to be found in other contemporary mathematical practices as well. As the topologist and former Field medallist *Thurston* has proposed, mathematicians working in the same field and thus familiar with the same practice share the same “mental model” [22.26], which seems to refer precisely to the structure of the particular field and the amount of procedures that can be automatized or elided. To sum up, the diagram is a static object, but it becomes kinaesthetic thanks to the language that refers to it as a constructed and manipulable object: the proof is based on a practical invariance. In Netz' careful analysis, this is the best solution to the problem of generality that could be afforded at the time, given the means of communication at hand. If this is true, then any reconstruction as formalization, such as the one proposed by Hilbert, would not be faithful to the Greek practice. Moreover, Netz argues that Greek mathematics did not deal with philosophical matters. In the sources, nothing like a developed theory supporting this solution can be found.

### 22.3.2 Exact and Co-Exact Properties

Netz' approach is not the only one based on practical invariances. Consider Manders' contribution in an article that has been – in *Mancosu's* words – “an underground classic” [22.27, p. 14] and that was finally published in 2008 (in its original version, which dates back to 1995) [22.28]. In a later introductory paper, *Manders*

presents some of the philosophical issues that emerge from diagrammatic reasoning in geometry [22.29]. For him, Euclidean practice deserves philosophical attention, even only for the simple reason that it has been a stable and fruitful tool of investigation across diverse cultural contexts for over 2000 years. Up to the nineteenth century, no one would have denied that such a practice was rigorous; by contrast, it was rather considered as the most rigorous practice among the various human ways of knowing. Also in Manders' view, the Euclidean practice is based on a distribution of labor between two artifact types – the diagram and the text sequence – that have to be considered together. Note that once again the notion of artifact comes onto the scene as referring to diagrams as well as to text, that is, natural language plus letters linking the text to the diagram. Humans, due to their limited cognitive capabilities, cannot control the production and the interpretation of a diagram so as to avoid any case of alternative responses to it. For this reason, the text is introduced with the aim of tracking equality information. As Manders explains, in practice, the diagram and the text share the responsibility of allowing the practitioners to respond to physical artifacts in a “stable and stably shared fashion” [22.28, p. 83].

In Manders' reconstruction, proofs in traditional geometry have two parts: one verbal – the *discursive text* – and the other graphical – the *diagram*. The very objects of traditional geometry seem to arise in the diagram: in his words, “We enter a diagonal in a rectangle, and presto, two new triangles pop up” [22.28, p. 83]. The text ascribes some features to the diagram, and these features are called *diagram attributions*. Letters are introduced to facilitate cross-references between the text and the diagram – also Manders' Euclidean diagram is *lettered*. Defining diagram attributions, Manders introduces a distinction between *co-exact* and *exact* features of the diagram that has become, as will be shown, very influential. A *co-exact* feature is a directly attributable feature of the diagram, which has certain perceptual cues that are fairly stable across a range of variations. Moreover, such a feature cannot be readily eliminated, thanks to what Manders calls *diagram discipline*, that is, the proper exercise of skill in producing diagrams that is required by the practice. To clarify, if one continuously varies the diagram in Fig. 22.3, its *co-exact* attributes will not be affected. Imagine deforming the two circles no matter how: this would not change the fact that there still is a point at which the two figures intersect. The distinction thus concerns the control that one can have on the diagram and on its possible continuous deformations. This would be in line with the basic general resource of traditional geometrical practice, that, is diagram discipline: the appearance of

diagrams is controlled by standards for their proper production and refinement. Diagram discipline governs the possible constructions.

Consider the features of the diagram of a triangle. Such a diagram would *have to be* a nonempty region bounded by three visible curves, and these curves are straight lines. The first property is *co-exact* and the second is *exact*. Paradigmatic *co-exact* properties are thus features such as a region containing another – unaffected if the boundaries are shifted or deformed – or the existence of an intersection point such as the one required in Euclid I.1, as already discussed. By contrast, *exact* features are affected by deformation, except in some isolated cases. If one varies the diagram of the equilateral triangle, lines might no longer be straight or angles might lose their equality. In this framework, what is typically alleged as *fallacy of diagram use* rests on reading off from a diagram *exact* conditions of this kind – for example, that the lines in a triangle are not straight. However, the practice – the diagram discipline – *never allows* such a situation to happen. As already mentioned, practitioners created the resources to control the recourse to diagrams, so as to allow the resolution of disagreement among alternative judgements that are based on the appearance of diagrams, and therefore to limit the risk of disagreement for *co-exact* attributions. Things become trickier when it comes to *exact* properties, and this is the reason why the text comes in as support. In fact, since *exact* attributes are, by definition, unstable under the perturbation of a diagram, they can be priorly licensed by the *discursive text*. To go back to Euclid I.1, that the curves introduced in the course of the proof are circles is licensed, for example, by Postulate 3; furthermore, it is recorded in the *discursive text* that other subsequent *exact* attributions are to be licensed, such as the equality of *radii* (by Definition 15, again in the *discursive text*).

To sum up, for Manders, the diagram discipline is such that it is able to supervise the use of appropriate diagrams. In the remainder of the chapter, it will be shown how Manders' ideas have influenced other research in diagrammatic reasoning also going beyond traditional Euclidean geometry.

### 22.3.3 Reasoning in the Diagram

*Macbeth* has proposed a reading of the Euclidean diagram that is in line with the ones that have just been presented [22.30]. For the purpose of the chapter, it is interesting to note that her aim in reconstructing the practice of Euclidean geometry is to see whether a clarification of the nature of this practice might ultimately tell us something about the nature of mathematical practice in general. She criticizes the interpretation of the

*Elements* as an axiomatic system and proposes to see it instead as a system of natural deduction. Common notions, postulates, and definitions are not to be intended as premises, but as *rules* or *principles* according to which to reason. Moreover, in her view, a diagram is not an instance of a geometrical figure, but an *icon*. Such a feature of the Euclidean diagram makes the demonstration in the Euclidean system general throughout.

In order to clarify such a claim, Macbeth introduces Grice's distinction between *natural* and *nonnatural* meaning [22.31]. For Grice, natural meaning is exemplified by sentences, such as *These spots mean measles*. By contrast, a sentence, such as *Schnee means snow*, expresses nonnatural meaning. Let us suppose then that a drawing is an instance of a geometrical figure, that is a particular geometrical figure. If this is the case, it would have natural meaning and a semantic counterpart. For example, in Fig. 22.3, one sees a particular triangle ABC that is one instance of some sort of geometrical entity called an *equilateral triangle*. But let us instead hypothesize that the drawing has nonnatural meaning and therefore is not an instance of an equilateral triangle but *is taken for* an equilateral triangle. Then, the crucial step would be to recognize the *intention* that is behind the making of the drawing. This is the reason one can also draw an imprecise diagram – for example, drawing a circle that looks like an ovoid – as long as the intention – the one of drawing a circle – is clear. Such an intention is expressed throughout the course of the demonstration. Also, Azzouni has suggested that the proof-relevant properties are not the actual (physical) properties of singular diagrammatic figures, but conventionally stipulated ones, the recognition of which is *mechanically executable* [22.25].

To sum up, in Macbeth's reconstruction, the Euclidean diagram has nonnatural meaning and is, by intention, general. Moreover, by following Pierce's distinction again, it is an icon because it *resembles* what it signifies. However, resemblance here cannot be intended as resemblance in appearance. The Euclidean diagram resembles what it signifies by displaying the same relations of parts, that is, by being *isomorphic* to it. The circles in Fig. 22.3 are icons of a geometrical circle because there is a likeness in the relationship of the parts of the drawings. Specifically, the resemblance is in the relation of the points on the drawn circumference to the drawn center compared to the relation of the corresponding parts of the geometrical concept. Such a resemblance can be a feature of the diagram because the geometer means or intends to draw a circle, that is, to represent points on the circumference that are equidistant from the center. Given this intention, it is not important whether or not the figure is precise, that is, whether or not the points on the circumference in the

drawn figure really look that way. There is a correspondence between the iconicity of the Euclidean diagram as introduced by Macbeth and co-exact properties in Manders' terms. Also in Macbeth's reading, the diagram is intended to show the relations that are constitutive of the various kinds of geometrical entities involved. As she summarizes, "A Euclidean diagram does not instantiate content but instead formulates it" [22.30, p. 250].

Finally, Macbeth aims to show that the chain of reasoning in Euclidean geometry involving diagrams is not diagram-based but *diagrammatic*. According to her terminology, a reasoning is diagram-based when its moves are licensed or justified by the diagram; by contrast, it is diagrammatic when the mathematician is asked to reason *in* the diagram. Consider again Fig. 22.3. There is a sense in which this figure is analogous to the Wittgensteinian duck–rabbit picture, where one alternates between seeing it as the picture of a duck and seeing it as the picture of a rabbit. In a similar fashion, in order for the demonstration to go through, the mathematician has to alternate between seeing certain lines in the figure as icons of *radii* – and therefore equal in length – and as icons of the sides of a triangle – so as to draw the conclusion that the appropriately constructed triangle is in fact equilateral. The point then is that the physical marks on the page have the potential to be regarded in radically different ways. By pointing at such a feature of the Euclidean diagram, Macbeth aims to make sense of Manders' view, saying that geometrical relations *pop out* of the diagram as lines are added to it. The mathematician uses the diagram to reason *in* it and to make new relations appear.

Moreover, according to Macbeth, the Euclidean diagram has three levels of articulation in the way it can be parsed by the geometer's gaze. At a first level, there are the primitive parts: points, lines, angles, and areas. At the second level, there are geometrical objects that are intended to be represented in the diagram. At the third level, there is the whole diagram, which is not in itself a geometrical figure but, in some sense, contains the objects at the other levels. In the course of the demonstration, the diagram can thus be configured and reconfigured according to different intermediate wholes. Thanks to such a function of diagrams, significant and often surprising geometrical truths can be proved. In Macbeth's account, the site of reasoning is the diagram, and not the accompanying text. Her conclusion is that Euclidean geometry is [22.30, p. 266]

"a mode of mathematical enquiry, a mathematical practice that uses diagrams to explore the myriad discoverable necessary relationships that obtain among geometrical concepts, from the most obvious to the very subtle."

Another more recent study has complemented Manders and Macbeth's account by emphasizing even more strongly how the Euclidean diagram has a role of *practical synthesis*: to draw a figure means to balance multiple desiderata, making it possible to put together insight – that is timeless – and constructions – that are given in time [22.32]. We also mention here that Macbeth has applied similar arguments to the role of Frege's *Begriffsschrift* as exhibiting the inferentially articulated contents of mathematical concepts [22.33]. Despite the interest of this account, for the reasons given in Sect. 22.1, we will not give here the details of such a study.

In Sect. 22.4, we will come back to the notion of iconicity and see how the productive ambiguity to which Macbeth alludes to in talking about the parsing of the Euclidean diagram can also be found in other cases of diagrammatic reasoning.

### 22.3.4 Concrete Diagrams and Quasi-Concrete Geometrical Objects

Another view on the generality of the Euclidean diagrams has recently been proposed by Panza [22.34]. His aim is to analyze the role of diagrams in Euclid's plane geometry, that is, the geometry as expounded by Euclid in the first six books of the *Elements* and in the *Data*, and as largely practiced up to early-modern age (see also [22.35]). In his view, Euclid's propositions are general insofar as they assert that there are some admitted rules that have to be followed in constructing geometric objects. Once again, what matters for generality are construction procedures. These admitted rules allow the geometer to construct an object having certain properties and relations. To put it briefly, it would be impossible for one to follow the rules and end up with constructing an object without the requested properties.

Panza argues that arguments in the Euclidean system are *about* geometrical objects: points, segments of straight lines, circles, plane angles, and polygons. Taking inspiration from Parsons [22.36], he defines such geometrical objects as *quasi-concrete*. Their quasi-concreteness depends precisely on the relation they have with the relevant diagrams, which are instead *concrete* objects: the Euclidean diagram is a configuration of points and lines, or better is what is common to equivalence classes of such configurations. Two claims describe the peculiarity of the relation between quasi-concrete geometrical objects and concrete diagrams. First, the identity conditions of the geometrical objects are provided by the identity conditions of the diagrams that represent them. In his definition, this is the *global* role of diagrams in Euclid's arguments: a diagram is taken as a starting point of licensed procedures for

drawing diagrams and a geometrical object can be given in the Euclidean system when a procedure is stipulated for drawing a diagram representing it. Second, the geometrical objects inherit some properties and relations from these diagrams. This is the *local* role of Euclidean diagrams. Such properties and relations are recognized because a diagram is compositional. So understood, a diagram is a configuration of concrete lines drawn on an appropriate flat material support. According to Panza, Euclid's geometry is, therefore, neither an empirical theory nor a contentual one in Hilbert's sense, that is, a theory of "extra-logical discrete objects, which exist intuitively as immediate experience before all thought" [22.37, p. 202]. In his view, differently from the approaches described so far, it is crucial to define an appropriate ontology for the Euclidean diagram. In fact, his objective is to argue against the view that arguments in Euclid's geometry are not about singular objects, but rather about something like general schemas, or only about concepts. Such a view, according to which Euclidean geometry would deal with purely ideal objects, is often taken to be Platonic in spirit and is supposed to have been suggested by Proclus [22.38, 39]. Panza's proposal is instead closer to an Aristotelian view that geometric objects result by abstraction from physical ones, but the author claims that it is not his intention to argue that Euclid was actually guided by an Aristotelian rather than a Platonic insight.

In the same spirit, also Ferreiros suggests that the objects of Greek geometry are taken to be the diagrams and other similarly shaped objects [22.21, Chap. 5]. Of course, the diagram in this context is not intended to refer to the physically drawn lines that are empirically given, but to the *interpreted* diagram, which is perceived by taking into account the idealizations and the exact conditions conveyed in the text and derived from the theoretical framework in the background. For the geometer, the figure one works with is not intended as an empirical token but as an ideal type. Nonetheless, it is crucial to remark that such an ideal type does not exist outside the mind of the geometer and becomes available only thanks to the diagram. Therefore, on the one hand, the object of geometry is the diagram, and, as a consequence, the diagram *constitutes* the object of geometry; on the other hand, the diagram has to be interpreted in order to make the object emerge, and accordingly it also *represents* the object of geometry. Moreover, quoting Aristotle, Ferreiros points out that Greek geometry remains a form of theoretical and not practical geometry, for the reason that its objects are conceived as *immovable and separable*, without this necessarily leading to the thesis that there exist *immovable and separable* entities [22.40].

## 22.4 The Productive Ambiguity of Diagrams

This brief section will be devoted to the discussion of the role of ambiguity in diagrammatic reasoning. Grosholz has devoted her work to develop a pragmatic approach to mathematical representations, by arguing that the appropriate epistemology for mathematics has to take into account the pragmatic as well as the syntactic and semantic features of the tools that are used in the practice of mathematics. The post-nineteenth century philosophy of mathematics wants all mathematics to be reduced to logic; by contrast, Grosholz claims that philosophy should account for all kinds of mathematical representations, since they are all means to convey mathematical information. Moreover, the powers and limits of each of them should be explored. One format might be chosen among the others for reasons of convenience, depending on the problem to solve in the context of a specific theory or in a particular historical moment. Even the analysis of the use of formal language can thus be framed in terms of its representational role in a historical context of problem-solving. As Grosholz explains [22.41, p. 258],

“Different modes of representation in mathematics bring out different aspects of the items they aim to explain and precipitate with differing degrees of success and accuracy.”

In such a picture, a central cognitive role is played in mathematics by a form of controlled and highly structured ambiguity that potentially involves all representations, and is particularly interesting in the case of diagrams. Grosholz as well adopts the general Peircean terminology and distinguishes between *iconic* and *symbolic* uses of the same representation. These two different uses make representations potentially ambiguous.

To clarify, consider as an example Galileo’s treatment of free fall and projectile motion in the third and fourth days of his *Discourses and Mathematical Demonstrations Concerning Two New Sciences*. Galileo draws a geometrical figure to prove that (Fig. 22.4),

“The spaces described by a body falling from rest with uniformly accelerated motion are to each other as the squares of the time-intervals employed in traversing these distances.”

In the right-hand figure, the line HI stands for the spatial trajectory of the falling body, but is articulated into a sort of ruler, where the intervals representing distances traversed during equal stretches of time, HL, LM, MN, etc., are indicated in terms of unit intervals, which are represented by a short cross-bar, and

in terms of intervals, whose lengths form the sequence of odd numbers (1, 3, 5, 7, . . .), which are represented by a slightly longer cross-bar. The unit intervals are intended to be counted as well as measured. In the left-hand figure, AB represents time, divided into equal intervals AD, DE, EF, etc., with perpendicular instantaneous velocities raised upon it – EP, for example, represents the greatest velocity attained by the falling body in the time interval AE – generating a series of areas which are also a series of similar triangles. Thanks to an already proven result from Th. I, Prop. 1, Galileo builds the first proposition, according to which the distance covered in time AD (or AE) is equal to the distance covered at speed  $1/2$  DO (or  $1/2$  EP) in time AD (or AE). Therefore, the two spaces that we are looking for are to each other as the distance covered at speed  $1/2$  DO in time AD and the distance covered at speed  $1/2$  EP in AE. Th. IV, Prop. IV tells us that “the spaces traversed by two particles in uniform motion bear to one another a ratio which is equal to the product of the ratio of the velocities by the ratio of the times”; in this case, given the similarity of the triangles ADO and AEP, AD and AE are to each other  $1/2$  DO and  $1/2$  EP. Then, the proportion between the two velocities compounded with the time intervals is equal to the proportion of the time intervals compounded with the time intervals, and therefore  $[V_1 : V_2]$  compounded with  $[T_1 : T_2]$  equals  $[T_1 : T_2]^2$ . As a consequence, the spaces described by the falling body are proportional to the squares of the time intervals:  $[D_1 : D_2]^2 = [T_1 : T_2]^2$ . Look now at the left-hand diagram. Consider the sums

Fig. 22.4 Galileo, *Discorsi*, third day, naturally accelerated motion, Theorem II, Proposition II

$1 + 3 = 2^2$ ,  $1 + 3 + 5 = 3^2$ ,  $1 + 3 + 5 + 7 = 4^2$ , and so forth. These sums represent distances and are proportional to the squares of the intervals. Therefore, the time elapsed is proportional to the final velocity and the distance fallen will be proportional to the square of the final velocity.

Galileo's use of the diagram can be analyzed in relation to the different *modes of representation* that are employed to express his argument to prove the theorem. First, he refers to at least four modes of representation: proportions, geometrical figures, numbers, and natural language. Second, the same geometrical diagram serves as an icon and at the same time as a symbol. As an icon, it is configured in such a way that it can stand for a geometrical figure and exhibit patterns of relations among the data it contains. For example, when proportions are taken as finite, they are represented iconically. When the proportions are taken as infinitesimal (because one may take "any equal interval of time whatsoever" [22.41, p. 14]), the diagram is instead used as a symbol. In this case, the configuration of the diagram changes because it is now intended to represent dynamical, temporal processes. Therefore, despite the fact that an appropriate parsing of the diagram cannot represent iconically something that is dynamical or temporal, it can still do it symbolically. In Grosholz' view, the distinction between iconic and symbolic use of a mode of representation sheds light on the importance of semantics in mathematics. In fact, for a mode of representation to be intended not only iconically but also symbolically, the reference to some background knowledge is necessary. The representation does not have to be intended in its *literal* configuration but from within a more elaborated context of use, which provides a new interpretation and a new meaning for it. Galileo's diagram must thus be interpreted in two ways: intervals have to be seen as finite – so that Euclidean results can be applied – and also as infinitesimals – so as to represent accelerated motion. In the proof, errors are prevented by a careful use of ratios.

Compare this example with Macbeth's discussion of Euclid I.1 in the previous section. Here as well, there is only one set of diagrams, but, in order for the demonstration to go through, it must be read and interpreted in different ways. However, Macbeth and Grosholz employ Peirce's distinction in a different way. Macbeth

talks of Euclidean diagrams as icons for geometrical relations, while Grosholz refers to two possible different uses – iconic or symbolic – of the same diagram. Moreover, Macbeth's Gricean distinction between natural and nonnatural meaning does not coincide with the distinction between the literal and nonliteral – conventional – uses of the representation made here by Grosholz.

Grosholz' approach is not limited to diagrams in mathematics, unless one wants to say that all mathematical representations are diagrammatic. In fact, in her view, another straightforward example of productive ambiguity is Gödel's representation of well-formed formulas through natural numbers, whose efficacy stems from their unique prime decomposition. In her terminology, the peculiarity of Gödel's proof of incompleteness is that the numbers in it must stand iconically for themselves – so as to allow the application of number theoretic results – and symbolically for well-formed formulas – so as to allow transferring those results to the study of completeness and incompleteness of logical systems. Without going into details, it is sufficient to say that Grosholz points out that this particular case shows how much even logicians exploit the constitutive ambiguity of some of the representations they use. In her view, the recourse to ambiguous formats is, in fact, typical of mathematical reasoning in general, and this is precisely the feature of mathematics that has not been recognized by the standard post-nineteenth century approaches, which have focused on the possibility of providing a formal language that would avoid ambiguities. As Grosholz explains [22.41, p. 19]

"the symbolic language of logistics is allegedly an ideal mode of representation that makes all content explicit; it stands in isomorphic relation to the objects it describes, and that one-one correspondence insures that its definitions are 'neither ambiguous nor empty'."

In Grosholz's view, ambiguity and iconicity then seem to be not only a mark of diagrams such as Galileo's one, but also crucial features of mathematical representations – formulas not being an exception.

In the following sections, other examples of productive ambiguity and iconicity in contemporary mathematics will be given.

## 22.5 Diagrams in Contemporary Mathematics

As shown in the previous sections, most examples of diagrams that have been discussed in the literature so far are taken from the history of mathematics; furthermore, the focus has been on geometric diagrams. It is worth

mentioning here an interesting study by Chemla about Carnot's ideas on how to reach generality in geometry, where she analyzes Carnot's treatment of the so-called *theorem of Menelaus* [22.42]. In her reconstruction,

Carnot believes that, at least in the case of the theorem of Menelaus, the diagram must be considered as a configuration, appropriately chosen with the aim of finding the solution to the problem in question. As a consequence, the theorem no longer concerns a specific quadrilateral, but any intersection between a triangle and a straight line. Chemla claims that Carnot’s ideas were nonstandard at his time, because he introduced a way of processing information that relies on individuating what a general diagram is in opposition to a multitude of particular figures.

This section will be devoted to briefly introducing some works on diagrammatic reasoning in present-day mathematics. The studies have been divided into three categories: analysis, algebra, and topology. Differently from the Euclidean or the theory of number case, the examples taken from contemporary mathematics deserve much more technical machinery in order to be understood, that is, even only to introduce the diagram, much mathematics is required. For reasons of space, it is therefore impossible to give here all the mathematical details, and I invite the reader to refer to the original papers.

### 22.5.1 Analysis

In two different articles, *Carter* analyzed a case study of diagrammatic reasoning in free probability theory, an area introduced by Voiculescu during the 1980s [22.43, 44]. The aim of free probability theory was to formulate a noncommutative analog to classical probability theory, with the hope that this would lead to new results in analysis. In particular, Carter discusses a section of a paper written by *Haagerup* and *Thorbjørnsen* [22.45], where a combinatorial expression for the expectation of the trace of the product of so-called *Gaussian random matrices* (GRMs) of the following form is found

$$E \circ \text{Tr}_n[B^* B^p]. \tag{22.8}$$

The authors show that this expression depends on the following

$$E \circ \text{Tr}_n[B_1^* B_{\pi(1)} \dots B_p^* B_{\pi(p)}]. \tag{22.9}$$

The indices  $\pi(i)$  are symbols denoting the values of a permutation  $\pi$  on  $\{1, 2, \dots, p\}$ . Therefore, the value of the expression depends on the existence and properties of the permutation that pairs the matrices off  $2 \times 2$ .

Diagrams can be introduced to represent the permutations, and this is a crucial move, since such diagrams make it possible to study permutations independently from the fact that they were set forth as indices of the GRM. Moreover, the recourse to diagrams makes it easier to evaluate the properties of the permutations. Once

the relevant properties of the permutation are identified, thanks to the diagram, they can then be reintroduced into the original setting.

To give an idea of what the diagrams representing permutations look like, consider two examples of constructing the permutation  $\hat{\pi}$ . Let  $p = 4$ , so that  $\pi : \{1, 2, 3, 4\} \rightarrow \{1, 2, 3, 4\}$ .

Instead of writing

$$B_1^* B_{\pi(1)} B_2^* B_{\pi(2)} B_3^* B_{\pi(3)} B_4^* B_{\pi(4)}, \tag{22.10}$$

we rewrite the expression in the following form

$$C_1^* \cdot C_2 \cdot C_3^* \cdot C_4 \cdot C_5^* \cdot C_6 \cdot C_7^* \cdot C_8. \tag{22.11}$$

Suppose then that  $\pi(1) = 2$  and  $\pi(3) = 4$ , giving

$$B_1^* \cdot B_2 \cdot B_2^* \cdot B_1 \cdot B_3^* \cdot B_4 \cdot B_4^* \cdot B_3. \tag{22.12}$$

What the permutation  $\hat{\pi}$  is supposed to do is to tell us which of the  $C_s$  are identical, in terms of their indices. By comparing the two expressions, we see that  $C_1 = C_4$ ,  $C_2 = C_3$ ,  $C_5 = C_8$ , and  $C_6 = C_7$ . In terms of the permutation  $\hat{\pi}$ , this means that  $\hat{\pi}(1) = 4$  and  $\hat{\pi}(2) = 3$ , and so on. Both permutations can be represented by the diagrams in Fig. 22.5.

Another example could be  $\pi(1) = 3$  and  $\pi(2) = 4$ , giving

$$B_1^* \cdot B_3 \cdot B_2^* \cdot B_4 \cdot B_3^* \cdot B_1 \cdot B_4^* \cdot B_2. \tag{22.13}$$

By rewriting it in terms of  $C_i$ ’s and comparing again, we obtain  $C_1 = C_6$ ,  $C_2 = C_5$ ,  $C_3 = C_8$ , and  $C_4 = C_7$ , as shown in Fig. 22.6.

First, diagrams would suggest definitions and proof strategies. In Carter’s example, the definitions of a pair of neighbors, or of a noncrossing and a crossing permutation as well as of cancellation of pairs – manipulations that are all clearly visible in the diagrams – are *inspired* by them. Moreover, as confirmed by the very authors of the study, also the formal version of at least a part of the proofs is inspired by the proof based on

Fig. 22.5 (a)  $\pi$  is the permutation (12)(34); (b) the correspondent  $\hat{\pi}$

Fig. 22.6 (a)  $\pi$  is the permutation (13)(24); (b) the correspondent  $\hat{\pi}$

diagrams. Second, diagrams function as *frameworks* in parts of proofs: Although they are not used directly to give rigorous proofs, they still play an essential role in the discovery and formulation of both mathematical theorems and proofs, and thus in the practice of the mathematical reasoning.

Carter's idea is that certain properties of the diagrams correspond to formal definitions. In her case study, some diagrams are used to represent permutations and similar diagrams to represent equivalence classes. Diagrams thus make it possible to perform *experiments* on them; for example, the crossings identify the number of the equivalence classes and therefore the definition of a crossing is given an algebraic formulation. Likewise, the concepts of a neighboring pair and of removing pairs (from the diagram) are translated into an algebraic setting. To sum up, the relations used in the proof based on the diagram represent relations that *also* hold in the algebraic setting. As Carter explains, the notions of crossing and neighboring pairs are, in Manders-inspired terminology, examples of co-exact properties of the diagrams. In a Peircean semiotic perspective, the diagram in this case would again be *iconic*, and it is for this reason that one can translate the diagrammatic proof into an algebraic proof. In this example, from contemporary mathematics, we are in a sense certainly far from the Euclidean diagram, but we still see that the proof includes an accompanying text; only when the appropriate text is added, do text and diagram – taken together – constitute a proof. The text is also important to disambiguate diagrams that can be interpreted as representing different things (recall Manders' view on the Euclidean diagram).

In a more recent article, Carter discusses at length her reference to Peirce's terminology. Her reconstruction of Peirce's discussion of the use of representation in mathematics is based on some of the most recent studies about Peirce's mathematical philosophy [22.46]. Note that the central notion for Peirce is the one of *sign*, that is, in his words, "Something that stands for something else" [22.24, 2.228]. A sign can stand for something else not in virtue of some of its

particular features, but thanks to an interpretant that links the sign to the object. For Peirce, signs are then divided into three categories: icons, indices, and symbols; icons are signs in virtue of a relation of likeness with their objects, indices are actually connected to the objects they represent, and symbols represent an object because of a rule stipulating such a relation. Central to Peirce's conception of reasoning in mathematics is that all such reasoning is *diagrammatic* – and therefore iconic. Moreover, Peirce employs the term *diagram* in a much wider sense than usual. In his view, even spoken language can be diagrammatic. Consider a mathematical theorem that contains certain hypotheses. By fixing the reference with certain indices, it is possible to produce a diagram that displays the relations of these referents. In statements concerning basic geometry, the diagram could be a geometric diagram such as the Euclidean diagram. But in other parts of mathematics, it may take a different form. In Carter's view, the diagrams in her case study are iconic because they display properties that can be used to formulate their algebraic analogs. Moreover, the role of indices – the numbers – in the diagram is to allow for reinserting the result into its original setting. Once such a framework is assumed, then diagrams as well as other kinds of representations used in mathematics become an interesting domain of research. As already discussed when presenting Grosholz's work, the objects of inquiry extend from mathematical diagrams to mathematical signs – mathematical representations – in general, including, for example, also linear or two-dimensional notations. In the final section, we will say more about this issue. A further point made by Carter is that the introduced diagrams also enable us to break down proofs into manageable parts, and thus to focus on certain details of a proof. By using diagrams at a particular step of the proof, one needs only to focus on one component, thus getting rid of irrelevant information. In an unpublished paper, Manders makes a similar point by introducing the notions of responsiveness and indifference in order to address the topic of progress in mathematics [22.47]. In the following section, more details about this paper will be given.

It is interesting to note that Carter discusses a potential ambiguity of the term *visualization*, used as (i) representation, as in the example given, and as (ii) mental picture, helping the mathematician see that something is the case. In this second meaning, diagrams would be *fruitful frameworks* to trigger imagination. Carter's claim is that there is not a sharp distinction to be drawn here between concrete pictures and mental ones, but quite the opposite: a material picture may trigger our imagination, producing a mental picture, and

vice versa a mental picture may be reproduced by a concrete drawing. We will come back also to this issue later.

### 22.5.2 Algebra

Another case study from contemporary mathematics is taken from a relatively recent mathematical subject: *geometric group theory*. Starikova has discussed how the representation of groups by using *Cayley graphs* made it possible to discover new geometric properties of groups [22.48, 49]. In this case study, groups are represented as graphs. Thanks to the consideration of the graphs as metric spaces, many geometric properties of groups are revealed. As a result, it is shown that many combinatorial problems can be solved through the application of geometry and topology to the graphs and by their means to groups.

The background behind Starikova's work is the analysis proposed by Manders in the unpublished paper already mentioned in presenting Carter's work [22.47]. In this paper, Manders elaborates more on his study on Euclidean diagrams, this time taking into account the contribution of Descartes' *Géométrie* compared to Euclid's plane geometry. He gives particular stress to the introduction of the algebraic notation. In fact, in mathematical reasoning, we often produce and respond to artifacts that can be of different kinds: natural language expressions, Euclidean diagrams, algebraic or logical formulas. In general, mathematical practice can be defined as the control of the *selective responses* to given information, where response is meant to be *emphasizing* some properties of an object while *neglecting* others. According to Manders, artifacts help to implement and control these selective responses, and therefore their analysis is crucial if the target is the practice of the mathematics in question. Moreover, selective responses are often applied from other domains. Think of the introduction of algebraic notation to apply fast algebraic algorithms. In Descartes' geometry, geometric problems are solved through solving algebraic equations, which represent the geometric curves. Also here, the idea is that by using different representations of the same concepts, new properties might become noticeable. Starikova's study would show a case where a change in representation is a valuable means of finding new properties: drawing the graphs for groups would help discovering new features characterizing them. In this perspective, mathematical problem-solving involves the creation of the right strategies of selection: at each stage of practice, some information is taken into account and some other information is disregarded. It is only by responding to some elements coming from the mathematical context and not paying attention to others that we can control

each step of our reasoning. Of course, this control and coordination may have different levels of *quality* across practices. Manders' conclusion is that mathematical progress is based on this coordinated and systematic use of responsiveness and indifference, and that such a coordination is implemented by the introduction and the use of the various representations. The role of the accompanying text is still crucial, since diagrams are produced according to the specifications in the text. Thanks to the text, the depicted relations become reproducible and therefore stable; diagram and text keep supporting each other.

To give the reader an idea of what a Cayley graph for a group looks like, we consider first the definition of a *generating set*. Let  $G$  be a group. Then, a subset  $S \subseteq G$  is called a generating set for the group  $G$  if every element of  $G$  can be expressed as a product of the elements of  $S$  or the inverses of the elements of  $S$ . There may be several generating sets for the same group. The largest generating set is the set of all group elements. For example, the subsets  $\{1\}$  and  $\{2, 3\}$  generate the group  $(\mathbb{Z}, +)$ .

A group with a specified set of generators  $S$  is called a *generated group* and is designated as  $(G, S)$ . If a group has a finite set of generators, it is called a *finitely generated group*. For example, the group  $\mathbb{Z}$  is a finitely generated group, for it has a finite generating set, for example,  $S = \{1\}$ . The generated group  $\mathbb{Z}$  with respect to the generating set  $\{1\}$  is usually designated as  $(\mathbb{Z}, \{1\})$ . The group  $(\mathbb{Q}, +)$  of rational numbers under addition cannot be finitely generated. Generators provide us with a *compact* representation of finitely generated groups, that is, a finite set of elements, which by the application of the group operation gives us the rest of the group.

We can now define a Cayley graph. Let  $(G, S)$  be a finitely generated group. Then the Cayley graph  $\Gamma(G, S)$  of a group  $G$  with respect to the choice of  $S$  is a directed colored graph, where vertices are identified with the elements of  $G$  and the directed edges of a color  $s$  connect all possible pairs of vertices  $(x, sx)$ ,  $x \in G$ ,  $s \in S$ .

In the following, we can see three examples of Cayley graphs: the Cayley graph for the first given example,  $(\mathbb{Z}, \{1\})$ , that is, an infinite chain (Fig. 22.7), another Cayley graph for the same group  $\mathbb{Z}$  with generators  $\{1, 2\}$ , which can be depicted as an infinite ladder (Fig. 22.8), and finally the Cayley graph for the group  $(\mathbb{Z}\{2, 3\})$  (Fig. 22.9). By *geometric* properties of groups, Starikova intends the properties of groups that can be revealed by thinking of their corresponding Cayley graphs as metric spaces. In other words, the idea is to look at groups *through* their Cayley graphs and try to see new (geometric) properties of groups, and then

Fig. 22.7 The Cayley graph of the group  $(\mathbb{Z}\{1\})$

Fig. 22.8 The Cayley graph of the group  $(\mathbb{Z}\{1, 2\})$ , where bold stands for  $\{1\}$

Fig. 22.9 The Cayley graph of the group  $(\mathbb{Z}\{2, 3\})$ , where bold stands for  $\{3\}$

to return to the algebra and check which groups share these properties and under which constraints. Many of these geometric properties turn out, in fact, to be independent from the choice of generators for a Cayley graph. For this reason, they are considered to be the properties of the groups themselves. Such a practice of introducing graphs to represent groups makes it possible to place groups in the same research–object category as classical metric spaces. This can happen because, in Manders’s terminology, we can be indifferent to the discrete structure of the group metric space and at the same time respond to the perceptual similarity of particular Cayley graphs having the same metric space. These responses would be unavailable to the combinatorial approach. Moreover, when responding geometrically to Cayley graphs, we perceive them as objects embedded in a space and having geometric elements. But then the response is *modified*, and some diagrammatic features are neglected in order to highlight more abstract properties. By introducing Cayley graphs, a group theorist thus has the opportunity to use them to define a metric of the group and then exploit its geometry, to define geometric counterparts to some algebraic properties of the group, and finally to clas-

sify groups having these geometric properties. This case study would show how sometimes the right choice of representation of an abstract object might lead to a significant development of a key concept.

### 22.5.3 Topology

Other case studies from contemporary mathematics concern topology.

The first one focuses on the identification and the discussion of the role of diagrammatic reasoning in *knot theory*, a branch of topology dealing with knots. A *knot* is a smooth closed simple curve in the Euclidean three-dimensional space, and a *knot diagram* is a regular projection of a knot with relative height information at the intersection points. *De Toffoli* and *Giardino* have discussed how knot diagrams are *privileged* points of view on knots: they display only a certain number of properties by selecting the relevant ones [22.50]. In fact, a single knot diagram cannot exhaust all the information about the knot type, and, for this reason, it is necessary to look at many diagrams of the same knot in order to *see* its different aspects. For example, both diagrams in Fig. 22.10 represent the unknot – that is, as the name suggests, a not knotted knot type – and we can transform the first into the second by *pulling* down the middle arc. However, this move alone does not allow us to conclude that both diagrams represent the unknot; to see that, we would have to apply further similar moves. In the article, a formalization for these possible modifications is provided.

The general idea behind this work is that diagrams are *kinaesthetic*, that is, their use is related to procedures and possible moves imagined on them. In topology, which is informally referred to as *rubber-band geometry*, a practitioner develops the ability to imagine continuous deformations. Manipulations of topological objects are guided by the consideration of concrete manipulations that would be performed on rubber or other deformable material. Accordingly, experts have acquired a form of imagination that prompt them to re-draw diagrams and calculate with them, performing “epistemic actions” [22.20]. This form of imagination

Fig. 22.10a,b Two nontrivial diagrams of the unknot

derives from our interaction with concrete objects and our familiarity with manipulating them. Moreover, the meaning of a knot diagram is fixed by its context of use: diagrams are the results of the interpretation of a figure, depending on the moves that are allowed on them and at the same time on the space in which they are embedded. Once the appropriate moves are established, the ambient space is fixed, thus determining the different equivalence relations. The context of use does not have to be predefined, preserving this kind of ambiguity that is not “damaging” [22.9], but productive. Actually, the indetermination of meaning makes different interpretations co-habit, and, therefore, allows attending to various properties and moves.

The same authors have also analyzed the practice of proving in low-dimensional topology [22.51]. As a case study, they have taken a specific proof: Rolfsen’s demonstration of the equivalence of two presentations of the Poincaré homology sphere. This proof is taken from a popular graduate textbook: *Knots and Links* by Rolfsen [22.52]. The first presentation of Poincaré homology sphere is a *Dehn surgery*, while the second one is a *Heegaard diagram* (Fig. 22.11).

Without going into the details, the aim of the authors is to use this case study to show that, analogously to knot theory, *seeing* in low-dimensional topology means imagining a series of possible manipulations on the representations that are used, and is, of course, modulated by expertise. Moreover, the actual practice of proving in low-dimensional topology cannot be reduced to formal statements without loss of intuition. Several examples of representationally heterogeneous reasoning – that is neither entirely propositional nor entirely visual – are given. Both the very representations introduced and the manipulations allowed on them – what the authors, following a terminology proposed by Larvor [22.53], call *permissible actions* – are epistemologically relevant, since they are integral parts both of the reasoning and the justification provided. To claim that inferences involving visual representations are permissible only within a specific practice is to consider them as context dependent. A consequence would be that it is no longer

Fig. 22.11a,b The surgery code and the Heegaard diagram for the Poincaré homology sphere

possible to establish general criteria for mathematical validity, since they can only be local. The picture of mathematics emerging from these kinds of studies is thus very different from the one proposed from the post-nineteenth century philosophy of mathematics.

A final remark about representations in topology concerns a point about their materiality, already raised by Carter in a different context. To avoid confusion, it is necessary to keep in mind the distinction between the material pictures and the imagination process, which, especially in the case of trained practitioners, tends to vanish. Actual topological pictures trigger imagination and help see modifications on them, but experts may not find it necessary to actually draw all the physical pictures. The same holds for algebra where experts skip transitions that nontrained practitioners cannot avoid writing down explicitly. This does not mean that experts do not need pictures to grasp the reasoning, but only that, thanks to training and thus to their familiarity with drawing and manipulating pictures, they are sometimes able to determine what these pictures would look like even without actually drawing them. More generally, for each subfield, it would be possible to define a set of *background pictures* that are common to all practitioners, which would determine what Thurston has called the *mental model*. To go back to Netz’ analysis of the Euclidean diagram, here as well diagrams allow for procedures to be automatized or elided.

## 22.6 Computational Approaches

In this section, studies about the possibility of automatizing diagrammatic reasoning in mathematics are briefly introduced. Such attempts are worth being mentioned because they start from the observation that diagrammatic reasoning is crucial, at least in some ar-

eas of mathematics, and furthermore that any possible formalization for it should reflect its straightforwardness and directness. We will introduce the attempts of developing an automated reasoning program for plane geometry and for theory of numbers in turn.

### 22.6.1 (Manders') Euclid Reloaded

The analysis and the definitions provided by Manders about Euclidean geometrical reasoning were used to establish a formalization for diagrams in line with what he calls the diagram discipline. Such a project has brought about the creation of two logical systems, *E* [22.54] and *Eu* [22.55, 56], thanks to the work of Avigad, Dean and Mumma. Both systems produce formal derivations that line up closely with Euclid's proofs, in many cases following them step by step. (Another system that has been created to formalize Euclidean geometry is *FG* [22.57]. For details about *FG* and *Eu* and for a general discussion of the project in relation to model-based reasoning, see Chap. 23.). As summarized in a recent paper [22.58], the proof systems are designed to bring into sharp relief those attributes that are fundamental to Euclid's reasoning as characterized by Manders in his distinction between exact and co-exact properties. Nonetheless, the distinction is made with respect to a more restricted domain.

The Euclidean diagram has some components, which can be simple objects, such as points, lines, segments, and circles, and more complex ones, such as angles, triangles, and quadrilaterals. These components are organized according to some relations, which are the diagram attributes. Exact relations are obtained between objects having the same kind of magnitude: for example, for any two angles, the magnitude of one can be greater than the magnitude of the other or the same. Co-exact relations are instead positional: for example, a point can lie inside a region, outside it, or on its boundary. Co-exact relations concerning one-dimensional objects exclusively, such as line segments or circles, are intersection and nonintersection, while those concerning regions, one-dimensional or two-dimensional, are containment, intersection, and disjointness. Take the diagram in Fig. 22.12, representing the endpoint *A* as lying inside the circle *H* (a co-exact property), along with a certain distance between the point *A* and the circle's center *B* (an exact property). (Consider that in reproducing the diagram from Mumma's original article, the co-exact features were not affected, while the exact ones probably were.) Following Manders, in a proof in Euclid's system, premises and conclusions of diagrammatic inferences are composed of co-exact relations between geometric objects. In Fig. 22.13, an inference is shown (Fig. 22.13a) together with one of its possible associated diagrams (Fig. 22.13b).

In order to develop a formal system for these inferences, the main tasks in developing the programs were two: first, to specify the formal elements repre-

Fig. 22.12 A Euclidean diagram depicting exact and co-exact relations

Fig. 22.13a,b An inference in Euclid's system according to Manders' reconstruction

sented co-exact relations; and second, to formulate the rules in terms of the elements whereby diagrammatic inferences can be represented in derivations. The main difference between *Eu* and *E* is how the first task is modulated. *Eu* possesses a diagrammatic symbol type intended to model what is perceived in concrete physical diagrams, while *E* models the information directly extracted from concrete physical diagrams by providing a list of primitive relations recording co-exact information among three object types: points, lines, and circles. In Fig. 22.14, the formalization in *Eu* of the inference in Fig. 22.13a is shown. In Fig. 22.15, the formalization of the same inference in *E* is shown, with the primitive *on(A, l)* meaning *point A is on line l*.

In addition, the formalizations do not only have formal elements corresponding to Euclidean diagrams, but also formal elements corresponding to the Euclidean text, so as to also record exact information. In order to give a proof, the two kinds of representations have to interact.

### 22.6.2 Theorem Provers

Not only formalizations of Euclidean geometry have been provided. Jamnik developed a semi-automatic proof system, called DIAMOND (*Diagrammatic Reasoning and Deduction*), to formalize and mechanize diagrammatic reasoning in mathematics, and in particular to prove theorems of arithmetic using diagrams [22.59]. Interestingly, Jamnik starts by recording a simple cognitive fact, that is that given some basic mathematical training and our familiarity with spatial manipulations – remember the study on knot theory – it suffices to look at the diagram representing a theorem to understand not only what particular theorem it represents, but also that it constitutes a proof for it. As a consequence, one arrives at the belief that the theorem is correct. From here, the question is: Is it possible to simulate and formalize this kind of diagrammatic reasoning on machines? In other words, is this an example of intuitive reasoning that is particular to humans and machines are incapable of?

The first part of Jamnik’s book provides a nice overview of the different diagrammatic reasoning systems that have been developed in the past century, such as, for example, *Gelernter’s Geometry Machine* [22.60] or *Koedinger and Anderson’s Diagram Configuration Model* [22.61]. For reasons of space, these systems will not be discussed here. In order to develop her proof system, she considers many different visual proofs in arithmetic and some of the analyses that have been given for them, by relying on the already mentioned collection edited by *Nelsen* [22.18, 19]. Such an analysis enables her to define a *schematic proof* as “a recursive function which outputs a proof of some proposition  $P(n)$  given some  $n$  as input” [22.59, p. 52].

Consider inductive theorems with a parameter, which, in Jamnik’s proposed taxonomy, are theorems where the diagram that is used to prove them represents one particular instance. An example of a theorem pertaining to this category is the *sum of squares of Fibonacci numbers*. According to this theorem, the sum of  $n$  squares of Fibonacci numbers equals the product of the  $n$ -th and  $(n + 1)$ -th Fibonacci numbers. In symbols,

$$Fib(n + 1) \times Fib(n) = Fib(1)^2 + Fib(2)^2 + \dots + Fib(n)^2. \quad (22.14)$$

The formal recursive definition of the Fibonacci numbers is given as

$$Fib(0) = 0, \quad Fib(1) = 1, \quad Fib(2) = 1, \\ Fib(n + 2) = Fib(n + 1) + Fib(n). \quad (22.15)$$

Fig. 22.14a–c The given inference in *EU*

a)	b)	c)
A, B points	on (A, m)	
l line	on (B, m)	intersects (l, m)
Not same side (A, B, l)		

Fig. 22.15a–c The given inference in *E*

Consider now Fig. 22.16. By looking at the spatial arrangement of the dots, we first take the rectangle of length  $Fib(n + 1)$  and height  $Fib(n)$ . Then, we split it in a square of magnitude  $Fib(n)$ , that is, the smaller side of the rectangle. We continue decomposing the remaining rectangle in a similar fashion until it is exhausted, that is, for all  $n$ . The sides of the created squares represent the consecutive Fibonacci numbers, and the longer side of every new rectangle is equal to the sum of the sides of two consecutive squares, which is precisely how the Fibonacci numbers are defined. As noted by Jamnik, the proof can also be carried out inversely, that is, starting from a square of unit magnitude ( $Fib(1)^2$ ) and joining it on one of its sides with another square of unit magni-

Fig. 22.16 Sum of squares of Fibonacci numbers

tude ( $Fib(2)^2$ ): we have a rectangle. Then we can take the rectangle and join to it a square of the magnitude of its longer side, so as to create another rectangle. The procedure can be repeated for all  $n$ .

The schematic diagrammatic proof for this theorem would then be a sequence of steps that need to be performed on the diagram in Fig. 22.16:

1. Split a square from a rectangle. The square should be of a magnitude that is equal to the smaller side of a rectangle (note that aligning squares of Fibonacci numbers in this way is a method of generating Fibonacci numbers, that is,  $1, 1, 1 + 1 = 2, 1 + 2 = 3, 2 + 3 = 5$ , etc.).
2. Repeat this step on the remaining rectangle until it is exhausted.

These steps are sufficient to transform a rectangle of magnitude  $Fib(n + 1)$  by  $Fib(n)$  to a representation of the right-hand side of the theorem, that is,  $n$  squares of magnitudes that are increasing Fibonacci numbers [22.59, p. 66].

## 22.7 Mathematical Thinking: Beyond Binary Classifications

The reader already acquainted with the topic of diagrammatic reasoning in mathematics might wonder why there has not yet been any explicit reference to the work of *Giaquinto*, who was undeniably one of the first philosophers to revive the attention toward mathematical visualization [22.62]. In one of his papers, we also find a nice overview of the literature concerning the possibility of obtaining rigorous proofs by reasoning diagrammatically [22.63]. The reason for this choice is that *Giaquinto* has not only been a pioneer in the renewed study of diagrammatic reasoning in mathematics, but also and even more interestingly he has given suggestions about the directions that future research should take. In this section, first his ideas on the role of visualization in mathematical discovery will be briefly presented, and then his proposal about how to consider mathematical thinking in general will be discussed (in the course of the final revisions of the present chapter, I discovered that *Giaquinto* recently published an entry on a topic that is related to ours, see for reference [22.64]).

As *Giaquinto* makes it clear, his original motivation for studying visual thinking in mathematics was to provide an epistemology of individual discovery and of actual mathematical thinking, so as to reopen the investigation of early thinkers from Plato to Kant, who indeed had as an objective to explore the nature of the individual's basic mathematical beliefs and skills.

A schematic proof is thus a schematic program which by instantiation at  $n$  gives a proof of every proposition  $P(n)$ . The constructive  $\omega$ -rule justifies that such a recursive program is indeed a proof of a proposition for all  $n$ . This rule is based on the  $\omega$ -rule, that is, an infinitary logical rule that requires an infinite number of premises to be proved in order to conclude a universal statement. The uniformity of this procedure is captured in the recursive program, for example,  $\text{proof}(n)$ . *Jamnik's* attempt is thus to formalize and implement the idea that the generality of a proof is captured in a variable number of applications of geometrical operations on a diagram, and as a consequence to challenge the argument according to which human mathematical reasoning is fundamentally noncomputational, and, therefore, cannot be automatized. Details about *DIAMOND's* functioning cannot be given here. We just point out that also in this case diagrammatic reasoning is interpreted as a series of operations on a particular diagram, which can be repeated on other diagrams displaying the same geometric features.

His strategy is thus first to acknowledge that there is more than one kind of thinking in mathematics, and then to assess the epistemic status of each of these kinds of mathematical thinking. For this reason, and as he himself admits, his view is in some sense much more *traditional* than many of the works produced by the post-nineteenth philosophers of mathematics. Discovery is a very crucial issue for the practice of mathematics and another topic that unfortunately has been neglected by post-nineteenth century approaches, which focused mainly on logic, proof, and justification. *Giaquinto* tries to give an account of the complexity of mathematical thinking, and to this aim he also inquires into fields of research other than philosophy, thus trespassing disciplinary boundaries. His belief is that cognitive science constitutes a new tool that can be helpful for understanding mathematical thinking: though cognition has always been the object of philosophy, the development of cognitive science surely represents an advantage for the philosophers of our century over the scholars of earlier times. Another discipline that could be an ally in disclosing mathematical thinking is mathematical education, traditionally categorized as an applied field unable to provide conclusive hints for theoretical research. Moreover, *Giaquinto* assigns an important role to history, both the history of mathematics and the history of philosophy.

The main epistemological thesis of the book is that there is no reason to assume a uniform evaluation that would fit all cases of visual thinking in mathematics, since visual operations are diverse depending on the mathematical context. Moreover, in order to assess this thesis, we do not need to refer to advanced mathematics: basic mathematics is already enough to account for the process of mathematical discovery by an individual who reasons visually. In fact, only the final part of the book goes beyond very elementary mathematics.

It should be mentioned that also Giaquinto defends a neo-Kantian view according to which in geometry we can find cases of synthetic a priori knowledge, that is cases that do not involve either analysis of meanings or deduction from definitions. In fact, he refers to the already mentioned study by *Norman*, which is neo-Kantian in spirit, as a strong case showing that following Euclid's proof of the proposition that the internal angles of a triangle sum to two right angles require visual thinking, and that visual thinking is not replaceable by nonvisual thinking [22.23]. Nonetheless, the focus in this section will be mostly on the last chapter of the book, where Giaquinto discusses how the traditional twofold division between *algebraic* thinking versus *geometric* thinking is not appropriate for accounting for mathematical reasoning. His conclusion, which can be borrowed also as a conclusion of the present chapter, is that there is a need for a much more comprehensive taxonomy for spatial reasoning in mathematics, which that would include operations such as visualizing motion, noticing reflection symmetry, and shifting aspects. In fact, if one considers thinking in mathematics as a whole, then there arises a sense of dissatisfaction with any of the common binary distinctions that have been proposed between algebraic thinking on the one hand and geometric thinking on the other; the philosopher's aim should be to move toward a much more discriminating taxonomy of kinds of mathematical reasoning.

Consider, for example, *aspect shifting* as precisely one form of mathematical thinking that seems to elude standard distinctions. Aspect shifting is the same cognitive ability that Macbeth describes in discussing the way in which the Greek geometer – and every one of us today who practices Euclidean geometry – reasoned in the Euclidean diagram. Take again the visual proof given in Sect. 22.1 for the Pythagorean theorem. As *Giaquinto* explains, it is possible to look at the square in Fig. 22.1b – that has letters in it, and, therefore, is a kind of *lettered diagram* – and see that the area of the larger square is equal to the area of the smaller square plus the area of the four right-angled triangles [22.62, pp. 240–241]. How do we acquire this belief? Giaquinto's reply is that first we have to reason *geometrically* and shift

between aspects, so as to recognize that the area of the square is both  $(a+b)^2$  and  $2ab+c^2$ . From here, we then have to proceed *algebraically* as follows

$$a^2 + 2ab + b^2 = 2ab + c^2, \quad a^2 + b^2 = c^2. \quad (22.16)$$

At this point, by looking back at the figure, we realize – *geometrically* again – that the smaller square is also the square of the hypotenuse of the right-angled triangle. Finally, from the formula, we conclude that the area of the square of the hypotenuse is equal to the sum of the squares of its other two sides. Then the question is: Is this argument as a whole to be considered as primary algebraic or geometric? It seems that neither of these two categories would be fully appropriate to capture it.

This is an interesting point also relative to other kinds of mathematical reasoning by means of some particular representation. Consider a notation that is used in topology and take as an example the *torus* that can be defined as a square with its sides identified. In order to obtain the torus from a square, we identify all its four sides in pairs. The square in Fig. 22.17a has arrows in it indicating the gluings, that is, the identifications. First, we identify two sides in the same direction, so as to obtain the *cylinder* (Fig. 22.17b); then, we identify the other two, again in the same direction: in Fig. 22.17c, one can see the torus with two marked curves, where the gluings, that is, the identifications, were made.

In discussing the role of notation in mathematics, *Colyvan* takes into consideration diagrams such as the one in Fig. 22.17a, and points out that this notation is “something of a halfway house between pure algebra and pure geometry” [22.65, p. 163]. In *Colyvan*'s view these diagrams are, on the one hand, a piece of notation, but, on the other, also an indication on how to construct the object in question. The first feature seems to belong to algebra, while the second to geometry. Moreover, note that if we identify two sides of the square

Fig. 22.17a–c Constructing the torus

in the same direction and the other two in the opposite direction, we obtain the *Klein bottle*, which is a very peculiar object, since it is three-dimensional but needs four spatial dimensions for its construction, and, even more interestingly, has no inside or outside. The Klein bottle demonstrates how powerful such a notation is: it leads to objects that would be otherwise considered as nonsense, and it also allows us to deduce their properties. As *Colyvan* summarizes, “Whichever way you look at it, we have a powerful piece of notation here that does *some genuine mathematical work for us*” ([22.65, p. 163], emphasis added). Diagrams, as well as other *powerful* notations, operate *at our place*. Moreover, at least some of them seem to be some kinds of *hybrid* objects, trespassing boundaries. They are geometric and algebraic at the same time.

Consider again the relations between the algebra of combinatorial groups and their geometry (Sect. 22.5.2). As *Starikova* tells us, first the combinatorial group theory was amplified with a geometric element – a graph –

where *geometric* refers mostly to geometric constructions as methods of geometry rather than algebra. But eventually this geometric element was significantly expanded and groups became geometric objects in virtue of their revealed geometric properties. The introduction of graphs thus provided mathematicians with a powerful instrument for facilitating their intuitive capacities and furthermore gave a good start for further intuitions which finally lead to advanced conceptual links with geometry and the definition of a broader geometric arsenal to algebra. Also in the knot theory example (Sect. 22.5.3), knot diagrams are shown to have at the same time diagrammatic and symbolic elements, and, as a consequence, their nature cannot be captured by the traditional dichotomy between geometric and algebraic reasoning. All this is to show that *Giaquinto’s* invitation to define a “more discriminating and more comprehensive” [22.13, p. 260] taxonomy for mathematical thinking going beyond twofold divisions is still valid, and that more on this topic needs to be done.

## 22.8 Conclusions

The objective of the present chapter was to introduce the different studies that have recently been devoted to diagrammatic reasoning in mathematics. The first topic discussed was the role of diagrams in Euclidean and Greek geometry in general (Sect. 22.3); then, the productive ambiguity of diagrams was defined (Sect. 22.4) and case studies in contemporary mathematics were briefly reviewed (Sect. 22.5). It has been shown how some attempts have tried to automatize diagrammatic reasoning in mathematics, in particular to formalize arguments in Euclidean geometry and proofs in theory of numbers (Sect. 22.6); finally, it has been argued that the attention to diagrammatic reasoning in mathematics can shed light on the fact that mathematics makes use of different kinds of representations that are so intertwined that it is difficult to draw sharp distinctions between the different subpractices and the corresponding reasoning (Sect. 22.7). We started from the study of diagrammatic reasoning and we arrived at the consideration of mathematical thinking as a whole, and of the role of notations and representations in it. Mathematicians use a vast range of cognitive tools to reason and communicate mathematical information; some of these tools are material, and, therefore, they can easily be shared, inspected, and reproduced. Specific representations are introduced in a specific practice and, once they enter into the set of the available tools, they may have an influence on the very same practice. This process plays a significant role in mathematics.

There is a last remark to make at the end of this survey, that is, that in diagrammatic reasoning, we have seen the continuity and the discreteness of space operating. Continuous was the space of the Euclidean diagram, discrete (at least in part) the space of the diagrams for Galileo’s theorem and for the sum of the Fibonacci numbers. Diagrammatic reasoning thus seems to have fundamentally a geometric nature, since it organizes space. Nonetheless, we have also shown that a diagram never comes alone, but always with some form of text giving indications for its construction or stipulating its correct interpretation. The relation between the diagram and text is defined each time by the specific practice. As a consequence, diagrams appear to be very interesting hybrid objects, whose nature cannot be totally captured by standard oppositions. They are cognitive tools available for thought, whose effectiveness depends on both our spatial and our linguistic cognitive nature.

**Acknowledgments.** My thanks go to the people quoted in the text, for their work and for the fruitful discussions in which I have taken part at recent conferences and workshops. I am particularly indebted to Mario Piazza and Silvia De Toffoli, with whom I have extensively reflected upon the topic of diagrammatic reasoning in mathematics. I am also grateful to Albrecht Heffer, who gave me the occasion of working on this chapter and to the *Université de Lorraine* and the *Région Lorraine* for having sustained my research.

## 23. Deduction, Diagrams and Model-Based Reasoning

John Mumma

A key piece of data in understanding mathematics from the perspective of model-based reasoning is the use of diagrams to discover and to convey mathematical concepts and proofs. A paradigmatic example of such use is found in the classical demonstrations of elementary Euclidean geometry. These are invariably presented with accompanying geometric diagrams. Great progress has been made recently with respect to the precise role the diagrams plays in the demonstrations, so much so that diagrammatic formalizations of elementary Euclidean geometry have been developed. The purpose of this chapter is to introduce these formalizations to those who seek to understand mathematics from the perspective of model-based reasoning.

The formalizations are named **FG** and **Eu**. Both are based on insights articulated in Ken Manders'

seminal analysis of Euclid's diagrammatic proofs. The chapter presents these insights, the challenges involved in realizing them in a formalization, and the way **FG** and **Eu** each meet these challenges. The chapter closes with a discussion of how the formalizations can each be thought to prespecify a species of model-based reasoning.

The formalization of mathematical knowledge has been a mainstay of the philosophy of mathematics since the end of the nineteenth century. The goals and assumptions characteristic of the enterprise are foundationalist. A piece of mathematics is formalized to obtain a clear view of it within the context of justification. The various lemmas, theorems and corollaries of the mathematics are translated into sentences of a fixed formal language, whereby it becomes possible to ascertain with precision the logical relationships of the lemmas, theorems and corollaries to one another and to a group of sentences distinguished as axioms. The end result is a picture of the how the mathematics is – or at least can be – grounded on a collection of its basic truths.

Formalization would thus seem to be of little use to those who seek to understand mathematics from the perspective of model-based reasoning. The goal from this perspective is to obtain a clear view of the mathematics within the context of discovery. What is of interest is how the lemmas, theorems, and corollaries of the mathematics came to be known in the first place. A fundamental premise is that the process is a *reasoning* process, where the reasoning involved is

different in kind from the strictly regulated procedures of inference prescribed by a formalization. Inference concerning some mathematical subject is driven by the reasoner's engagement with representations modeling  $X$ , rather than the logical form of sentences expressing claims about  $X$ . For a paradigmatic example of such an  $X$  consider elementary geometry. From the perspective of the tradition that investigates mathematical knowledge via formalization, what is fundamental are *sentences* expressing the axioms and theorems of elementary geometry in a fixed formal language. Geometric reasoning is depicted as a progression of sentences laid out along the rigid pathways defined by the formalization's rules. From the perspective of model-based reasoning, what is fundamental are the *diagrams* that model the geometric situations that the axioms and theorems concern. Geometric reasoning is an open-ended process in which mind and diagram interact.

A curious recent development has been the appearance of formalizations advanced to show that diagrams of elementary geometry can be understood as part of the formal syntax of the subject's proofs. These specifically

are the proof systems **FG** [23.1] and **Eu** [23.2]. Since the target of the formalizations is the use of diagrams in proving geometric theorems, one may think that they provide a model-based reasoning picture of mathematical proof. At the same time, by the very fact that they are formalizations, one may take them to miss what is important about geometric diagrams from the perspective of model-based reasoning. Perhaps the formal objects identified as geometric diagrams within them are best understood as sentences formulated with an unconventional notation.

In this chapter I present **FG** and **Eu** with the aim of illuminating their potential relevance to researchers

in model-based reasoning. For the presentation of a formal proof system closely related to **Eu** – termed *E* – see [23.3]. For a discussion of the utility of the analyses of **Eu** and *E* in understanding Euclidean diagrammatic reasoning from a cognitive perspective, see [23.4]. The formalizations are based on principles formulated in [23.5], *Ken Manders’* seminal analysis of Euclid’s diagrammatic proof method in the *Elements*. In the chapter’s first section I present this analysis. In the second, I sketch **FG** and **Eu** as formal proof systems. Finally, in the chapter’s third section, I advance an interpretation of the systems where each characterizes a kind of model-based reasoning.

## 23.1 Euclid’s Systematic Use of Geometric Diagrams

For most of its long history, Euclid’s *Elements* was the paradigm for careful and exact mathematical reasoning. In the past century, however, it has been just the opposite. Its proofs are often invoked to illustrate what rigor in mathematics does *not* consist of. Though some steps of Euclid’s proofs are respectable as logical inferences, a good many are not. With these, one cannot look only at the logical form of the claims in the proof and understand what underlies them. One is forced, rather, to look at the accompanying diagram. The modern opinion is that Euclid’s proofs exhibit deductive gaps at such places.

*Ken Manders* set out to explode this story in [23.5]. His analysis of Euclid’s diagrammatic proof method reveals that Euclid employs diagrams in a controlled, systematic way. It thus calls into question the common, negative assessment of the rigor of the *Elements*. Moreover, the specifics of Manders’ analysis suggest that Euclid’s proof can be understood to adhere to a formal diagrammatic logic.

The first step in understanding the role of diagrams in Euclid’s *Elements* is simply to recognize them as components of proofs, rather than as mere illustrations of the proofs’ sentences. Accordingly, Manders characterizes the proofs as proceeding along two tracks: a discursive one resulting in a sequence of assertions, and a graphic one resulting in a geometric diagram. A proof step within the discursive, or sentential, track consists of the addition of a new assertion to the sequence, and a proof step within the diagrammatic track consists of the addition of a new graphic object to the diagram. The graphic objects in the diagram are linked to assertions in the text via labels. Crucially, it is not just previous assertions that license the addition of a new assertion within the sentential track; the diagram can directly license such an addition as well.

Central to Manders’ account of how diagrams do this is his distinction between the *exact* and *co-exact* features of diagrams. Being drawn by human hands, Euclidean diagrams cannot fully realize the properties geometric lines and circles are conceived to possess. There are bound to be small variations from the ideal of perfectly straight lines and perfectly circular circles in the diagrams produced by ruler and compass. Manders defines as *co-exact* any attribute of a diagram that is stable under such variations or perturbations. Exact attributes are then whatever is not so stable. In a diagram in which a segment is extended from a vertex of a triangle to the side opposite the vertex, for example, the triangle’s containment of the segment is a *co-exact* attribute of the diagram. The precise ratio between the two angles induced by the segment is not.

Manders’ key observation is that Euclid’s diagrams contribute to proofs only through their *co-exact* attributes. Euclid never infers an exact attribute from a diagram unless it follows directly from a *co-exact* attribute. Geometric claims concerning other exact attributes either are assumed from the outset or are proved via a chain of inferences in the text. It is not difficult to hypothesize why Euclid would have restricted himself in such a way. It is only in their capacity to exhibit *co-exact* relations that diagrams seem capable of functioning effectively as symbols of proof. The exact relations depicted by diagrams are too refined to be easily reproducible and to support determinate judgments [23.5, Sect. 4.2.2].

For an example of how diagrams carry *co-exact* information for Euclid, consider the proof of proposition 5 of the *Elements*. The proposition states that all isosceles triangles have equal base angles. The proof as given in [23.6] is as follows:

*Proof:*

Let  $ABC$  be an isosceles triangle having the side  $AB$  equal to the side  $AC$ ; and let the straight lines  $BD$ ,  $CE$  be produced further in a straight line with  $AB$ ,  $AC$  (postulate 2).

I say that the angle  $\angle ABC$  is equal to the  $\angle ACB$ , and the angle  $\angle CBD$  to the angle  $\angle BCE$ .

Let a point  $F$  be taken at random on  $BD$ ; from  $AE$  the greater let  $AG$  be cut off equal to  $AF$  the less (proposition I, 3); and let the straight lines  $FC$ ,  $GB$  be joined (postulate 1).

Then, since  $AF$  is equal to  $AG$  and  $AB$  to  $AC$ , the two sides  $FA$ ,  $AC$  are equal to the two sides  $GA$ ,  $AB$ , respectively; and they contain a common angle, the angle  $\angle FAG$ . Therefore, the base  $FC$  is equal to the base  $GB$ , and the triangle  $AFC$  is equal to the triangle  $AGB$ , and the remaining angles will be equal to the remaining angles respectively, namely those which the equal sides subtend, that is, the angle  $\angle ACF$  to the angle  $\angle ABG$ , and the angle  $\angle AFC$  to the angle  $\angle AGB$  (proposition I, 4).

And, since the whole  $AF$  is equal to the whole  $AG$ , and in these  $AB$  is equal to  $AC$ , the remainder  $BF$  is equal to the remainder  $CG$ .

But  $FC$  was also proved equal to  $GB$ ; therefore the two sides  $BF$ ,  $FC$  are equal to the two sides  $CG$ ,  $GB$  respectively; and the angle  $\angle BFC$  is equal to the angle  $\angle CGB$ , while the base  $BC$  is common to them;

therefore the triangle  $BFC$  is also equal to the triangle  $CGB$ , and the remaining angles will be equal to the remaining angles respectively, namely those which the equal sides subtend; therefore angle  $\angle FBC$  is equal to the angle  $\angle GCB$ , and the angle  $\angle BCF$  to the angle  $\angle CBG$ .

Accordingly, since the whole angle  $\angle ABG$  was proved equal to the angle  $\angle ACF$ , and in these the angle  $\angle CBG$  is equal to the angle  $\angle BCF$ , the remaining angle  $\angle ABC$  is equal to the remaining angle  $\angle ACB$ ; and they are at the base of the triangle  $ABC$ . But the angle  $\angle FBC$  was also proved equal to the angle  $\angle GCB$ ; and they are under the base. ■

Two steps of the proof rely on the diagram. The first is the application of the equals-subtracted-from-equals rule (common notion 3 in the *Elements*) to infer the equality of lengths  $BF$  and  $CG$ , the second is the application of the same rule to infer the equality of angles  $\angle ABC$  and  $\angle ACB$ . A requirement for the correct application of the common notion is that certain co-exact containment relations hold. In order to apply equals-subtracted-from-equals in the last step for instance, angle  $\angle ABG$  is required to contain  $\angle ABC$  and  $\angle CBG$ , and angle  $\angle ACF$  is required to contain  $\angle ACB$  and  $\angle BCF$ . On Manders' account the diagram of the proof licenses the inference that these co-exact conditions are satisfied.

Generally, the results of elementary geometry depend on nonmetric positional relations holding between the components of a configuration. A method for proving the results, then, must provide a means for recording such information about a configuration, and grounding inferences with respect to it. According to Manders' account of Euclid's method, diagrams fulfill this function, and do so in a mathematically legitimate way – i. e., they do not compromise the rigor of the method.

## 23.2 Formalizing Euclid's Diagrammatic Proof Method

Both **FG** and **Eu** were created to flesh out Manders' account in formal terms by characterizing Euclid's diagrams as syntactic objects in a formal proof system. Carrying the project out amounts to three tasks:

1. The definition of a class of syntactical objects that serve to represent Euclid's diagrams in the formal system
2. The specification of the geometric information expressible with the formal diagrams of the system
3. The specification of a method for regulating the information expressible by formal diagrams of the system in geometric proofs.

The structure of the concrete diagrams accompanying presentations of Euclid's arguments defines the first task. The abstract formal diagrams of the formal proof system ought somehow to embody this structure. How the formal system accomplishes task 2 constitutes the system's analysis of Manders' notion of co-exactness. With such an analysis in place, the third task becomes possible. The method furnished by the proof system for employing diagrams in proofs must be geometrically sound relative to the geometric information expressed by the system's diagrams.

Below I describe how **FG** and **Eu** fulfill tasks 1)–3). Beforehand it is worth discussing in more detail what

task 3 involves, as its successful completion amounts to a solution of the *generality* problem surrounding Euclid's proofs.

The generality problem arises with Euclid's proofs because the diagram used for a proof is always a *particular* diagram. Euclid clearly did not intend his propositions to concern just the figure on display beside the proposition. They are applied in subsequent proofs to other figures which are not exact duplicates of the original. And so, for Euclid, consultation of the original diagram, with all its particular features, is somehow supposed to license a generalization. But Euclid leaves the process by which this is done obscure. And so we are left with some doubt as to whether the jump from the particular to general is justified. Even before the nineteenth century, when the legitimacy of Euclid's methods was taken for granted, philosophers recognized that there was something to be explained with this jump.

Manders' exact/co-exact distinction provides the basis for a partial explanation. The co-exact properties of a diagram can be shared by all geometric configurations in the range of a proof, and so in such cases one is justified in reading off co-exact properties from the diagram. In a proof about triangles for instance, variation among the configurations in the range of the proof is variation of exact properties – e.g., the measure of the triangles' angles or the ratios between their sides. They all share the same co-exact properties – i.e., they all consist of three bounded linear regions which together define an area.

This is not a full answer because Euclid's proofs typically involve constructions on an initial configuration type. With the proof of proposition 5, for example, a construction on a triangle is specified. In such cases, a diagram may adequately represent the co-exact properties of an initial configuration. But the result of applying a proof's construction to the diagram cannot be assumed to represent the co-exact properties of all configurations resulting from the construction. One does not need to consider complex geometric constructions to see this. Suppose for instance the initial configuration type of a proof is a triangle. Then the diagram

serves to represent the co-exact properties of this type. Suppose further that the first step of a proof's construction is to drop the perpendicular from a vertex of the triangle to the line containing the side opposite the vertex. Then the result of carrying this step out on the diagram, i.e.,

ceases to be representative. That the perpendicular falls within the triangle in the diagram is a co-exact feature of it. But there are triangles with exact properties different from the initial diagram where applying the construction step results in a perpendicular lying outside the triangle. For example, with the triangle

the result of applying the construction step is

And so, carrying out a Euclidean construction on a representative diagram can result in an unrepresentative diagram. If a formal system is to provide a compelling analysis of Euclid's diagrammatic proofs it must account for this in carrying out task 3.

### 23.2.1 The Formal System FG

#### Task 1 in FG: FG Diagrams

The four fundamental syntactical notions of **FG** are *frame*, *dot*, *solid segment*, and *dotted segment*. Every **FG** diagram possesses a frame, characterized as “a rectangular box drawn in the plane” [23.1, p. 22]). Within it dots, solid segments, and dotted segments can lie. The dots of an **FG** diagram are point-like graphic objects. Solid segments and dotted segments are one-dimensional graphic objects that do not intersect any other objects of the diagram and terminate either in dots or the diagram's frame. Solid segments serve to represent line segments, and dotted segments serve to represent arcs of circles. Accordingly, an **FG** diagram comes equipped with a partition on its set of solid segments and a partition on its set of its dotted segments. The *dlines* of the diagram are the components of the former partition, and the *dcircles* of the diagram are the components of the latter. See Fig. 23.1 for an example of an **FG** diagram.

Aside from the requirement that solid and dotted segments do not intersect anything (including themselves), there are no constraints imposed upon them. They are free to bend and curve any which way between the dots that bound them. Consequently, there is no upper bound on the number of times sets of such objects can intersect one another at dots within an **FG**

Fig. 23.1 Example FG diagram

frame. There are upper bounds, however, on the number of times Euclidean lines and circles can intersect one another in points. Two distinct lines, for instance, intersect in at most one point. Thus, so that dlines and dcircles intersect one another like Euclidean lines and circles, they are required to satisfy a variety of conditions. One of these conditions, for instance, ensures that two dlines do not intersect at more than one dot in an FG diagram. For the details see [23.1, Sect. 2.1]. As illustrated in the discussion of FG's completion of task 3 below, such conditions play an essential role in FG's formalization of Euclid's proofs.

### Task 2 in FG: Corresponding Graph Structures

These conditions notwithstanding, the FG definition of a diagram leaves room for a great deal of variation. Consider those FG diagrams with a fixed number of dots, dlines and dcircles – say  $k$ ,  $m$  and  $n$ . The range of ways such objects can differ from one another is vast. Task 2 within FG amounts to specifying which differences matter in proofs. The task, in particular, is to specify which differences among FG diagrams with  $k$  dots,  $m$  dlines, and  $n$  dcircles express geometric differences among planar configurations of  $k$  points,  $m$  lines and  $n$  circles.

This is done in topological terms. What matters about a FG diagram in a proof, roughly, are the way its dlines and dcircles divide the region defined by the frame into smaller connected regions, and the position (inside or outside) of its dots and dsegments relative to these regions. The notion making this precise is that of a FG diagram's *corresponding graph structure* [23.1, Sect. 2.2]. It is via this notion that the representational link is made between FG diagrams as proof symbols and Euclidean configurations as mathematical objects. Any Euclidean configuration of points, lines and circles can be understood as an FG diagram by enclosing the configuration within a suitably large rectangle. Consequently, any Euclidean configuration has its own corresponding graph structure (as any suitably large rectangle is decomposed into regions by the configuration in the same way that the frame of an FG diagram is decomposed by its dlines and dcircles). What an FG diagram represents, then, are all Euclidean

configurations that have the diagram's corresponding graph structure.

### Task 3 in FG: FG Case Analysis

The generality problem arises in FG as follows. The basic Euclidean operations of constructing a segment, extending a segment, and constructing a circle are paralleled within FG by the syntactic operations of adding a dline, extending a dline, and adding a dcircle. And so for any Euclidean construction there is a parallel FG construction. Yet Euclidean constructions, in general, do not yield unique corresponding graphs structures. Consequently, if we are given a Euclidean construction and produce an FG diagram  $D$  according to the parallel FG construction, we cannot assume that the corresponding graph structure of  $D$  is shared by all configurations produced by the construction. For a simple example, suppose that  $D'$  is the diagram

and a circle is constructed on the segment as radius to obtain  $D$

The Euclidean configurations that have  $D'$ 's corresponding graph structure are simply those consisting of a segment and a point off of it. Constructing a circle from the segment in each such configuration does not always result in a configuration with the corresponding graph structure of  $D$ . The point may not lie outside the circle.

The problem is resolved in FG via the implementation of a uniform case-branching method. Suppose that within an FG derivation a construction step is to be applied to a configuration represented by the diagram  $D'$ . In performing the construction step, one must not only add to  $D'$  the object of the construction step to obtain a diagram  $D$ . One must also produce diagrams for all FG cases that could result from the construction step, where the notion of 'FG case' is specified in terms of the notions of a corresponding graph structure and an FG diagram. Specifically, if  $E'$  is a diagram with the same corresponding graph structure as  $D'$  and  $E$  is an FG diagram obtained by adding the object of the construction step to  $E'$ , then the corresponding graph structure of  $E$  is an FG case of the construction step. Since the definition of an FG diagram does not require

dlines to be straight or dcircles to be circular, there may be **FG** cases that are not Euclidean cases – i. e., some corresponding graph structures may not be realized by any Euclidean configuration. But all Euclidean cases will be an **FG** case. And so a relation that appears in all **FG** cases of the construction step holds in all Euclidean cases of the construction step.

Accordingly, the **FG** method for isolating the invariant co-exact relations of a construction is to produce all **FG** cases of the construction, and determine which co-exact relations are obtained in all cases. Such a method is satisfactory, of course, only if there is a procedure for producing all the **FG** cases of the construction. *Miller* has implemented such a procedure in a computer program **CDEG**, the general principles behind which he describes in section 3.5 of [23.1]. To understand how the procedure works, consider the step in the construction of proposition I, 5 in which the segment from *F* to *C* is added. The configuration on which the construction is performed can be represented by the following **FG** diagram (the hashmarks in the diagram represent equality of lengths according to the standard convention).

The parallel construction step in **FG** is to add a dline connecting the points representing *F* and *G*. The cases that result from this step are individuated by the ways the new dline can snake through the regions of the corresponding graph structure of *D'*. If the dline were conceived simply as a one-dimensional curve, some of these cases would be

A dline, however, is a one-dimensional curve required to satisfy certain constraints. One of these, as pointed out above, is that a dline cannot intersect another dline in more than one dot. This eliminates all but the first and last case

Generally, **FG** cases can arise when a dline is added to a diagram, when a dcircle is added to a diagram, or when a dline is extended. For each possibility, the conditions on dlines and dcircles are such that the possible routes of the added element through the corresponding graph structure of the diagram are sufficiently restricted – i. e., the resulting **FG** cases are finite in number and can be systematically enumerated.

A side note: **FG** is a purely diagrammatic formal system. Thus, the techniques whereby one recognizes parts of an **FG** diagram (e.g., its dots) in terms of Euclid’s verbal presentation of a construction (e.g., *the point F*, *the point G*) are taken from the beginning to be external to it. As discussed in the next section, **Eu** is a heterogeneous system – i. e., it possesses both a diagrammatic and a sentential syntax. Sentential symbols label its diagrams, and formalize (to a certain extent) a means for relating sentential and diagrammatic representations. The labels also provide a means for classifying two diagrams as equivalent with respect to the geometric information they express. Nothing in the definition of **FG** diagrams prevents the development of a heterogeneous version of **FG** with these features.

### 23.2.2 The Formal System Eu

#### Task 1 in Eu: Eu Diagrams

Common to all **Eu** diagrams is a discrete two-dimensional array structure that serves to model the spatial background within which diagrammatic points, lines and circles are constructed. The arrays are square and of arbitrary finite dimension. An example is the  $7 \times 7$  array

The array elements are identified by their coordinates, with the lowest, left-most element having coordinates  $(0, 0)$  and the highest, right-most element in an  $n \times n$  array having coordinates  $(n - 1, n - 1)$ .

A point of an **Eu** diagram is a distinguished array element. An example of an **Eu** diagram with two points is

A linear element of an **Eu** diagram is a linear subset of its array elements – i. e., a subset of array elements whose coordinates satisfy a linear equation. The elements of a linear element can be further constrained by inequalities on its first or second coordinate. If there is one inequality to be satisfied the linear element is a ray; if there are two it is a segment. The linear element of the diagram below is a segment defined by the conditions:  $y = x + 1, 1 \leq x \leq 5$

Finally, a circle of an **Eu** diagram is a subset of array elements that form the perimeter of a convex polygon.

The correspondence between the abstract, formal diagrams of **Eu** and the concrete diagrams they model is not one-to-one, but many-to-one. Specifically, a single concrete diagram is modeled in **Eu** by a set of **Eu** diagrams with the same syntactic type. What is and is not possible with the concrete diagram modeled is determined by all **Eu** diagrams with the concrete diagram's syntactic type.

Roughly, having the same syntactic type means differing only with respect to the number of underlying array entries. Given a diagram  $\delta$  we can increase the number of array entries it contains while leaving the relative position of its objects within the array fixed. Since the resulting **Eu** diagram has the same objects with the same relative positions, it is taken to model the same concrete diagram  $\delta$  does.

The procedure of refinement addresses a worry one may have about the suitability of **Eu**'s diagrams. As discrete objects, they will fail in general to produce the intersection points that appear in Euclid's diagrams. For instance, in the diagram

we can join the points above and below the line to obtain the diagram

Given what this diagram is intended to represent, we ought to be able to produce an intersection point between the segment and the line. But the underlying array of the diagram is too coarse. An array entry does not exist where a point ought to be.

This can always be dealt with by refining an **Eu** diagram into one of the same syntactic type. The equation that characterizes a line (and the circumference of a circle) is linear, expressed in terms of the coordinates of the array entries. Since the arrays are discrete, the coefficients of the equation are always integers. Thus, the solution for two equations characterizing geometric elements of a diagram will always be rational.

This means that if two geometric elements ought to intersect but don't in a diagram, we can always find a diagram of the same syntactic type where they do. It will just be the original diagram with a more refined underlying array. In particular, if the original diagram has dimension  $n$  and the solution between the two equations is a rational with an  $m$  in its denominator, the new diagram will have dimension  $m(n - 1) + 1$ .

For the diagram above, then, adding the desired intersection point is a two-step process. First, the diagram is refined to an equivalent diagram of dimension 7.

Then the intersection point is added.

Another natural worry has to do with the circles of diagrams. The circles that appear in Euclid's diagrams actually appear circular. The circles of diagrams, however, are rectilinear. If Euclid exploits the circularity of his circles in his proofs, then the diagrams of **Eu** would fail to capture this aspect of Euclid's mathematics. Eu-

clid, however, never does this. All he seems to assume about circles is that they have an interior. Thus, with respect to the project of formalizing Euclid's proofs, **Eu** circles suffice. If on the other hand the circular appearance of Euclid's circles were deemed for other reasons to be important, the **Eu** syntax could be modified accordingly. **Eu** circles could be defined as regular polygons with, say, at least 1000 sides.

### Task 2: Semantic Equivalence

The relation *syntactic equivalence*, discussed above, serves to abstract from the features of **Eu** diagrams irrelevant to them as representations of concrete symbols. The relation of *semantic equivalence* serves to abstract from those features irrelevant to them as proof symbols. Two **Eu** diagrams carry the same information in a proof if and only if they satisfy the relation of semantic equivalence. It is an equivalence relation analogous to that of two **FG** having the same corresponding graph structure.

The relation is based ultimately on certain positional relations that can hold between pairs of objects in a diagram. For any two kinds of objects of an **Eu** diagram, we can stipulate a disjunctive range of mutually exclusive qualitative relations. For instance, with point  $p$  and circle  $c$  the range of relations stipulated are

$p$  lies inside  $c$ ,  $p$  lies on  $c$ ,  $p$  lies outside  $c$

Similarly, the relation range of a point and a linear element contains all the possible positions a point can have to a linear element. For a point  $p$  and a line  $l$  these are

$p$  on one side of  $l$ ,  $p$  on the other side of  $l$ ,  
 $p$  lies on  $l$

where sidedness is determined by labels on the end-arrows of  $l$  fixing the line's orientation. When the linear element  $l$  is a ray (or segment), the relation range contains the additional possibility (or possibilities) of  $p$  lying on an extension of  $l$ . The relation range for a line and circle lists the possible relations of tangency, intersection or nonintersection between them, and the relation range for two circles lists the possible relations of containment, tangency or intersection between them. Finally, the relation range between two linear elements is defined in terms of the positions of their endpoints and/or end arrows to one another.

The rough idea is that two diagrams are semantically equivalent if pairs of corresponding objects realize the same qualitative relation in the relation range stipulated for object types of the pair. More precisely,

semantic equivalence is a relation between *labeled Eu* diagrams. A labeling of an **Eu** diagram assigns variables to the points, circles and end arrows of the diagram. If the same variables label the same object types in two diagrams, then the labeling induces a one-to-one correspondence between the objects of the two diagrams. This is a precondition of semantic equivalence. The two diagrams are then semantically equivalent if corresponding pairs of objects realize the same relation in the appropriate relation range. For an example of two semantically equivalent **Eu** diagrams, see Fig. 23.2.

### Task 3: Single Diagram Proofs

The generality problem arises in **Eu** similarly to the way it does in **FG**. The syntactic operations that parallel the basic Euclidean operations do not in general preserve semantic equivalence. That is, applying the same syntactic operation to two semantically equivalent **Eu** diagrams does not in general result in two semantically equivalent **Eu** diagrams. In contrast to **FG**, however, **Eu** does not demand that every case be listed in the course of a geometric construction. A guiding ideal behind the design of **Eu** derivations is what could be called the *one proof-one diagram* conception of geometric proof. (The name is taken from [23.5]. In the second footnote of the paper *Manders* comments "Euclid, by and large, lives by *one proof, one diagram*" [23.5, p. 85]). According to it, a single diagram ought to be enough to establish a geometric proposition. Not all **Eu** derivations can be understood to correspond to proofs that rely on a single diagram. The formal system provides a framework, however, in which many of Euclid's proofs can be understood as such.

Within the framework, the task of establishing a geometric proposition with a single diagram divides into two subtasks. The first is the task of *producing* a geometric diagram as a concrete graphic object satisfying certain formal conditions. The second is the task of *reasoning* with the object produced. The reasoning consists, specifically, of verifying that certain qualitative positional relations exhibited by the diagram – such as the position of a segment within an angle – are representative of all the configurations within the scope of the proposition.

Fig. 23.2 Two equivalent **Eu** diagrams

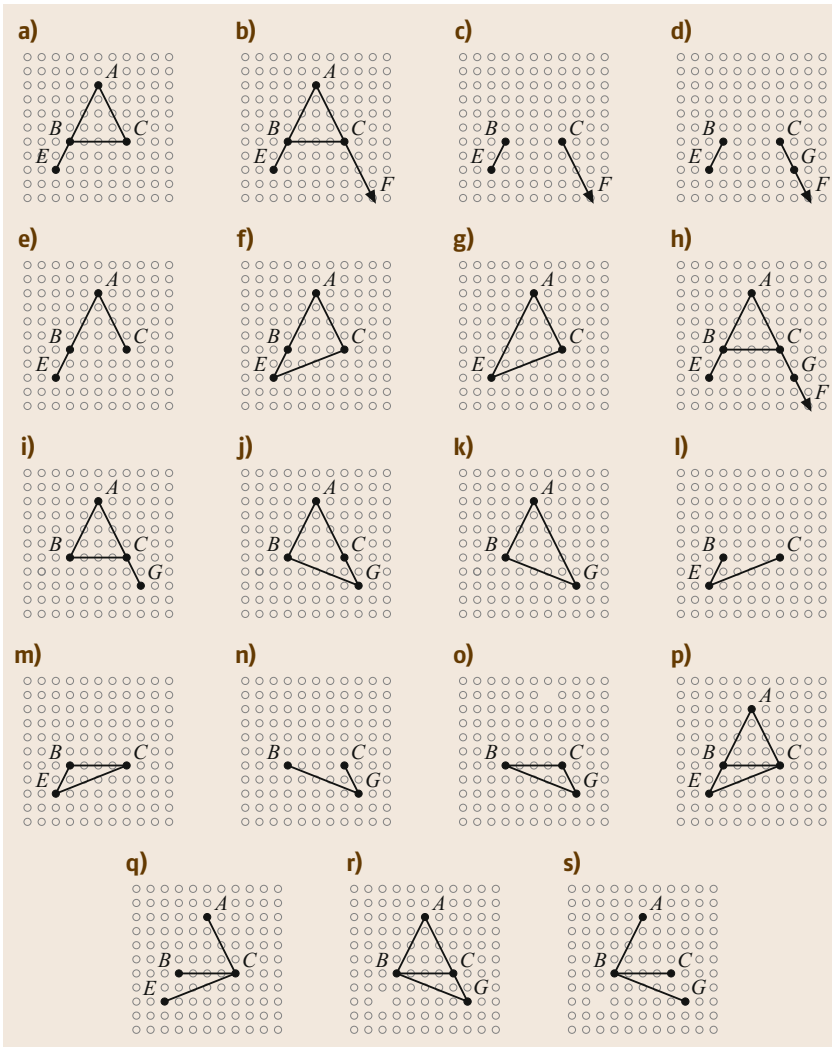

Fig. 23.3 **Eu** demonstration sequence for proposition I, 5

An **Eu** derivation thus splits into two stages, a *construction* stage and a *demonstration* stage. The construction stage is intended to correspond to the production of a geometric diagram as a concrete object, while the demonstration stage is intended to correspond, in part, to the reasoning carried out with the concrete object. (The demonstration stage also serves to record reasoning carried out with sentences representing relations between geometric magnitudes.) Both the construction and the demonstration stage in an **Eu** derivation can (and in most cases of interest do) contain many distinct **Eu** diagrams, even in the canonical case of a derivation that is intended to model a single diagram proof. And so, how the distinct, abstract **Eu** diagrams of such a derivation are to be understood in relation to the concrete diagram of single diagram proof requires some explanation. The general idea is

as follows: the different **Eu** diagrams of the construction correspond to different stages in the construction of a single concrete diagram  $\mathcal{D}$ ; each of the different **Eu** diagrams of the demonstration correspond to the product of an act of attention directed at  $\mathcal{D}$ .

Consider for instance the **Eu** diagrams in Figs. 23.3 and 23.4. These are the diagrams that appear in an **Eu** derivation modeling a single diagram proof of proposition 5, book I of the *Elements*. The final **Eu** diagram of the construction sequence (Fig. 23.4) corresponds to the proof's concrete diagram  $\mathcal{D}$ . The **Eu** diagrams preceding it correspond to stages in the construction of  $\mathcal{D}$ . All the **Eu** diagrams of the demonstration sequence (Fig. 23.3) are subdiagrams of the final diagram of the construction sequence. They correspond to acts of attention whereby certain relationships present in  $\mathcal{D}$  are verified to hold in general. The sequence thus repre-

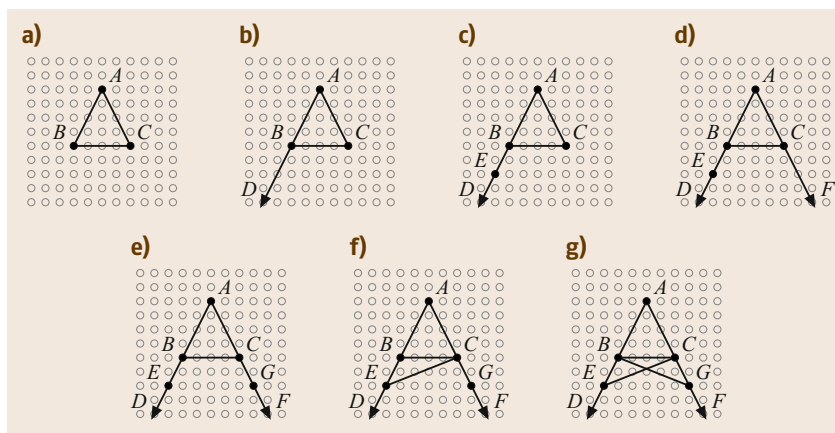

Fig. 23.4 Eu construction sequence for proposition I, 5

sents a reasoning process verifying that the position of  $CB$  within angle  $\angle ACE$  and the position of  $BC$  within  $\angle ABG$  hold in general.

As it is only the demonstration sequence that is intended to correspond to a reasoning process, it is only

the demonstration stage that is governed by the relation of semantic equivalence in **Eu**. Specifically, the rules that license the addition of a diagram to the demonstration sequence given previous diagrams in the sequence must preserve semantic equivalence.

### 23.3 Formal Geometric Diagrams as Models

In itself, a formalization is just a system of rules for producing formal objects. They must be interpreted in order to have any epistemological significance. For instance Peano arithmetic, understood purely as a formal system, simply prescribes a method for producing formal symbols from a fixed formal vocabulary. It is only after one systematically relates the formal structure of these sequences to logical and arithmetical concepts that we arrive at a foundational analysis of arithmetic. The sequences then come to be seen as sentences asserting facts about natural numbers.

Similarly, when understood purely as formalizations, **FG** and **Eu** simply provide rules for producing certain kinds of formal structures. These structures are, to be sure, different in kind from an axiomatization in first-order logic like Peano arithmetic. They are nevertheless formal and have no epistemological significance with respect to elementary geometry without some kind of interpretation.

One option for such an interpretation is furnished by a first-order axiomatization of elementary geometry (e.g., the axiomatization given in [23.7]). The formal structures of **FG** and **Eu** can be systematically related to the formal sentences of the axiomatization. Accordingly, the formal structures of **FG** and **Eu** would then amount to an idiosyncratic, and very indirect, notation for sentences asserting facts about the Euclidean plane. In this concluding section I explore the prospect of an

alternative interpretation of the proof systems where each formalizes a species of model-based reasoning.

Elementary geometry is a mathematical subject, and proofs in mathematical subjects are deductive. And so, an interpretation of **FG** and **Eu** in line with the model-based reasoning perspective ought to proceed from a conception of deduction in line with the model-based reasoning perspective. *Lorenzo Magnani* articulates such a conception in [23.8]. Interestingly, he does so by considering proofs in elementary geometry.

Magnani specifically refers to *Hintikka* and *Remes*' investigations into the logic of geometric proof in [23.9]. (For *Hintikka*'s most recent discussion of geometric proof see [23.10].) One of *Hintikka*'s central points is that the logic of proof in elementary geometry is best understood in terms of the method of semantic tableau. Take the proof of proposition 5 from book 1 of the *Elements* as an example. The proposition asserts that for any collection of points and segments forming an isosceles triangle, the angles opposite the equal sides of the triangle are equal. Thus the logical form of the proposition is

$$\forall x_1, x_2, \dots, x_n [\varphi_1(x_1, \dots, x_n) \rightarrow \varphi_2(x_1, \dots, x_n)],$$

where  $\varphi_1$  corresponds to the conditions defining an isosceles triangle, and  $\varphi_2$  to the condition that the angles opposite the equal sides of the triangle are equal.

Now, at the heart of the proof of a statement of the above form within the semantic tableau setting is the proof of a conditional

$$\varphi_1(a_1, \dots, a_n) \rightarrow \varphi_2(a_1, \dots, a_n)$$

in which  $a_1, \dots, a_n$  are understood as arbitrary, and the formulas  $\varphi_1(a_1, \dots, a_n)$  and  $\varphi_2(a_1, \dots, a_n)$  come to be linked via logical operations, axioms and previously proven theorems. With respect to proposition 5, the  $a_1, \dots, a_n$  represent an *instantiation* of the theorem. Thus, according to the framework of semantic tableau, at the heart of the reasoning establishing proposition 5 is the consideration of representations understood to instantiate the theorem. The  $a_1, \dots, a_n$  serve, in other words, *to model* the type of configuration the proposition concerns, and it is by interacting with this modeling that the proposition is established.

Hintikka's work leads us thus to the following abstract characterization of deduction from a model-based reasoning perspective. Deductive inference concerns a complex of interrelated objects. The complex is assumed to satisfy certain conditions  $\varphi_1$ , and is inferred to satisfy further conditions  $\varphi_2$ . The inference proceeds via consideration of a representation modeling the complex. An important aspect of deduction understood in this way, emphasized by both Hintikka and Magnani but passed over in the above discussion of proposition 5, is that the representation modeling the complex can be enriched. One need not restrict oneself to the objects the deduction explicitly concerns in constructing a model for it. One may add to the representation additional objects to facilitate the reasoning. With respect to a proof of elementary geometry, this simply amounts to performing a construction on the initial configuration of the proof.

Call this the model-based reasoning, or MBR, conception of deduction. The conception differs from the standardly accepted one in that what is front and center are representations of objects and their relations, rather than sentences asserting relations between objects. It is such representations that drive the deductive inference that any collection of objects satisfying conditions  $\varphi_1$  also satisfy the conditions  $\varphi_2$ . To perform such an inference, one must recognize that the conditions  $\varphi_1$  impose constraints upon a collection of objects with respect to the relations in  $\varphi_2$ . This act is accomplished by representing an instantiation of  $\varphi_1$  and  $\varphi_2$ , augmented perhaps with additional objects. The representation serves to reveal the constraints the conditions  $\varphi_1$  impose upon objects with respect to the relations in  $\varphi_2$  directly.

How do representations of instantiations do this? It is not immediately clear from the general logical perspective Hintikka assumes. From this perspective, the only way to represent an instantiation is sententially – i. e., via predicates and singular terms. If the singular terms are understood simply to denote objects in the broadest logical sense, a listing of predicates that the singular terms satisfy reveals on its own only trivial constraints. Suppose we have a three-place predicate  $B$  and singular terms  $a_1, a_2, a_3$  and  $a_4$ . Then

$$B(a_1a_2a_3) \quad B(a_2a_3a_4)$$

qualifies as a sentential representation of an instantiation. But the only constraint on  $a_1, a_2, a_3$  and  $a_4$  that the representation reveals, if our conception of the objects is the broadly logical one, is that the triples  $\langle a_1, a_2, a_3 \rangle$  and  $\langle a_2, a_3, a_4 \rangle$  must satisfy  $B$ . Aside from the two sentential expressions that negate  $B(a_1a_2a_3)$  and  $B(a_2a_3a_4)$  – i. e.,  $\neg B(a_1a_2a_3)$  and  $\neg B(a_2a_3a_4)$  – we are free to add to the representation any sentential expression with the singular terms  $a_1, a_2, a_3$  and  $a_4$ .

This observation shows, at the very least, that if the MBR conception of deduction is to be of any interest, the operative conception of object in a deductive inference has to be richer than the austere one furnished by logic. There has to be, in other words, background knowledge with respect to the objects and their combination in complexes – e.g., what relations can and cannot obtain among the objects of a complex, what additions can be made to a given complex, and so on. If this is accepted, the question then becomes: how does this background knowledge exert itself when a representation of an instantiation is considered in the course of a deduction?

Here is where proven theorems and/or axioms come into play in a semantic tableau formalization. At the initial stage, before any theorems are proven, all background knowledge about the objects under consideration is encoded in unproven axioms. We look to these for what can and cannot be done with representations of instantiations. These then allow us to use such representations to deduce nontrivial theorems via semantic tableau, which then can be used in future deductions. For an example of how this works, consider the three-place predicate  $B$  again, and suppose that it denotes the relation of betweenness for points on a geometric line. Suppose further we are at a point where the basic fact about betweenness given by

$$\forall x, y, z, w [(B(xyz) \wedge B(yzw)) \rightarrow B(xyw)]$$

is known, either as an axiom or a theorem. Then in any instantiation

$$B(a_1a_2a_3) \quad B(a_2a_3a_4)$$

within a semantic tableau, we can add

$$(B(a_1a_2a_3) \wedge B(a_2a_3a_4)) \rightarrow B(a_1a_2a_4)$$

Application of the rules of the semantic tableau to these formal representations eventually shows that the conditions  $B(a_1a_2a_3)$  and  $B(a_2a_3a_4)$  impose a constraint on betweenness with respect to  $a_1$ ,  $a_2$  and  $a_4$  – i. e., the relation  $B(a_1a_2a_4)$  in fact holds.

The virtue of semantic tableau is that it provides a topic-neutral formal framework for investigating the MBR conception of deduction. It does not follow from this, however, that it is the *only* formal framework that functions in accordance with the MBR conception. It does not follow, that is, if the conception's central principle is that that deduction is accomplished via representations of instantiations. A formal framework could very well be designed for representing instantiations of object complexes of a particular kind. Within such a framework, the formal structures for representing instantiations would do (at least some of) the work done by the axioms in the semantic tableau framework. Background knowledge of what is and is not possible within a complex would be embedded in the constraints on producing these formal structures.

This is what is in fact happening, I maintain, with the **FG** and **Eu** formalizations. The function of its diagrammatic syntax is not to convey conjunctions of geometric conditions with an idiosyncratic notation, but to present instantiations of geometric configurations for the sake of facilitating deductions. Consider again a configuration made up of points  $a_1, a_2, a_3$  and  $a_4$  on a geometric line, where  $a_2$  is between  $a_1$  and  $a_3$ , and  $a_3$  is between  $a_2$  and  $a_4$ . Within **FG**, such a configuration is represented as

while in **Eu** it is represented as:

With both, the constraint that  $B(a_1a_2a_3)$  and  $B(a_2a_3a_4)$  imposes on the relative positions of  $a_1, a_2$  and  $a_4$  is immediately evident. Generally, the diagrammatic syntax of **Eu** and **FG** embodies what must be laid down as axioms in an axiomatization. As *Miller* puts it with respect to his system [23.1, p. 40]

“[...] many of the facts that Hilbert adopts as his axioms of incidence and order [in [23.11]] are consequences of the diagrammatic machinery built into the definitions of **FG**.”

We thus have, I maintain, with **FG** and **Eu** two formal characterizations of deduction carried out according to the principles of model-based reasoning. With **FG**, the diagrammatic representation of instantiations serve to give the reasoner direct access to a range of geometrical possibilities. The diagrams of **Eu**, in contrast, allow the reasoner to consider all the components of a geometric configuration in one place and to focus on those components relevant to a proof. The precise formal pictures they provide can provide a basis for further investigations into the relation between instantiation and deduction in mathematics.

## 24. Model-Based Reasoning in Mathematical Practice

Joachim Frans, Isar Goyvaerts, Bart Van Kerkhove

The nature of mathematical reasoning has been the scope of many discussions in philosophy of mathematics. This chapter addresses how mathematicians engage in specific modeling practices. We show, by making only minor alterations to accounts of scientific modeling, that these are also suitable for analyzing mathematical reasoning. In order to defend such a claim, we take a closer look at three specific cases from diverse mathematical subdisciplines, namely Euclidean geometry, approximation theory, and category theory. These examples also display various levels of abstraction, which makes it possible to show that the use of models occurs at different points in mathematical reasoning. Next, we reflect on how certain steps in our model-based approach could be achieved, connecting it with other philosophical reflections on the nature of mathematical reasoning. In the final part, we discuss a number of specific purposes for which mathematical models can be used in this context. The goal of this chapter is, accordingly, to show that embracing modeling processes

as an important part of mathematical practice enables us to gain new insights in the nature of mathematical reasoning.

In this chapter, we explore the significance of model-based reasoning for mathematical research. In Sect. 24.1, we start by outlining an account of the nature of scientific modeling, and how it could be applied to mathematics. This becomes more clear in Sect. 24.2, where this account will be briefly applied to three specific examples coming from different mathematical subdisciplines, and also exhibiting a different level of abstraction, namely Euclidean geometry, approximation theory, and category theory re-

spectively. Section 24.3 reflects on how specific transitional steps in the model-based argument schemes presented are to be achieved, and more particularly on what are commonly called types of plausible reasoning that thus arguably play an important role in mathematical discovery. In Sect. 24.4, some of the alleged epistemic merits or purposes of model-based reasoning as presented in the context of mathematical practice are considered. Section 24.5 concludes the chapter.

### 24.1 Preliminaries

*Aris* [24.1] has proposed the following definition (as quoted in *Davis* and *Hersh* [24.2, p. 78]):

“A mathematical model is any complete and consistent set of mathematical equations which are designed to correspond to some other entity, its pro-

totype. The prototype may be a physical, biological, social, psychological or conceptual entity, perhaps even another mathematical model.”

*Davis* and *Hersh* [24.2, p. 78–79] have commented on this:

“One might substitute the word *structure* for *equations* [in the above quote], for one does not always work with a numerical model. Some of the purposes for which models are constructed are:

1. To obtain answers about what will happen in the physical world.
2. To influence further experimentation or observation.
3. To foster conceptual progress and understanding.
4. To assist the axiomatization of the physical situation.
5. To foster mathematics and the art of making mathematical models.

The realization that physical theories may change or may be modified [...], that there may be competing theories, that the available mathematics may be inadequate to deal with a theory in the fullest sense, all this has led to a pragmatic acceptance of a model as a *sometime thing*, a convenient approximation to a state of affairs rather than an expression of eternal truth.”

*De Vries* [24.3], for another, has depicted the process of mathematical modeling as follows:

We from our part shall argue that, *making abstraction* from mathematical reality, in the sense explained below, aspects of mathematical practice can be seen as a sort of modeling, in case the prototypes referred to in

the Aris quote already are certain mathematical structures.

First of all, let us specify what can be meant by *making abstraction* from mathematical reality in our present context. We intimately follow the treatment of this subject by *Davis* and *Hersh* [24.2, pp. 126–36]. The term *abstraction* is used in different but related senses in mathematics; *Davis* and *Hersh* distinguish *abstraction as idealization* and *abstraction as extraction*. The idealizations in this context proceed from the world of spatial experience to the mathematical world. Aristotle is referred to in this respect, pointing out that [24.2, p. 127]:

“the mathematician strips away everything that is sensible, for example, weight, hardness, heat, and leaves only quantity and spatial continuity.”

It is then said that the development of contemporary mathematical models exhibits updated versions of this (Aristotle’s) process. The visualization of this type of abstraction process provided by *Davis* and *Hersh* [24.2, pp. 129], has quite some similarities with the sketch of the process of mathematical modeling of *de Vries* quoted above (To serve comparison though, we have rotated *Davis* and *Hersh*’s diagram 90° counter clockwise.):

Therefore, as already mentioned earlier, we dare claim that model-based reasoning can and does occur within mathematical practice.

## 24.2 Model-Based Reasoning: Examples

In this section, we briefly elaborate three examples; a very *basic problem-solving* one, one at an intermediate level of abstraction, and finally an utmost conceptual one, calling on some notions from category theory. In Sect. 24.4, we shall argue that this model-based way of reasoning exhibits features that are similar to the five purposes models are designed for in other sciences (as described earlier by *Davis* and *Hersh*).

### 24.2.1 First Example: From Euclidean Geometry

Imagine one is given a right-angled triangle  $T$ , whose legs  $a$  and  $b$  measure 4 and 3 cm respectively. A second

right-angled triangle  $T'$  is given as well, its legs  $a'$  and  $b'$  measuring 3 and 2 cm, respectively. Now suppose we care about knowing the length of the hypotenuses of  $T$  and  $T'$ , denoted by  $c$  and  $c'$ . Clearly, a first and most evident technique consists in just measuring these lengths with a marked ruler. One finds that this is something like 5 cm for  $c$  and approximately 3.6 cm for  $c'$ .

One satisfied with these results can carry on without asking the question of *why*  $c$  and  $c'$  measure exactly as they do. If however one does not suffice with these mere numerical results, he or she might notice at some point, after further inquiry, that indeed something deeper is going on. Note that we largely ignore at this point *how* this is realized, as we also disregard for the sake of

the present discussion how the following observations are (to be) made. We indeed suppose that all steps in the cycle described *can* actually be carried out at some point. In Sect. 24.3, we shall explore the alleged importance of informal reasoning (including analogies and visualizations) in the process of inductive and deductive mathematical inference (see however also the other contributions in the current part of this volume.).

Thus, in whichever way, inductive reasoning, by reading and *taking in* the given information described above, makes one realize that  $a$  and  $b$ ,  $a'$  and  $b'$  are legs of two right-angled triangles. Mathematical inference teaches us that for such triangles, the universal regularity called Pythagoras' theorem holds, which assures us that the square of the length of the hypotenuse equals the sum of the squares of the lengths of the legs. This means that by deduction, plugging in the values of  $a$  and  $b$  in this result, we find that

$$c^2 = a^2 + b^2 ;$$

hence  $c = 5$ , as lengths are positive real numbers. Similarly, plugging in  $a'$  and  $b'$  in Pythagoras' theorem, we find that  $c' = \sqrt{13}$  (observing that 3.6 is relatively close to this). Schematically depicted, we arrive at the following *more or less* commutative diagram (by commutative diagram we mean that the diagram has the property that all directed paths with the same start and endpoint lead to the same result by following the arrows.):

Some brief remarks with respect to this diagram are appropriate. First of all, we added *more or less* when talking about the above diagram's being commutative. This is because we indeed are disregarding the issue of actually establishing the link between *measuring* the hypotenuses on the one hand, and *theoretically deducing* their *real* lengths from Pythagoras' theorem on the other. Given the discussion of ever *perfectly* measuring length, 5 as well as  $\sqrt{13}$  in this case, one might indeed wonder if it could *at all* be feasible to render a *down-to-earth* diagram as the one given (involving empirical verification) commutative. We do hold that for both pedagogical and conceptual reasons, arriving at *the* measures of  $c$  and  $c'$  by following the induction–mathematical inference–deduction route of the diagram, is way more satisfactory than just measuring their *approximate* values.

### 24.2.2 Second Example: From Approximation Theory

Our second case comes from the mathematical field called approximation theory, one of the central goals of which it is to “represent an arbitrary function in terms of other functions which are nicer or simpler or both” (*Hrushikesh and Devidas* [24.4, p. 1]). This area of research is thus mostly concerned with how functions can be better approximated with easier functions, and with how the errors occurring in this process can be characterized. The point is that, in many cases, it is difficult or even impossible to extract exact analytical information from an arbitrary function  $f$ . In such cases, it is nevertheless useful and therefore important to be able to approximate  $f$  with a simpler function. Intuitively speaking, in cases like these, mathematicians sometimes look for a function  $g$ , such that the relevant calculation can be performed on the function  $g$  while  $g$  is *close enough to*  $f$  in the sense that the outcome of the calculation performed on  $g$  gives us meaningful information about  $f$ .

Let us give a concrete and simple example to clarify what the role of approximation theory can be. The example is inspired by *Christensen and Christensen* [24.5]. Assume that we want to compute the following integral

$$\int_0^1 e^{-\frac{x^2}{2}} dx .$$

Now, a primitive function of the function

$$f(x) = e^{-\frac{x^2}{2}}$$

cannot be expressed as a combination (sum, composition, multiplication, quotient) of elementary functions (polynomials, trigonometric, logarithmic functions, and their inverses). So in order to obtain numerical values of the above integral, other means are called for. This is where approximation theory enters the picture. One of the goals is to search a function  $g$  for which (i)  $\int_0^1 g(x)dx$  can be calculated, and (ii)  $g(x)$  is *close to*

$$e^{-\frac{x^2}{2}}$$

for  $x \in [0, 1]$ , in the sense that we can keep under control how much  $\int_0^1 g(x)dx$  deviates from

$$\int_0^1 e^{-\frac{x^2}{2}} dx .$$

A possible way of doing so, is to find a positive integrable function  $g$  for which, for some  $\epsilon > 0$ ,

$$-\epsilon \leq e^{-\frac{x^2}{2}} - g(x) \leq \epsilon, \quad \forall x \in [0, 1],$$

$$-\epsilon + g(x) \leq e^{-\frac{x^2}{2}} \leq \epsilon + g(x), \quad \forall x \in [0, 1].$$

Consequently, one can obtain that

$$-\epsilon + \int_0^1 g(x) dx \leq \int_0^1 e^{-\frac{x^2}{2}} dx \leq \epsilon + \int_0^1 g(x) dx.$$

As a result,  $\int_0^1 g(x) dx$  gives us an approximate value for the desired integral. Now the question remains, of course, of how to determine or *choose*  $g$ . Approximation theory is the field where precisely this type of questions are further discussed and developed. This quest has led to several powerful and useful mathematical techniques, such as the theory of Chebyshev polynomials or Fourier analysis. From the point of view of concrete numerical computations, such a transformation is often preferable, because it gives a simple way of obtaining information about the function which would otherwise be difficult to collect, or could not even be traced at all. Following our take on model-based reasoning in mathematics, we can present this practice in the following, by now familiar scheme:

### 24.2.3 Third Example: From Category Theory

Finally, we would also like to provide an illustration from *higher level* mathematical practice, sketching some of the features of research in category theory. In order to appreciate the results and techniques from this

field, it might be helpful to recall some of the mathematical notions involved. Therefore, without going into full detail, we briefly develop some of those ideas, or at least an interpretation of them which is relevant to our setting, in the appendix.

Groups are algebraic objects intimately related to the notion of symmetry. Hopf algebras (over a field  $k$ ) are – slightly more complicated – algebraic objects, group algebras being an important class of examples of such structure. As explained in the appendix, groups can be seen as Hopf monoids (HM) in the braided monoidal category of sets, denoted  $\widehat{\text{Sets}}$ . Similarly, Hopf algebras are simply Hopf monoids in  $\widehat{\text{Vect}}_k$ .

As remarked in *Verduyn* [24.6] (§5.1), most of the theory of (classical) Hopf algebras can be lifted to the setting of Hopf monoids in arbitrary braided monoidal categories (BMN), sometimes under additional assumptions (such as the existence and preservation of certain (co)limits); one such a result being the so-called Fundamental theorem (FT) for Hopf modules for instance (cf. *Takeuchi* [24.7]). Plugging in your favorite braided monoidal category (satisfying the necessary assumptions) will then give you a version of this theorem for Hopf monoids in that particular category.

This result can also be obtained through *direct manipulation* of particular objects in the chosen category as well. For Hopf algebras for instance, FT can be obtained directly by applying techniques from linear algebra (i. e., manipulation of  $k$ -vector spaces), that is, in case you choose to plug in  $\widehat{\text{Vect}}_k$  (actually, both  $\widehat{\text{Sets}}$  and  $\widehat{\text{Vect}}_k$  satisfy the necessary conditions for FT to hold). It should be noted that in many cases, the categorical proof is inspired by a *classical* (often linear algebraic) proof of the statement for some particular algebraic object. Again, this whole practice can schematically be recapitulated in the following way:

## 24.3 The Power of Heuristics and Plausible Reasoning

Before considering the epistemic merits of the reasoning model just presented, we want to briefly pause to reflect on how the appropriate steps or *transitions* in the above model-based diagrams are to be achieved, particularly in the induction and mathematical inference phases. Indeed, in the previous section, we have

remained utterly silent on how mathematicians safely arrive at the nodes in the upper half of the diagrams, that is, what particular intellectual processes are required in order to reach such a higher abstraction level. While it would take an in-depth study of these aspects as applied to the specific cases presented, in order to fully substan-

tiate why this is in fact possible, we nevertheless want to briefly explore this *context of discovery*-dimension here in somewhat more general terms.

An interesting starting point can be found in the work of Pólya. In *Induction and analogy in mathematics*, he states that all our knowledge outside mathematics and demonstrative logic consists of conjectures. It is certainly the case that some of these conjectures, such as those expressed in general laws of physical science, are highly reliable and commonly accepted. Other conjectures are neither reliable or respectable.

The support for conjectures is obtained by plausible reasoning, while our mathematical knowledge is secured by demonstrative reasoning. Mathematical proofs are part of demonstrative reasoning, while the inductive, circumstantial, or statistical evidence for a scientist belongs to plausible reasoning. One of the main differences between these two kinds of reasoning is that demonstrative reasoning leads to safe and final knowledge that is beyond revision. Plausible reasoning, on the other hand, leads to provisional and controversial knowledge.

What Pólya argues for is that, while mathematics is regarded as a demonstrative science, plausible reasoning also plays an important role in mathematics. He clarifies this by referring to finished mathematics and mathematics in the making (by way of a very nice metaphor, Reuben Hersh later called this the distinction between the front and the back in mathematics Hersh [24.8]). Finished mathematics appears to be purely demonstrative, consisting of only proofs. Yet mathematics in the making is similar to other human knowledge in the making. The following passage clarifies this (Pólya [24.9, p. 100]):

“You have to guess a mathematical theorem before you prove it, you have to guess the idea of the proof before you carry through the details. You have to combine observations and follow analogies, you have to try and try again. The results of the mathematician’s creative work is demonstrative reasoning, a proof; but the proof is discovered by plausible reasoning, by guessing.”

From this observation, Pólya concludes that students of mathematics should learn both kinds of reasoning.

A very similar story is told by Lakatos in his landmark study *Proofs and refutations* (Lakatos [24.10]), where he identifies three rough stages in mathematical reasoning. First, mathematicians use induction (in the sense of generalization on the basis of particular instances) to discover conjectures worth trying to prove. Then they develop and criticize highly *informal* proofs

of these conjectures. Only in a last phase of mathematical labor, they formalize these informal theories, establishing the deduction of the (by then) theorems by means of formal transformations on an axiomatic basis. Lakatos famously illustrates this practice with a (*rationaly*) reconstructed history of how the proof of Euler’s polyhedron formula  $V - E + F = 2$  came about,  $V$  being the number of vertices,  $E$  the number of edges, and  $F$  the number of faces of any given polyhedron.

Let us take a somewhat closer look at some of Lakatos’ terminology, which he used to outline various methods by which mathematical discovery (and subsequent justification) can occur. These methods describe ways in which mathematical concepts, conjectures, and proofs gradually evolve through interaction between mathematicians. Central to these practices, so Lakatos claims, are counterexamples, and he discusses several ways in which mathematicians or students can react to these: by surrender, monster-barring, exception-barring, monster-adjusting, or lemma-incorporation. In what follows, we briefly sketch the essence.

First of all, surrender amounts to abandoning a conjecture in the light of a counterexample. This is however not done lightly, so more frequent are other reactions. Monster-barring, for instance, which consists in ignoring or excluding an alleged counterexample. This implies that one has to show why it is not within the relevant concept definition. One can claim, for example, that a hollow cube, that is a cube with a cube-shaped hole in it, is not a counterexample to Euler’s conjecture, by arguing that the hollow cube is not in fact a polyhedron, and thus cannot threaten the conjecture. This means that the concept polyhedron is under discussion, soliciting a further explication of its definition.

As for exception-barring, Lakatos argues that exceptions, rather than simply being problematic for cases and thus dismissed as monsters, can lead to new knowledge. Two ways to deal with exceptions are discussed. One is piecemeal exclusion, for example, by excluding one type of polyhedron from the conjecture in order to set aside a whole class of counterexamples. The other is strategic withdrawal, which does not directly rely on counterexamples. Instead, positive examples of a conjecture are used in order to generalize to a class of objects, and consequently limit the domain of the conjecture to this class.

Yet another way of responding to counterexamples is termed monster adjusting. It is intended to meet the possible criticism that both monster-barring and exception-barring are not taking counterexamples serious enough. Here, the mathematicians reinterpret the counterexamples so that they indeed fall within the scope of the original formulation of the conjecture, and thus show how the anomalies are in fact unproblematic.

The method of lemma-incorporation differs from all the above methods in that it uses properties of the proof itself. The idea is to examine the proof in order to determine exactly which lemma has been refuted by the counterexample. The guilty lemma is then added as a condition to the conjecture, and is consequently no longer refuted by the counterexample.

The most important or general method for Lakatos, as the title of his work suggests, is that of proofs and refutations, which in a certain sense amounts to a dialectic form of the method of lemma incorporation. Lemma incorporation enables one to make a distinction between global and local counterexamples. Global counterexamples refute the main conjecture, while local counterexamples are counterexamples to specific proof steps only. If a counterexample is both global and local, and thus constitutes a problem for both argument and conclusion, one should modify the conjecture by incorporating the problematic step as a condition. If the counterexample is not global but just local, which means the conclusion can still be correct while one of the reasons for believing it is flawed, one should leave the conjecture unchanged and modify the proof. Finally, if the counterexample is global but not local, which

means that there is a problem with the conclusion without obvious problems for any of the reasoning steps, then one should look for a possible hidden assumption in one of the proof steps and modify the proof by making this assumption explicit.

Summarized, Lakatos' proposed method consists in exploiting proof steps to suggest counterexamples. By looking for objects violating an argumentative step, one can identify possible such candidates. Whenever a counterexample is actually found, one needs to determine of its kind and accordingly modify the proof or conjecture. Note that other modes of model-based reasoning, such as several ones touched upon elsewhere in this collection (metaphorical, analogical, and/or visual reasoning) can very much be at play in these particular stages of mathematical inquiry. Indeed are these not your exemplary instances of heuristic or plausible reasoning in the context of discovery? We shall not further explore this issue ourselves, and after this interlude return to our central topic, in order to consider how and why the reasoning model introduced in Sect. 24.2 should work, that is what its original (if perhaps not essential) contributions to mathematical research might be.

## 24.4 Mathematical Fruits of Model-Based Reasoning

Let us recall the purposes of model-based reasoning as listed by *Davis* and *Hersh* [24.2, pp. 78–9] in Sect. 24.2, and consider their translation to a mathematical context:

- “(1) To obtain answers about what will happen in the physical world.
- (2) To influence further experimentation or observation.
- (3) To foster conceptual progress and understanding.
- (4) To assist the axiomatization of the physical situation.
- (5) To foster mathematics and the art of making mathematical models.”

As this entire collection may testify, mathematical models are most important and powerful tools for the empirical sciences in order to gain fresh insights about aspects of the physical world. These insights can come in different forms, for example, as a prediction about what will probably happen, an explanation of something that has already happened, or a deeper understanding of (part of) the physical situation under investigation. A satisfactory account of how indeed a model can help answer such questions about reality

is the mapping account (*Pincock* [24.11]), where one adopts the view that there is an appropriate mapping between the target system and the model. The knowledge obtained in the model can be translated into knowledge about the target system, because the model's various aspects correspond (at least to a large enough extent) to elements in the real world.

Now it would be strange to argue that all the purposes of models exhibited in empirical science have their exact counterparts in mathematical practices. Take prediction (*purpose 1*), which obviously plays a crucial role in the sciences. Mathematics, on the other hand, is not exactly your kind of discipline that has room for the same kind of prediction. Surely, mathematicians make guesses about the nature of mathematical objects (*facts*) or about how a certain proof will (or should) look like, but this does not warrant the drawing of too a strong connection between mathematical and scientific prediction. Be that as it may, the central purpose of using models does remain in place, namely the conversion of knowledge obtained in the model into knowledge about the target system. Also, the reason for making this possible is similar: it is due to the existence of a mapping relation between the two domains. This, we think, has been nicely illustrated by the various examples we have

developed above on the basis of the diagram we had first introduced to visualize the process of model-based reasoning in mathematical practice. Mathematicians do not simply use abstraction in order to find a result at that particular level. For after obtaining results there, they often translate them back to the original *target* system, and consequently, via an abstraction detour, obtain their answers about this more basic mathematical domain.

Indeed, in our example of Euclidean geometry, one theoretically predicts the (approximated) length of the triangles in the real world or one verifies the theoretical result in the real world. Category theory tells us a similar story. Suppose one has some algebraic structure  $A$  of which one can prove that it is a (Hopf) monoid in a certain (braided) monoidal category  $\underline{\mathcal{C}}$ . At the level of monoidal category theory, some general theorem  $T(-)$  that holds for all (Hopf) monoids in any (braided) monoidal category exists (sometimes assuming some small extra conditions on  $\underline{\mathcal{C}}$ ), such as the Fundamental theorem for instance. If you then *plug in* the category  $\underline{\mathcal{C}}$  you get a version of the theorem  $T(A)$  for the algebraic structure  $A$  you started from. Sometimes this theorem  $T(A)$  is known and has been shown to be true before. Then we can speak of *algebraic world verification* in some sense. This verification is not always a priori possible in every field of mathematical research. For instance, in the example of approximation theory, we are given answers to questions that would be unsolvable in certain cases. However, it is always the case that the information gained within the model can be and often is translated back to the mathematical structure it represents.

Does this also imply (*purpose 2*) that modeling allows for further experimentation or observation in mathematics? To answer this, one may first have to wonder what a mathematical experiment is or can be. First of all, the *experimental mood* of the mathematician might be referred to, as a way of personal exploration in the mathematical field. However, this will not do here. A genuine experiment should at least have an element of systematic data-generating or testing. Notice that a field called *experimental mathematics* does in fact exist, and also has its own journal of that name. Let us quote from its editorial policy statement [24.12]:

“While we value the theorem-proof method of exposition, and do not depart from the established view that a result can only become part of mathematical knowledge once it is supported by a logical proof, we consider it anomalous that an important component of the process of mathematical creation is hidden from public discussion. It is to our loss that most of us in the mathematical community are

almost always unaware of how new results have been discovered. [...]

*Experimental Mathematics* was founded in the belief that theory and experiment feed on each other, and that the mathematical community stands to benefit from a more complete exposure to the experimental process. The early sharing of insights increases the possibility that they will lead to theorems [...]. Even when the person who had the initial insight goes on to find a proof, a discussion of the heuristic process can be of help, or at least of interest, to other researchers. There is value not only in the discovery itself, but also in the road that leads to it. [...]

The word *experimental* is conceived broadly: Many mathematical experiments these days are carried out on computers, but others are still the result of pencil-and-paper work, and there are other experimental techniques, like building physical models.”

Obviously, we particularly have to pick up this last sentence here. Next to number crunching (checking as many cases as possible) or probabilistic reasoning techniques, which – either or not aided by computers – have a distinct inductive and thus experimental ring to them, clearly also model building enters the picture.

This issue has been touched upon by *Van Bendegem* [24.13], characterizing an experiment as involving certain actions such as the manipulation of objects, setting up processes in the real world and observing possible outcomes of these processes. An example from mathematics that he discusses is the work of nineteenth-century Belgian physicist Plateau on minimal surface area problems. Plateau build several geometrical shapes of wire, and by dipping these into a soap solution he was able to investigate specific aspects of the minimum surface bounding various particular shapes. Here, we see how a physical experiment leads to relevant information of a mathematical problem. In such cases, we see how both the model and the physical prototype can influence further experiments and observations. On one hand, the physical experiments help one to formulate some general principles about a connected mathematical domain. On the other hand, the mathematician will set up his experiment in such a way to answer specific mathematical questions. However, such experiments are extremely rare in mathematical practice.

Another starting point can be the notion of a mathematical thought experiment, which *Van Bendegem* [24.14, pp. 9–10] characterizes as follows:

“If it is so that what mathematicians are searching for are proofs within the framework of a mathemati-

cal theory, then any consideration that (a) in the case where the proof is not yet available, can lead to an insight to what the proof could possibly look like, and, (b) in the case where the proof is available, can lead to a better understanding of that proof, can be considered to be a mathematical thought experiment.”

A specific example is a description of the octonions by means of (monoidal) category theory (rudimentary background information for this case is presented in the appendix.). It was shown in *Bulacu* [24.15] that octonions are in fact a weak Hopf algebra in the (braided) monoidal category constructed in *Albuquerque* and *Majid* [24.16], revealing thus more details of their algebraic structure. So in this sense, the work executed by Albuquerque and Majid influenced further *experimentation/observation*, leading eventually to a result which might have not been easily deduced by *algebraic world verification* alone, that is without using the results from [24.16]. The similarity with approximation theory, where the model provides information that remains hidden in the target system, should be clear. Since models can give us new information, this can lead to further experimentation or observation.

The notion of understanding (*purpose 3*), in its turn, is closely linked to that of explanation. Indeed, most of the traditional accounts of explanation state that understanding is centrally involved in it. *Achinstein* [24.17, p. 16] writes that there is a “fundamental relation between explanation and understanding”. *Kitcher* [24.18] argues that a “a theory of explanation shows us how scientific explanation advances our understanding” (p. 330). *Woodward* [24.19, p. 249] similarly says that any theory of explanation should “identify the structural features of such explanation which function so as to produce understanding in the ordinary user”.

Recently, we have seen an increasing interest in the topic of mathematical explanation as well (See *Mancosu* [24.20] for a useful overview of the literature.). Philosophical work on it can be divided into two main strands, namely focussing on extra-mathematical and intra-mathematical explanation, respectively. Extra-mathematical explanation is essentially about the role mathematics plays in the natural or social sciences, more precisely whether mathematics is or can provide explanations for physical phenomena. When considering intra-mathematical explanation, on the other hand, one looks into the role of explanation within mathematics itself, for example by distinguishing between explanatory and nonexplanatory proofs. The underlying idea is that all proofs tell us *that* a theorem is true, but only some proofs go further and tell us *why* a theorem is true. Steiner and Kitcher provided the

two best-known and the most discussed approaches to intra-mathematical explanation.

*Steiner* [24.21] uses the concept of *characterizing property* to draw a distinction between explanatory and nonexplanatory proofs. A characterizing property is a property unique to a given entity or structure within a *family* or domain of such entities or structures. The concept of a family is left undefined. According to Steiner, an explanatory proof always makes reference to a characterizing property of an entity or structure mentioned in the theorem. Furthermore, it must be evident that the result depends on the property (if we substitute the entity for another entity in the family which does not have the property, the proof fails to go through) and that by suitably *deforming* the proof while holding the *proof-idea* constant, we can get a proof of a related theorem. Though many of Steiner’s concepts (family, deformation, proof-idea) remain vague, he discusses several examples to clarify his account. He presents, for example, a proof of the irrationality of the square root of 2 as an explanatory proof since it depends on the unique prime factorization of 2 and since similar proofs for the irrationality of the square roots of other numbers can be given. Following this approach to explanations, models can foster understanding if the model produces proofs that depend on characterizing properties, or where it is easier for the mathematicians to identify these characterizing properties.

*Kitcher* [24.22, p. 437] also argues that his account covers mathematical explanations as well:

“The fact that the unification approach provides an account of explanation, and explanatory asymmetries, in mathematics stands to its credit.”

Let us briefly go over the model of unification that Kitcher proposes. Take a consistent and deductively closed set  $K$  of beliefs. A systematization of  $K$  is any set of arguments that derive some sentences of  $K$  from other sentences of  $K$ . The explanatory story, called  $E(K)$ , corresponds to the systematization with the highest degree of unification. The degree of unification is determined by the number of argument patterns, the stringency of patterns and the set of consequences derivable. Finally, an argument pattern is an argument that consists of schematic sentences, filling in instructions and classification of the sentences. Following Kitcher, and contrary to Steiner, there are no criteria that help us to analyze the explanatory power of a singular proof. Rather, explanation is presented as a value of a unified theory or systematization. Within this view, models can foster understanding if the model shows how mathematical results that were considered unrelated are in fact related. We can see, for example, how category the-

ory can advance such understanding. Category theory allows us to see the universal components of a family of structures of a given kind, and show how structures of different kinds are interrelated. Mathematical models can thus advance our understanding of mathematical results. But there are often different models that address the same mathematical result. Furthermore, the background knowledge and skills of a certain mathematician will play a role in determining whether a model grants understanding for this mathematician. The explanatory value of a mathematical model is, in this sense, a contextual notion.

Axiomatization (*purpose 4*) is undoubtedly another important aspect of mathematical practice. How can models assist it? A first observation is that axiomatization can appear quite arbitrary. Although axioms were once seen as self-evident truths about the constitution of the physical world, the emphasis nowadays mostly seems to be on deducing as much as possible from a minimum number of axioms, while the exact nature of these axioms is of secondary importance. Nevertheless, several mathematicians have argued against this so-called arbitrariness (Weyl [24.23], pp. 523–524), (Nevanlinna [24.24, p. 457]):

“One very conspicuous aspect of twentieth century mathematics is the enormously increased role which the axiomatic approach plays. Whereas the axiomatic method was formerly used merely for the purpose of elucidating the foundations on which we build, it has now become a tool for concrete mathematical research. [...] [However] without inventing new constructive processes no mathematician will get very far. It is perhaps proper to say that the strength of modern mathematics lies in the interaction between axiomatics and construction.

The setting up of entirely arbitrary axiom systems as a starting point for logical research has never led to significant results. [...] The awareness of this truth seems to have been dulled in the last few decades, particularly among younger mathematicians.”

Schlimm [24.25] (Sect. 3) has identified four nonarbitrary sources of (new or adapted) axioms from within mathematical practice:

1. Reasoning from accepted theorems, that is backward so to say, by wondering what axioms would be in need in order to substantiate current theories
2. Manipulation of existing axioms, as a way of (game-like) exploration
3. Conceptual analysis of a mathematical domain, such as e.g., number or set theory; and

4. Proofs and refutations, or the combination of the previous origins through the “various applications of initial conjectures, deductive arguments, semantic considerations, and different kinds of refinements” [24.25, p. 62].

It should be rather easily appreciated that model-based reasoning as it has been proposed by us here has an obvious role to play in processes like these.

The following example about structures called Hopf algebroids may be a good illustration [24.26]:

“A Hopf algebroid is a (possibly noncommutative) generalization of a structure which is dual to a groupoid (equipped with atlas) in the sense of space-algebra duality. This is the concept that generalizes Hopf algebras with their relation to groups from groups to groupoids.”

In Vercruyse [24.6], it is remarked that due to the asymmetry in this notion, several different notions of Hopf algebroid were introduced in the literature. Some of these were shown to be equivalent, although this was far from being trivial. The now seemingly overall accepted notion of a Hopf algebroid was introduced by Böhm and Szlachányi [24.27]. Lu [24.28] introduced a nonsymmetric version over a noncommutative base ring, hereby being able to include quite some examples. The definition by Schauenburg [24.29] allows one to recover a version of FT (Sect. 24.2) in this noncommutative setting, amongst other things. Only recently, Bruguières et al. [24.30] provided an interpretation of Schauenburg’s notion by means of so-called Hopf monads (Vercruyse [24.6, §5.2.2.1]):

“It took quite a long time to establish the correct Hopf-algebraic notion over a noncommutative base. The reasons for the difficulties are quite clear. First of all, if  $R$  is a noncommutative ring then the category of right  $R$ -modules is no longer monoidal (in general). Therefore we have to look instead to the category of  $R$ -bimodules, which is monoidal, but in general still not braided. So Hopf monoids cannot be computed *inside* this category. However, we can compute Hopf monads *on* this category (...) Historically, Hopf algebroids were constructed first in a more direct way, and the interpretation via Hopf monads is only very recent.”

The latter approach shows that for certain applications, it is preferable to use Schauenburg’s definition as being *conceptually* the most interesting one. The price to pay, however, is that it cannot include examples that are included in the slightly weaker notions

of Böhm and Szlachányi [24.27] and Lu [24.28], the definition from the latter source in its turn not being adapted to prove *categorically flavored* theorems (such as e.g., FT). As it seems, all depends what flavor one prefers.

Finally, that model-based reasoning should be able to foster mathematics and the art of making mathematical models (*purpose 5*), is of course self-evident in the context of mathematical inquiry itself, at least given all that has been elaborated above. The essence of mathematics resides in inventing methods, tools, strategies, and concepts for solving problems. That is the very answer to the question of why mathematicians prove theorems. From this view, Rav [24.31] concludes that proofs are the primary focus of mathematical interests, because these particular end products embody the methods, tools, strategies and concepts mentioned, and are therefore the true bearers of mathematical knowledge. Note that this goes against the received view that mathematicians are only interested in the mere truth of a theorem. Dawson [24.32] has in this respect discussed no less than eight reasons for mathematicians to look for multiple proofs of the same theorem:

1. To remedy perceived gaps or deficiencies in earlier arguments
2. To employ reasoning that is simpler, or more perspicuous, than earlier proofs
3. To demonstrate the power of different methodologies
4. To provide a rational reconstruction (or justification) of historical practices
5. To extend a result, or to generalize it to other contexts
6. To discover a new route
7. Concerns for methodological purity
8. Role analogous to the role of confirmation in the natural sciences.

Note that several of these reasons have been discussed in previous paragraphs. Indeed it is not hard to see that model-based reasoning plays an important role in fostering mathematics in the sense that its practitioners are interested in the values of *specific* (and not just of *any*) proofs of both conjectures and existing theorems, which enables the mathematician to discover new routes, demonstrate the power of different methodologies, search for a simple argument, etc.

## 24.5 Conclusion

As announced at the outset of this chapter, we have been focusing here on the philosophical significance of one specific aspect of mathematical practice, namely model-based reasoning as a general methodological framework. By presenting three cases, taken from different mathematical subdisciplines and with varying levels of abstraction, we showed how mathematicians engage in model-based reasoning. We are well aware that the general account of such reasoning remains silent on how mathematicians go from one level to another level. Philosophers such as Pólya and Lakatos discuss the richness of different intellectual heuris-

tics that mathematicians use, and further research into these processes is certainly welcome. Nevertheless, the discussion of the mathematical fruits of model-based reasoning should convince the reader of the significance of the general framework of model-based reasoning, as it shows us how mathematical modeling is linked with several specific purposes of mathematical practice such as experimentation, understanding, or axiomatization. Hence, future reflections on the specifications of model-based reasoning in mathematics can provide crucial insights in several interesting questions about mathematical practice.

## 24.A Appendix

In this appendix, we briefly recall some notions from (monoidal) category theory. Classical references for category theoretical notions and constructions are Borceux [24.33] and Mac Lane [24.34]. We start with some basic notions from set theory. Let us consider two nonempty sets  $A$  and  $B$  and a set-theoretical map (or function)  $f$  between them. This situation can be depicted as follows:

$$A \xrightarrow{f} B$$

that is, this *process*  $f$  can be visualized by an *arrow*; the only requirement being that one must be able to tell for every element of the departure set  $A$  where it is going to. Now, let  $A, B, C$  be three sets and consider two

functions  $f$  and  $g$  as follows:

$$A \xrightarrow{f} B \xrightarrow{g} C$$

We can now consider the composition, denoted by  $g \circ f$ :

$$A \xrightarrow{f} B \xrightarrow{g} C$$

$$\quad \quad \quad \overset{g \circ f}{\curvearrowright}$$

The composition of functions has the associative property: whenever  $f, g, h$  are functions (that can be composed), one has  $(h \circ g) \circ f = h \circ (g \circ f)$ . Remark also that for any set  $A$ , we can consider the function that maps any element of  $A$  onto itself:

$$A \xrightarrow{1_A} A$$

This function  $1_A$  is called the identity function on  $A$ . It has the property that for any function  $f : A \rightarrow B$ , the following holds:  $f \circ 1_A = 1_B \circ f = f$ .

Let us now consider a more general scenario, not necessarily set-theoretic. Let  $A$  and  $B$  be *objects*:

$$A \qquad B$$

and replace the set-theoretical notion of map by just an arrow between these objects:

$$A \xrightarrow{f} B$$

We can now give an idea of the notion of *category*:

Roughly speaking, a *category*  $\underline{C}$  consists of objects and arrows (between objects) such that there is a *composition*  $\circ$  for the arrows and an identity arrow  $1_A$  for any object  $A$  of  $\underline{C}$ . These ingredients have to satisfy some conditions that mimic the associative behavior of composition of functions between sets and the above-mentioned property of the identity function on any set.

In this sense, following *Awodey* [24.35], category theory might be called *abstract function theory*.

We give some basic examples of categories:

- $C = \mathbf{Sets}$   
objects: sets  
arrows: functions between sets
- $C = \mathbf{Vect}_k$  ( $k$  being a field)  
objects:  $k$ -vector spaces  
arrows:  $k$ -linear maps.

Now we would like to illustrate the adjective *monoidal* in the term *monoidal category*. Therefore, let us introduce monoids.

A *monoid*  $(M, *, 1_M)$  consists of a set  $M$ , a function  $*$  :  $M \times M \rightarrow M$  and an element  $1_M \in M$  such that:

- We have  $1_M * m = m * 1_M = m$ , for any  $m \in M$
- For any three  $m, n, p \in M$  the following holds
 
$$(m * n) * p = m * (n * p).$$

We are ready to sketch what a monoidal category looks like. Very roughly speaking, a *monoidal category* is a category  $\underline{C}$ , in which we can *multiply* objects and arrows (this *multiplication* is denoted by  $\otimes$ ) and in which a *unit object* exists (denoted by  $I$ ) such that this  $\otimes$  (resp.  $I$ ) *imitate the behavior* of the operation  $*$  (resp. the element  $1_M$ ) from the monoid structure  $(M, *, 1_M)$ .

We will denote such a monoidal category  $(\underline{C}, \otimes, I)$  briefly by  $\underline{C}$  in the sequel.

Actually, in technical terms, the definition of monoidal category is precisely the *categorification* of the definition of monoid (here categorification aims at the name for the process as it was coined by *Crane* and *Yetter* in [24.36]).

Here are some examples of monoidal categorical structures:

- $(\underline{C}, \otimes, I) = (\mathbf{Sets}, \times, \{*\})$ , where:
  - $\times$  is the Cartesian product of sets.
  - $\{*\}$  is any singleton.
 We will briefly denote this monoidal category by  $\mathbf{Sets}$ .
- $(\underline{C}, \otimes, I) = (\mathbf{Vect}_k, \otimes_k, k)$ , where:
  - $\otimes_k$  is the tensor product over  $k$
  - $k$  is any field.

This example will be briefly denoted by  $\mathbf{Vect}_k$ .

Now we have a vague idea of what it means to be a monoidal category, in order to illustrate an example, we wish to glance at certain objects in such categories. More precisely, we start with considering *monoids* (sometimes called *algebras* in literature) in a monoidal category  $\underline{C}$ . The idea is that these objects mimic the behavior of *classical* monoids (i.e., sets with an associative, unital binary operation), the language of monoidal categories offering a natural setting to do so; this is an instance of the so-called microcosm principle of *Baez* and *Dolan* [24.37], affirming that “certain algebraic structures can be defined in any category equipped with a categorified version of the same structure.”

A *monoid* in  $\underline{C}$  is a triple  $A = (A, m, \eta)$ , where  $A \in \underline{C}$  and  $m : A \otimes A \rightarrow A$  and  $\eta : I \rightarrow A$  are arrows in  $\underline{C}$  (such that two diagrams – respectively mimicing the associativity and unitality condition – commute; we refer the reader to [24.6, Sect. 5.3.1] for instance).

Many algebraic structures can be seen as monoids in an appropriate monoidal category; we present some examples here, for details and more examples we refer the reader again to [24.6, Sect. 5.3.1] e.g.:

- Taking  $C$  to be the monoidal category  $\underline{\text{Sets}}$ , one can easily verify that, taking a monoid in  $C$ , one recovers exactly the definition of a classical monoid, as one expects.
- Similarly, a monoid in  $\underline{\text{Vect}}_k$  gives precisely the classical notion of (an associative, unital)  $k$ -algebra.
- A more surprising example is given by the octonions. The octonions  $\mathbb{O}$  are a normed division algebra over the real numbers. There are only four such algebras, the other three being the real numbers, the complex numbers, and the quaternions. Although not as well known as the quaternions or the complex numbers, the octonions are related to a number of exceptional structures in mathematics, among them the exceptional Lie groups. For more details, we refer to the excellent paper by Baez on this subject [24.38]. One of the properties of the octonions is that they are nonassociative (that is, considered as monoid in  $\underline{\text{Vect}}_k$ ). They can be seen, however, as an (associative) monoid in the monoidal category constructed by *Albuquerque* and *Majid* in [24.16].

In case a monoidal category  $\underline{C}$  exhibits moreover a *braided* structure (whatever this means), we denote  $\underline{C}$  equipped with this braided structure as  $\widetilde{C}$ . In this case, one can not only consider monoids in  $\widetilde{C}$ , one can impose more structure on the definition of monoid, obtaining such notion as *Hopf monoid in  $\widetilde{C}$* . To be a bit more precise, a Hopf monoid in  $\widetilde{C}$  is a bimonoid (which is a monoid also having a so-called comonoid structure, both structures being compatible), having an antipode. The reader is referred to [24.6, Sect. 5.3.2] for more details.

The categories  $\underline{\text{Sets}}$  and  $\underline{\text{Vect}}_k$  can be given a braided structure, which we denote by  $\widetilde{\text{Sets}}$  and  $\widetilde{\text{Vect}}_k$  respectively, such that – without going into the details – the notions of *group* and *Hopf algebra* can be recovered as being Hopf monoids in  $\widetilde{\text{Sets}}$  and  $\widetilde{\text{Vect}}_k$ , respectively.

## 25. Abduction and the Emergence of Necessary Mathematical Knowledge

Ferdinand Rivera

The prevailing epistemological perspective on school mathematical knowledge values the central role of induction and deduction in the development of necessary mathematical knowledge with a rather taken-for-granted view of abduction. This chapter will present empirical evidence that illustrates the relationship between abductive action and the emergence of necessary mathematical knowledge.

Recent empirical studies on abduction and mathematical knowledge construction have begun to explore ways in which abduction could be implemented in more systematic terms. In this chapter four types of inferences that students develop in mathematical activity are presented and compared followed by a presentation of key findings from current research on abduction in mathematics and science education. The chapter closes with an exploration of ways in which students can effectively enact meaningful and purposeful abductive thinking processes through activities that enable them to focus on relational or orientation understandings. Four suggestions are provided, which convey the need for meaningful, structured, and productive abduction actions. Together the suggestions target central features in

abductive cognition, that is, thinking, reasoning, processing, and disposition.

### 25.1 An Example from the Classroom

Table 25.1 provides a short transcript of a very interesting classroom episode on counting by six that happened in a US first-grade class. The task, which was about determining the total number of faces for four separate cubes, was given to the students to help them apply and practice the arithmetical strategy of *counting on*. Anna, Betsy, and all the students together in a chorus-like manner in lines 9, 13, and 17, respectively, eagerly modeled the same process of *putting the last known number in their head and counting six more*. The episode became interesting when Ian started to employ counting by five, an arithmetical skill that the class already knew, to help him count by six in a systematic

way. As conveyed in line 20, Ian initially *saw* multiples of five in the sequence (6, 12, 18, 24). In line 21, when he *added the ones* and saw that the numbers in his head matched the same numbers he saw on the teacher's board, the feeling of having *discovered* a wonderful idea caused him to exclaim *I was right!* and encouraged him to share his abduction with his classmates (lines 22–26).

*Shotter* [25.1] captures the following sense in which first-grade student Ian has embodied abductive thinking in relation to the number sequence (6, 12, 18, and 24): Ian was “carried away unexpectedly by an other or otherness to a place not previously familiar to him” [25.1,

**Table 25.1** Ian’s counting-by-six rule

Ms. Marla [M] presented the following task below during a board math session with her first-grade class	
Number of cubes	Number of faces
1	–
2	–
3	–
4	–
How many faces do four cubes have in all?	
1	M: Let’s say I have four cubes. I want to know how many faces four cubes have in all. So let’s count how many faces one cube would have.
2	
3	Students [Ss]: M points to the faces one by one. One, two, three, four, five, six.
4	M: Okay so how many faces does one cube have?
5	Ss: Six!
6	M: Now I want to know how many faces two cubes would have.
7	Ss: Twelve!
8	M: Let’s see. How would I figure that out?
9	Anna: Put six in your head and count six more.
10	M: Okay so?
11	Ss: 6, 7, 8, 9, 10, 11, 12.
12	M: Okay next.
13	Betsy: You put 12 in your head and count six more.
14	M: Okay everybody!
15	Ss: 12, 13, 14, 15, 16, 17, 18.
16	M: Then?
17	Ss: You put 18 in your head and count. 18, 19, 20, 21, 22, 23, 24.
18	M: So how many faces are there in all?
19	Ss: 24.
As the students began to count by six, Ian [I] decided to count by five using his right hand to indicate one set of 5.	
20	I: 5, 10, 15, 20.
He then used his right thumb and continued to count by one.	
21	I: And then you add the ones. 21, 22, 23, 24. I was right!
Ian eagerly raised his hand and shared his strategy with Ms. Marla and his classmates.	
22	I: Ms. M, I was thinking that in my head. . . Ms. M I know another idea . . .
23	because you have all those sixes and you count by fives and there’s only ones
24	left.
25	M: So you went 5, 10, 15, 20. [Ian nods].
26	I: 21, 22, 23, 24.
27	M: Excellent!

p. 225]. He was pleasantly surprised about how easy it was to count “all the sixes” by “counting by fives and adding the ones left”, which generated in him an intense feeling of discovering something new through a guess that made sense and that he was able to verify to be correct. The following passage below from *El Khachab* [25.2] provides another, and yet deeper, way of thinking about Ian’s experience. El Khachab foregrounds the significance of having a *purpose* as a way of motivating the emergence of new ideas, which is one way of explaining how learners sometimes find themselves being carried away during the process of discovery. The second sentence in the passage articulates in very clear terms the primary purpose of abduction and its central and unique role in the establishment of new knowledge [25.2, p. 172]:

“Before asking where new ideas come from, we need to ask what new ideas are for, and knowing what they are for, we can attune their newness to their purpose. And their purpose is, in the case of abduction, to provide true explanations following experimental verification.”

Ian saw purpose in counting by *five plus one* that encouraged him to further pursue his *new* idea. After verifying that his strategy actually worked on the available cases, he then articulated an explanation that matched what he was *thinking in his head*. The nature of what counts as a *true explanation* in abduction is explored in some detail in the succeeding sections. For now, it makes sense to think of abductive explanations as modeling instances of “relational or orientational

way of knowing”, which is a type of “embodied coping” that attends to [25.2, p. 172]

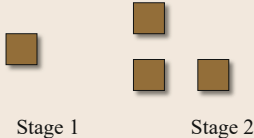

“the possible relations – what we might call the *relational dimensions* – that exist as a dynamical outcome of the interacting of objectively observable phenomena which are not in themselves objectively observable.”

Ian’s abductive thinking about counting by six is worth noting early in this chapter in light of recent findings on children’s algebraic thinking that show how many of them tend to use their knowledge of the multiplication table to help them generate and establish mathematical relationships and support their ability to construct explicit or function-based formulas involving linear patterns [25.3].

US eighth-grade student Dung’s figural processing of the two pattern generalization tasks shown in Figs. 25.1 and 25.2 illustrates another characterization of abductive thinking that “carries over a deeper similarity to a number of seemingly rather different sit-

uations” [25.1, p. 225]. Dung’s processing illustrates a kind of *double description* (i. e., in Bateson’s [25.5, p. 31] sense of “cases in which two or more information sources come together to give information of a sort different from what was in either source separately”) that is a necessary condition when students are engaged in mathematical thinking and learning. When Dung was presented with the ambiguous Fig. 25.1 task consisting of two beginning stages in a growing pattern, he constructed a growing sequence of L-shaped figures (Fig. 25.3). When he was asked to generate explicit rules for his pattern, he suggested  $s = n + n - 1$  and  $s = 2n - 1$ . When he was asked to justify them, Dung saw the pattern stages in terms of groups of squares. In the case of his first rule, each stage in his growing pattern consisted of the union of two variable units having cardinalities  $n$  and  $(n - 1)$  corresponding to the column and row of squares, respectively (see Fig. 25.3 stage 3 for an illustration). In the case of his second rule, two composite sides of squares that had the same number of squares on each side overlapped along the corner square (see Fig. 25.3 stage 5 for an example).

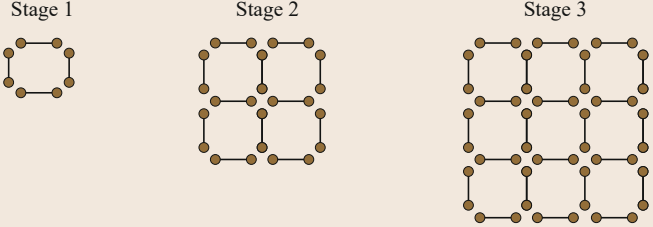

Below are the first two stages in a growing pattern of squares

1. Continue the pattern until stage 5.
2. Find a direct formula in two different ways. Justify each formula.
3. If none of your formulas above involve taking into account overlaps, find a direct formula that takes into account overlaps. Justify your formula.
4. How do you know for sure that your pattern will continue that way and not some other way?
5. Find a different way of continuing the pattern and obtain a direct formula for this pattern.

Fig. 25.1 Ambiguous patterning task in compressed form (after [25.4])

Consider the following array of sticks below

- A. Find a direct formula for the total number of sticks at any stage in the pattern. Justify your formula.
- B. Find a direct formula for the total number of points at any stage in the pattern. Justify your formula.

Fig. 25.2 Square array pattern (after [25.4])

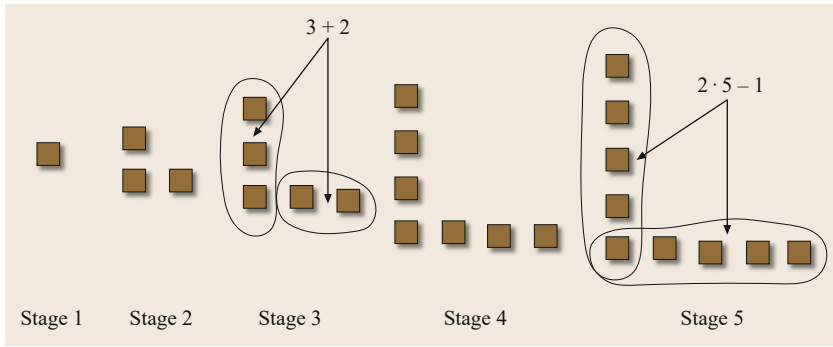

Fig. 25.3 Dung’s growing L shaped pattern (after [25.4])

For Dung, seeing pattern stages in terms of groups enabled him to justify his explicit rules, which became his abductive resource for constructing and justifying an explicit rule for the square array pattern shown in Fig. 25.2. Dung initially saw each pattern stage into parts of separate rows of squares and separate smaller squares per row (Fig. 25.4). Using stage 4, he parsed the whole figure into four disjoint rows and counted the number of sticks per row. In counting the number of sticks per row, he saw four disjoint squares for a total of  $4 \times 4 = 16$  sticks and then subtracted the three overlapping vertical sticks. He then counted the total number of horizontal and vertical sticks counting repetitions and obtained  $(4 \times 4) \times 4 = 52$ . In his written work, he immediately resorted to the use of a variable  $n$  to convey that he was thinking in general terms, which explains the expression  $(4n - (n - 1)) \times n$ . Since he also saw that the four disjoint rows had overlapping sides (i. e., the interior horizontal sticks), he then took away three ( $= 4 - 1$ ) groups of such four horizontal sticks from 52. That concrete step allowed him to complete his explicit rule

for the pattern, that is,  $s = (4n - (n - 1))n - (n - 1)n$ , which he then simplified to  $s = 2n^2 + 2n$ . Dung’s multiplicative thinking ability became his abductive – that is, double descriptive – abstracting resource that enabled him to infer deeper similarity among, and thus generalize to, different kinds of patterns.

In this chapter, we explore the relationship between abductive action and the emergence of necessary mathematical knowledge. The prevailing epistemological perspective on mathematical knowledge values the central role of induction and deduction in the development of necessary mathematical knowledge with a rather taken-for-granted view of abduction that in the past has been characterized as the creative, wild, and messy space of theory generation or construction. However, recent empirical studies on abduction and mathematical knowledge construction have begun to explore ways in which abduction could be implemented in more systematic terms beyond a way of reasoning by detectives from observations to explanations [25.6, p. 24] and merely “studying facts and devising a theory to ex-

A. Find a direct formula for the total number of sticks at any stage in the pattern. Justify your formula.

$$s = 4n^2 - (4n - (n - 1))n - (n - 1)n$$

$$s = 2n^2 + 2n$$

$$s = n(4n - (n - 1)) - n^2 + n$$

$$s = n(3n + 1) - n^2 + n$$

Fig. 25.4 Dung’s construction and justification of his formula for the Fig. 25.2 pattern (after [25.4])

plain them” because “its only justification is that if we are ever to understand things at all, it just be in that way” [25.7, p. 40]. For instance, *Mason et al.* [25.8] associate abductive processing with the construction of structural generalizations, while *Pedemonte* [25.9] situates abduction within a cognitive unity thesis that sees it as being prior and necessary to induction and ultimately deduction. Recent investigations in science and science education that pursue an abductive framework also underscore the central role of abduction in inference systems that model everyday phenomena. For instance, *Addis and Gooding* propose the iterative cycle of “abduction (generation) → deduction (prediction) → induction (validation) → abduction” in modeling the “scientific process of interpreting new or surprising findings by generating a hypothesis whose consequences are then evaluated empirically” [25.10, p. 38]. Another instance involves *Magnani’s* [25.11] formulation of actual computational models in which case abduction is seen as central to the development of creative reasoning in scientific discoveries and can thus be used to generate rational models.

In Sect. 25.2, we provide a characterization of the four types of inferences that students develop in mathematical activity. In Sect. 25.3 we note two key findings

from current research on abduction in mathematics and science education, which should provide the necessary context for understanding the ideas we pursue in the succeeding section. In Sect. 25.4 we explore ways in which students can effectively enact meaningful and purposeful abductive thinking processes and other [25.1, p. 224]

“kinds of *preparing activities* in mathematical learning contexts that will enable learners to become self-consciously engaged in, can get them *ready* to notice, immediately and spontaneously, the kinds of events relevant to their acquiring such relational or orientation understandings – where, by *being ready to do something* means what we often talk of as being in possessions of a *habit*, an *instinct*, an *inclination*, etc.”

Central to such processes and activities involves orchestrating effective tasks and other learning contexts that will engage all students in abductive thinking, which will go a long way in supporting growth in necessary mathematical knowledge and excellence in reasoning that is strategic and has “logical virtue (i. e., avoiding logical fallacies and learning what is and what is not admissible and valid)” [25.12, p. 269].

## 25.2 Inference Types

Table 25.2 lists the characteristics of four types of inferences that students develop in mathematical activity. *Abduction* involves generating a hypothesis or narrowing down a range of hypotheses that is then verified via *induction*. Abduction is the source of original ideas and is initially influenced by prior knowledge and experiences, unlike induction that basically tests an abductive claim on specific instances. The hope, of course, is that possible errors get corrected through the inductive route, which results in the construction of a generalization that draws on the available instances. Like induction, which performs the role of verifying an abductive claim, *deduction* produces results from general rules or laws and thus does not produce any original ideas. Unlike abduction, which is sensitive to empirical data, deduction relies on unambiguous premises in order to ascertain the necessity of a single valid conclusion. An *unambiguous* well-defined set or model assumes the existence of “a finite set of rules and without reference to context” that clearly defines membership or relationships among the elements in the set [25.10, p. 38].

Another useful way to think about abduction and deduction involves truth tables. Deductions depend on truth tables for validity, which also means to say that

the objects and rules of deduction all have to be well established and well defined. Abductions do not depend on truth tables and their validity is established via induction [25.10, p. 37–38]. *Deductive closure* conveys deductively derived arguments and instances and is a necessary condition for algebraic thinking in both symbolic and nonsymbolic contexts [25.13].

Consider, for example, the following four statements below that have been extracted from eighth-grade student *Cherrie’s* generalization of the Fig. 25.3 pattern:

Law (L): I think the rule is  $x = 2(n + 1)n$ .

Case (C): In stage 2, there’s two groups of three twice. There’s two four groups of three in stage 3. There’s two five groups of four in stage 4.

Result (R): Stages 1 through 4 follow the rule  $x$  equals two times  $(n + 1)$  times  $n$ .

All future outcomes (O): Stage 5 has  $26(5) = 60$  sticks, stage 10 has  $211(10) = 220$  sticks, and stage 2035 has 8 286 520 sticks in all.

Deduction assumes a general law and an observed case (or cases) and infers a necessary valid result, which also means that it does not have to depend on real or empirical knowledge for verification [25.14]. Cases

**Table 25.2** Types of inferences in mathematical activity and their characteristics

Inferential type	Inferential form	Intent	Inferential attitude	Sources	Desired construction	Nature of context, verification, and justification
Abduction	From result and law to case	Depth (intentional)	Entertains a plausible inference toward a rule Generates and selects an explanatory theory – that <i>something maybe</i> (conjectural)	Unpredictable (surprising facts; flashes; intelligent guesses; spontaneous conjectures)	Un/ Structured	Context-bound; Structured via induction
Induction	From result and more cases to law	Breadth (extensional)	Tests an abduced inference; measures the value and degree of concordance of an explanatory theory to cases – that <i>something actually is operative</i> (approximate)	Predictable (examples)	Structural based on abduction	Context-derived; empirical (e.g., enumeration, analogy, and experiments)
Deduction	From rule and case to result	Logical proof	Predicts in a methodical way a valid result – that <i>something must be</i> (certain)	Predictable (premises)	Structural (canonical form)	Decontextualized; Steps in a proof
Deductive closure	From an established deduction to future outcomes	Breadth (apply)	Assumes that all future outcomes will behave in the same manner as a result of a valid deductive hypothesis	Predictable (premises are valid deductions)	Structural based on an established deduction	Decontextualized; Mathematical induction (e.g., demonstration of a valid deductive claim)

are occurrences or instantiations of the stipulated law. When the first three statements above are switched in two different ways, we obtain the canonical structures for abduction and induction, which are ampliative because the conclusions “amplify or go beyond the information incorporated in the premises” [25.11, p. 511] and invalid (i. e., not necessary) from a deductive point of view. In a deductive closure, an established deduction becomes the cause or hypothesis that is then applied to future outcomes, which are effects. Figure 25.5 visually captures the fundamental differences among the four inferential types.

From a logicopsychological perspective, students need to learn to anticipate inferences that are sensible and valid in any mathematical activity. *Peirce* [25.15, p. 449], of course, reminds us that context matters despite our naturally drawn disposition toward “perpetually making deductions”. As an aside, kindergarten students (ages five to six years) in the absence of formal

learning experiences appear to consider deductive inferences as being more certain than inductive ones and other guesses [25.16].

Students also need to understand the limitations of each inferential process. For *Polya* [25.17], deduction exemplifies *demonstrative reasoning*, which is the basis of the “security of our mathematical knowledge” [25.17, p. v] since it is “safe, beyond controversy, and final”. Abduction and induction exemplify *plausible reasoning*, which “supports our conjectures” and could be “hazardous, controversial, and provisional” [25.17]. Despite such constraints, however, Peirce and Polya seem to share the view that abduction, induction, and deduction are epistemologically necessary. According to *Polya* [25.17], while “anything new that we learn about the world involves plausible reasoning”, demonstrative reasoning uses “rigid standards that are codified and clarified by logic” [25.17, p. v]. *Polya*’s perspectives are narrowly confined to how we come to understand and explain the nature of mathematical objects, unlike Peirce who formulates his view by drawing on his understanding of the nature of scientific practice. “All ideas of science come to it by way of abduction”, *Peirce* writes, which is the fundamental source of the emergence of ideas and “consists in studying facts and devising a theory to explain them” [25.7, p. 90].

In the next three subsections below, we discuss additional characteristics of each inferential type.

**Fig. 25.5** Differences among the four inferential types

### 25.2.1 Abduction

Abduction, the source of original ideas, discoveries, and explanatory theories, emerges and evolves in a continuum of thought processes, uncontrolled and instinctual (e.g., as initial impressions based on perceptions and informed guesses) in the early phase and structured and inferential (e.g., quasiductive) in a much later phase [25.2]. Through abduction, “descriptions of data, patterns, or phenomena” are inferred leading to plausible explanations, hypotheses, or theories “that deserve to be seriously entertained and further investigated” ([25.18, p. 1021], [25.11, p. 511]). Perceptual-like clues provide one possible source of abductive ideas [25.19]. The steps below outline a percept-based “formula that is similar to abduction” [25.19, p. 305].

“A well-recognized kind of object,  $M$ , has for its ordinary predicates  $P[1]$ ,  $P[2]$ ,  $P[3]$ , etc., indistinctly recognized. The suggesting object,  $S$ , has these same predicates,  $P[1]$ ,  $P[2]$ ,  $P[3]$ , etc. Hence,  $S$  is of the kind  $M$ .”

Iconic-based inferences also provide another possible source of abduction [25.19]. Icons, unlike percepts, are pure possible forms of the objects they represent or resemble. Iconic-based abductions employ the following abductive process [25.19, p. 306]:

$$\left. \begin{array}{l} P1 \\ H1 \end{array} \right\} \rightarrow \text{An iconic relationship between } P1 \text{ and } P2$$

$P1$  and  $P2$  are similar (iconically)

$\therefore$  Maybe  $H1$  (or something that is similar to  $H1$ ).

Abduction also involves “the problem of logical goodness, i.e., how ideas fulfill their logical purpose in the world” [25.2, pp. 159, 162]. *El Khachab* [25.2] uses the example of global warming to show how different stakeholders tend to model different kinds of goodness based on their purpose. Following Peirce, he notes that “the purpose of abduction is to provide hypotheses which, when subjected to experimental verification, will provide true explanations” [25.2, p. 162]. True explanations refer to “sustainable belief-habits, that is, as recurring settlements of belief about the world which rely on experientially or experimentally verifiable statements” [25.2, p. 163].

We note the following four important points below about abduction.

*First*, *Tschaep* [25.20] underscores the significance of guessing in abduction, that is [25.20, p. 117],

“guessing is the initial deliberate originary activity of creating, selecting, or dismissing potential solu-

tions to a problem as a response to the surprising experience of that problem.”

Having a guess enables learners to transition from the first to the second premise in Peirce’s general syllogism for abduction (i.e., the surprising fact,  $C$ , is observed; but if  $A$  were true,  $C$  would be a matter of course; hence, there is reason to suspect that  $A$  is true). Following *Kruijff* [25.21], *Tschaep* notes that guessing and perceptual judgment (i.e., observing a surprising fact  $C$ ) are “the two essential aspects that characterize the generation of ideas” [25.20, p. 117], where the event of surprise emerges from every individual knower’s experiences, which is perceptual in nature. Guessing, then [25.20, p. 117],

“follows perceptual judgment, signifying a transition between uncontrolled thought and controlled reasoning. [...] We guess in an attempt to address the surprising phenomenon that has led to doubt; it is our inchoate attempt to provide an explanation.”

*Second*, *Thagard* [25.22] makes sense in saying that an abductive process involves developing and entertaining inferences toward a law that will be tested via induction, which will then produce inferences about a case. For *Eco* [25.23], however [25.23, p. 203],

“the real problem is not whether to find first the Case or the Law, but rather how to figure out both the Law and the Case *at the same time*, since they are inversely related, tied together by a sort of chiasmus.”

*Third*, while the original meaning of abduction based on Peirce’s work refers to inferences that yield plausible or explanatory hypotheses, *Josephson* and *Josephson’s* [25.24] additional condition of *inferences that yield the best explanation* revises the structure of the original meaning of abduction in the following manner:

Case:  $D$  is a collection of data (facts, observations, givens).

Law:  $H$  explains  $D$  (would, if true, explain  $D$ ).

Strong Claim: No other hypothesis can explain  $D$  as well as  $H$  does.

Result:  $H$  is probably true.

*Paavola* [25.25] notes that while the original and revised versions of abductions share the concern toward generating explanations, they are different in several ways. The original version addresses issues related to the *processes of discovery* and the construction of plausible hypotheses, while the revised version models a nondeductive form of reasoning (except induction) that eventually establishes the true explanation. Across

the differences, it is instructive to keep in mind both *Adler's* “simple, conservative, unifying, and yields the most understanding” conditions for constructing strong abductions [25.26, p. 19] and *El Khachab's* logical goodness conditions that characterize good abductions. That is, they [25.2, p. 164]

“(1) need to be clear, i. e., they need to have distinguishable practical effects; (2) they need to explain available facts; and (3) they need to be liable to future experimental verification.”

*Fourth*, it is important to emphasize that abductions provide explanations or justifications that do not prove. Instead, they provide explanations or justifications that primarily assign causal responsibility in *Josephson's* [25.27, p. 7] sense below.

“Explanations give causes. Explaining something, whether that something is particular or general, gives something else upon which the first thing depends for its existence, or for being the way that it is. [...] It is common in science for an empirical generalization, an observed generality, to be explained by reference to underlying structure and mechanisms.”

### 25.2.2 Induction

Unlike abduction, induction tests a preliminary or an ongoing abduction in order to support a most reasonable law and thus develop a generalization that would both link and unite both the known and projected cases together in a meaningful way. By testing an abductive claim over several cases, induction determines whether the claim is right or wrong. So defined, a correct induction does not produce a new concept that explains (i. e., an *explanatory theory*), which is the primary purpose of abductive processing. Instead, it seeks to show that once the premises hold (i. e., the case/s and the result/s), then the relevant conclusions (i. e., the law) must be true by enumeration (number of observed cases), analogy (i. e., structural or relational similarity of features among cases), or scientific analysis (through actual or mental experiments) [25.28] and thus reflect causal relationships that are expressed in the form of (categorical inductive or universally quantified) generalizations [25.11]. In the case of enumeration, in particular, the goal is not to establish an exhaustive count leading to a precise numerical value, but it is about “producing a certain psychological impression [...] brought about through the laws of association, and creating an expectation of a continuous repetition of the experience” [25.28, p. 184]. In all three contexts of inductive justification, inductive inferences do

not necessarily yield true generalizations. However, “in the long run they approximate to the truth” [25.29, p. 207].

Four important points are worth noting about the relationship between abduction and induction, as follows:

*First*, *El Khachab* points out how both abduction and induction appear to be “unclear” about their “practical effects which are essentially similar” [25.2, p. 166]. However, they are different in terms of “degree”, that is [25.2, p. 166],

“an induction is an inference to a rule; an abduction is an inference to a rule *about* an occurrence, or in Peirce’s own words, *an induction from qualities* [...] Induction is a method of experimental verification leading to the establishment of truth in its long-term application.”

*Second*, abduction is not a requirement for induction. That is, there can be an abduction without induction (i. e., abductive generalizations). Some geometry theorems, for example, do not need inductive verification. In some cases, abduction is framed as conjectures that are used to further explain the development of schemes ([25.30] in the case of fractions). However, it is useful to note the insights of *Pedemonte* [25.9] and *Prusak et al.* [25.31] about the necessity of a structural continuity between an abduction argument process and its corresponding justification in the form of a logical proof. That is, a productive abductive process in whatever modal form (visual, verbal) should simultaneously convey the steps in a deductive proof.

Even in the most naïve and complex cases of inductions (e. g., number patterns with no meaningful context other than the appearance of behaving like objects in some sequence), learners initially tend to produce an abductive claim as a practical embodied coping strategy, that is, as a way of imposing some order or structure that may or may not prove to make sense in the long haul. Euler’s numerical-driven generalization of the infinite series  $\sum_{n=1}^{\infty} \frac{1}{n^2}$  is a good example. He initially established an analogical relationship between two different types of equations (i. e., a polynomial  $P$  of degree  $n$  having  $n$  distinct nonzero roots and a trigonometric equation that can be transformed algebraically into something like  $P$  but with an infinite number of terms). Euler’s abductive claim had him hypothesizing an anticipated solution drawn from similarities between the forms of the two equations. Upon inductively verifying that the initial four terms of the two equations were indeed the same, Euler concluded that [25.17, pp. 17–22]

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{6} .$$

Third, another consequence of the preceding discussion involves the so-called *inductive leap*, which involves establishing a generalization from concrete instances to a conclusion that seems to contain more than the instances themselves. On the basis of the characterizations we have assigned to abduction and induction, such a leap is no longer an issue since the leap itself is settled by abduction. Hence, criticisms that in effect cite “hazardous inductive leap” as an argument in relation to erroneous patterning questions such as the one shown in Fig. 25.6 is more appropriately and fundamentally a problem of abduction.

Fourth, neither abduction nor induction can settle the issue of *reasonable of context*. For example, the patterning situation in Fig. 25.7 can have a stipulated abduction and an inductively verified set of outcomes based on an interpreted explicit formula. However, as Parker and Baldrige [25.32] have noted, “there is no reason why the rainfall will continue to be given by that expression, or *any* expression”, which implies that the “question cannot be answered” [25.32, p. 90].

### 25.2.3 Deduction and Deductive Closure

While abduction and induction provide support in constructing or producing a theory, both deduction and deductive closure aim to exhibit necessity. Pace Smith [25.33]: “(R)epeated co-instantiation via induction is not the same as inferential necessity” [25.33, p. 5]. A valid deduction demonstrates a logical implication, that is, it shows how a law and a case as premises or hypotheses together imply a necessary result, conclusion, or consequence. It is a “self-contained process” because the validation process relies on “the existence of well-defined sets” and preserves an already established law, thus, “freeing us from the vagaries and changeability of an external world” [25.10, p. 37].

*A certain pattern begins with 1, 2, 4. If the pattern continues, what is the next number?*

- A. 1
- B. 2
- C. 7
- D. 8

**Fig. 25.6** An example of an erroneous generalization problem

It started to rain. Every hour Sarah checked her rain gauge. She recorded the total rainfall in a table. How much rain would have fallen after  $h$  hours?

Hours	Rainfall
1	0.5 in
2	1 in
3	1.5 in

**Fig. 25.7** An Example of a patterning task with an erroneous context (after [25.32])

Deductive closure emerges in students’ mathematical thinking and reasoning in at least two ways depending on grade-level expectations, as follows. Among elementary and middle school students, once they (implicitly) form a deduction, they tend to provide an empirical (numerical or visual) structural argument then a formal deductive proof as a form of explanation or justification. For example, Cherrie’s algebraic generalization relative to the pattern in Fig. 25.3 could be expressed in deductive form. When she began to correctly apply her result to any stage in her pattern beyond the known ones, her reasoning entered the deductive closure phase.

Among high school students and older adults, once they formulate a deduction, they tend to provide any of the following types of justification that overlap in some situations: an empirical structural argument; a logical deductive proof; or a mathematical induction proof. Figure 25.8 illustrates how a group of 34 US Algebra 1 middle school students (mean age of 13 years) empirically justified the fact that  $-a \times -b = -(a \times -b)$  by demonstrating a numerical argument following a statement-to-reason template [25.34, pp. 126–130]. Note that when the numbers in the empirical argument shown in Fig. 25.8 are replaced with variables, the argument transforms into a logical deductive proof in which case the steps follow a logical “recycling process” (Duvall, quoted in Pedemonte [25.9, p. 24]), that is, the conclusion of a foregoing step becomes the premise of a succeeding step from beginning to end. Deductive closure for these students occurred when they began to obtain products of integers (and, much later, rational numbers) involving negative factors without providing a justification.

Figure 25.9 shows a mathematical inductive proof of a classic theorem involving the sum of the interior angles in an  $n$ -sided convex polygon that has been drawn from Pedemonte’s [25.9] work with 102 Grade 13 students (ages 16–17 years) in France and in Italy. The “multimodal argumentative process of proof” [25.31, 35] evolved as a result of a structural continuity between a combined abductive-inductive action that was performed on a dynamic geometry tool, which focused on a perceived relationship between the process of constructing nonoverlapping triangles in a polygon and the effects on the resulting interior angle sums, and the accompanying steps that reflected the structure of a mathematical induction proof.

Based on the figure below, Let us illustrate why  $-3 \times 2 = -(3 \times 2)$  using properties of integers.  $-3 \times 2 = -(3 \times 2)$  means pull 3 groups of 2 cubes on the positive region to the negative region

$$\begin{aligned}
 -3 \times 2 &= (-3 \times 2) + 0 \\
 &= (-3 \times 2) + [(3 \times 2) + -(3 \times 2)] \\
 &= [(-3 \times 2) + (3 \times 2)] + -(3 \times 2) \\
 &= [(-3 + 3) \times 2] + -(3 \times 2) \\
 &= 0 + -(3 \times 2) \\
 &= -(3 \times 2)
 \end{aligned}$$

 Additive identity property

**Fig. 25.8** An empirical structural argument for  $-a \times -b = -(a \times -b)$  (after [25.34])

66. M: If n is equal to 3, f(n) is equal to  $180 \times 1$ ...  
 If n is equal to 4, f(n) is equal to 360, which is equal to  $180 \times 2$   
 67. L: N equal to 5, f(n) is equal to 540, which is equal to  $180 \times 3$ ...  
 68. M: So f(n) is equal to  $180 \times (n-2)$  ...  
 69. L: OK, now we have to understand why ...

70. M: OK... wait!  
 71. L: F(4) is equal to  $180 + f(3)$  because there is one triangle more... so  $180 + 180$ ...  
 72. M: OK, then f(5) is... is  $f(4) + 180$ ... that means that f(n) is equal to  $f(n-1) + 180$   
 73. L: You always add 180 to the previous one  
 74. M: OK we can write  $f(n+1)$  as  $f(n) + 180$ ...

Base  $F(3) = 180^\circ$   
 $F(n+1) = 180^\circ(n-1)$   
 $F(n+1) = F(n) + 180^\circ$   
 It is necessary to add  $180^\circ$  to  $F(n)$  because if we add a side to the polygon, we add a triangle too.  
 The sum of the triangles angles is  $180^\circ$ .  
 So:  
 $F(n+1) = 180^\circ(n-2) + 180^\circ$   
 $F(n+1) = 180^\circ(n-2+1)$   
 $F(n+1) = 180^\circ(n-1)$

**Fig. 25.9** A mathematical inductive proof for the sum of the interior angles in an  $n$ -sided convex polygon (after [25.8, p. 37–38])

The work shown in Fig. 25.10 was also drawn from the same sample of students that participated in Pedemonte's [25.9] study. Unlike Fig. 25.9, the analysis that the students exhibited in Fig. 25.10 shows a structural discontinuity between a combined abductive-inductive action, which primarily focused on the results or out-

comes in a table of values, and steps that might have produced either a valid empirical justification or a logical mathematical induction proof. Deductive closure for these students occurred when they began to obtain the interior angle sum measures of any convex polygon beyond the typical ones.

<p><i>Alice constructs the following table:</i></p> <table border="1" style="width: 100%; border-collapse: collapse; margin-bottom: 10px;"> <thead> <tr> <th style="padding: 5px;">Sides</th> <th style="padding: 5px;">Sum (Angles)</th> </tr> </thead> <tbody> <tr> <td style="padding: 5px; text-align: center;">3</td> <td style="padding: 5px;">180°</td> </tr> <tr> <td style="padding: 5px; text-align: center;">4</td> <td style="padding: 5px;">360°    180° × 2</td> </tr> <tr> <td style="padding: 5px; text-align: center;">5</td> <td style="padding: 5px;">540°    180° × 3</td> </tr> <tr> <td style="padding: 5px; text-align: center;">6</td> <td style="padding: 5px;">720°    180° × 4</td> </tr> </tbody> </table> <p>29. A: So the rule is probably <math>180 \times (n-2)</math> for an <math>n</math>-sided polygon</p> <p>30. L: Yes... <math>n</math> is the number of sides</p>		Sides	Sum (Angles)	3	180°	4	360°    180° × 2	5	540°    180° × 3	6	720°    180° × 4
Sides	Sum (Angles)										
3	180°										
4	360°    180° × 2										
5	540°    180° × 3										
6	720°    180° × 4										
<p>Base for <math>n = 3</math>  <math>180^\circ(3-2) = 180^\circ</math></p> <p>Step            Hp: <math>180^\circ(n-2)</math>            Ts: <math>180^\circ(n-1)</math></p> <p><math>S(n) = 180^\circ (n-2) = 180n - 360</math>  <math>S(n+1) = 180^\circ (n+1) - 360 = 180n + 180 - 360 = n + 1 - 2 = n - 1</math> Th            We have proved the thesis by a mathematical induction</p>											

**Fig. 25.10** Example of an erroneous mathematical inductive argument for the sum of the interior angles in an  $n$ -sided convex polygon (after [25.8, p. 36])

## 25.3 Abduction in Math and Science Education

A nonexhaustive survey of recent published studies dealing with abduction in mathematical and scientific thinking and learning yields two interesting findings, as follows.

### 25.3.1 Different Kinds of Abduction

Drawing on *Eco's* [25.23] work, *Pedemonte* and *Reid* [25.36] provided instances in which traditional 15–17-year-old Grades 12 and 13 students in France and Italy modeled overcoded, undercoded, and creative abductions in the context of proving statements in mathematics. For *Pedemonte* and *Reid*, abduction comes before deduction. Some students in their study generated overcoded abductions, which involve using a single rule to generate a case, while others produced undercoded abductions, which involve choosing from among several different rules to establish a case. Overcoded and undercoded abductions for *Magnani* [25.11] exemplify instances of selective abductions because the basic task involves selecting one rule that would make sense, which, hopefully, would also yield the best explanation. Medical diagnosis, for instance, employs selective abductions [25.11]. In cases when no such rules exist, students who develop new rules of their own yield what *Eco* [25.23] refers to as creative abductions, which also account for “the growth of scientific knowledge” [25.11, p. 511]. *Pedemonte* and *Reid* have noted that students are usually able to construct a deductive proof in cases involving overcoded abductions due to the limited number of possible sets of rules to choose from. Furthermore, they tend to experience considerable difficulties in cases that involve undercoded and creative abductions since they have to deal with

“irrelevant information in the argumentation process, thus confusing, and creating disorder” in their processing [25.36, p. 302]. An additional dilemma that students have with creative abductions is the need to justify them prior to using them as rules in a proof process. “Consequently”, *Pedemonte* and *Reid* write [25.36, p. 302],

“it seems that there is not a simple link between the use of abduction in argumentation and constructing a deductive proof. Both the claim that abduction is an obstacle to proof and the claim that abduction is a support, if considered in a general sense, are oversimplifications. Some kinds of abductions, in some context may make the elements required for the deductions used in a proof more accessible. Some are probably less dangerous to use and can make the construction of a proof easier to get to because they could make easier to find and to select the theorem and the theory necessary to produce a proof. However, other kinds of abductions present genuine obstacles to constructing the proof. This suggests that teaching approaches that involve students conjecturing in a problem solving process prior to proving have potential, but great care must be taken that the abductions expected of the students do not become obstacles to their later proving.”

Aside from selective and creative abductions, *Magnani* [25.11] pointed out the significance of theoretical and manipulative abductions in other aspects of everyday and scientific work that involve creative processing. Theoretical abductions involve the use of logical, verbal or symbolic, and model-based (e.g., diagrams and pic-

tures) processing in reasoning. While valuable, they are unable to account for other possible types of explanations (e.g., statistical reasoning, which is probabilistic; sufficient explanations; high-level kinds and types of creative and model-based abductions; etc.). Manipulative abductions emerge in cases that involve “thinking and discovering through doing”, where actions are pivotal in enabling learners to model and develop insights simultaneously leading to the construction of creative or selective abductions. They operate beyond the usual purpose of experiments and create “extra-theoretical behaviors” that [25.11, p. 517]

“create communicable accounts of new experiences in order to integrate them into previously existing systems of experimental and linguistic (theoretical) practices. The existence of this kind of extra-theoretical cognitive behavior is also testified by the many everyday situations in which humans are perfectly able to perform very efficacious (and habitual) tasks without the immediate possibility of realizing their conceptual explanation.”

Typical accounts of conceptual change processes in science tend to highlight theoretical abductions, however [25.11, p. 519],

“a large part of these processes are instead to due practical and *external* manipulations of some kind, prerequisite to the subsequent work of theoretical arrangement and knowledge creation.”

Manipulative abductions may also emerge in learning situations that provide “conceptual and theoretical details to already automatized manipulative executions” in which case either teacher or learner [25.11, p. 519]

“does not discover anything new from the point of view of the objective knowledge about the involved skill, however, we can say that his conceptual awareness is new from the local perspective of his individuality.”

For example, *Rivera* [25.37] provides a narrative account of US third-grade Mark’s evolving understanding of the long division algorithm involving multidigit whole numbers by a single-digit whole number. Mark’s initial visual representation processing of (sharing-partitive) division (Fig. 25.11) employed the use of place value-driven squares, sticks, and circles. In the case of the division task  $126 \div 6$ , when he could not divide a single (hundreds) box into six (equal) groups, he recorded it as a 0. He then ungrouped the box into ten sticks, regrouped the sticks together, divided the

Fig. 25.11 Mark’s initial visual processing of  $126 \div 6$

sticks into six groups, recorded accordingly, and so on until he completed the division process for all subcollections. His numerical recording in Fig. 25.11 also captured every step in his sequence of visual actions. Results of consistent visual processing enabled him to shift his attention away from the visual form and toward the rule for division, which was accompanied by two remarkable changes in his numerical processing. In Fig. 25.12, he performed division on each digit in the dividend from left to right with the superscripts indicating partial remainders that had to be ungrouped and regrouped. In Fig. 25.13, he made another subtle creative revision that remained consistent with his earlier work and experiences. When he was asked to explain his division method, Mark claimed that “it’s like how we do adding and subtracting with regrouping, we’re just doing it with division”. Mark’s manipulative abductive processing for division involving whole numbers necessitated a dynamic experience in which “a first *rough* and concrete experience” [25.11, p. 519] of the process enabled him to eventually develop a version of the long division process that “unfolded in real time” via thinking through doing.

### 25.3.2 Abduction in Mathematical Relationships

A study by *Arzarello* and *Sabena* [25.38] illustrates the important role of abduction in constructing mathematical relationships involving different signs. Signs pertain to the triad of signifier, signified, and an individual learner’s mental construct that enables the linking between signifier and signified possible. Arzarello and Sabena underscore their students’ use of semiotic and theoretic control when they argued and proved statements in mathematics. Semiotic control involves choosing and implementing particular semiotic resources (e.g., graphs, tables, equations, etc.) when they manipulate and interpret signs (i.e., type-1 semiotic action), while theoretic control involves choosing and implementing appropriate theories (e.g., Euclidean theorems) or parts of those theories and related conceptions when they “elaborate an argument or a proof” (i.e., type-3 semiotic action; [25.38, p. 191]). Between type-1 and

7. Eight-hundred thirty-seven divided by three $\begin{array}{r} 8237 \\ \div 3 \\ \hline 279 \end{array}$ $\begin{array}{r} 279 \\ \times 3 \\ \hline 837 \end{array}$	8. Eight-hundred fifty-two divided by three $\begin{array}{r} 8252 \\ \div 3 \\ \hline 284 \end{array}$ $\begin{array}{r} 284 \\ \times 3 \\ \hline 852 \end{array}$

type-3 semiotic action is a type-2 semiotic action that involves using abduction to identify relationships between signs and assessing the arguments. Based on their qualitative work with Grade 9 students, such [25.38, p. 202]

“relationships between signs are examined and checked with redundant local arguments, and (economic, explanatory, and testable) hypotheses are detected and made explicit by means of abductions.”

Furthermore, they note how [25.38, p. 204]:

“abduction has an important role at this point. There is an evolution from a phase where the attention is mainly on the given signs, towards a phase where the logical-theoretical organization of the argument becomes the center of the activities and evolves from abductive to deductive and more formal structures. [...] Such an evolution implies a passage from actions of type 1 to actions of type 2 and then 3, and a shift of control by the student, i. e., passing from actions guided by semiotic control to actions guided by theoretical control. [...] Passing from type 1- to type 3-semiotic actions means an evolution from the data to the truth because of theoretical reasons. It is exactly this distinction that makes the difference between [...] a *substantial argument* and an *analytical argument*, which is a mathematical proof.”

Arzarello and Sabena's study foregrounds the role of abduction in inferential processing and documents how a shift from abduction to deduction is likely to occur when students' mathematical thinking shifts in

focus from the semiotic to theoretical, respectively. Studies by *Pedemonte* and colleagues [25.9, 36, 39] and *Boero* and colleagues [25.40, 41] also note the same findings in both algebra and geometry contexts. Across such studies we note how abduction is conceptualized in terms of its complex relationships with induction and deduction. Other studies do not deliberately focus on such shifts and relationships, making it difficult for students to see the value of engaging in abductive processing in the first place. For example, *Watson* and *Shipman* [25.42] documented the classroom event that happened in a Year 9 class of 13–14 year-old students in the UK that investigated the following task: Find a way to multiply pairs of numbers of the form  $a + \sqrt{b}$  that results in integer products. While the emphasis of their study focused on learning through exemplification by using special examples to help students develop meaningful plausible structures, it seems that the abductive process for them became a matter of conjecturing relationships based on their experiences with their constructed examples. But certainly there is more to abductive processing than merely generating conjectures, as follows.

Several studies have suggested inferential model systems that show relationships between and among abduction, induction, and deduction. *Addis* and *Gooding* [25.10], for example, illustrate how the iterative cycle of

abduction (generation) → deduction (prediction) →  
induction (validation) → abduction

might work in the formation of consensus from beliefs. *Radford's* [25.43] architecture of algebraic pattern generalizations emphasizes a tight link between abduction and deduction, that is, hypothetico-deduction, in the fol-

Fig. 25.14 Cross-squares pattern

lowing manner:

abduction (from particulars  $p_1, p_2, \dots, p_k$   
to noticing a commonality  $C$ )  
→ transforming the abduction  
(from noticing  $C$  to making  $C$  a hypothesis)  
→ deduction (from hypothesis  $C$   
to producing the expression of  $p_n$ ).

The studies conducted by Rivera [25.44] with groups of elementary (i. e., first through third grade) and middle school (i. e., sixth through eighth grade) students in the US on similar pattern generalization tasks capture two different inferential structures. Prior to a teaching intervention that involved using multiplicative thinking to establish pattern rules, both elementary and middle school student groups employed the same inferential structure of

abduction → induction → deduction  
→ deductive closure

that enabled them to generalize (correctly and incorrectly). The abductive phase in such a structure tended to be instinctual and iconic- or perceptual-driven. After the teaching intervention, however, Rivera observed that while the elementary student groups continued to model the same inferential structure in pattern gener-

alizing, the middle school student groups skipped the induction phase and instead exhibited the following structure:

abduction and deduction → deductive closure .

Abduction in this phase was combined with deduction and thus became structured and inferential as a consequence of their ability to express generalizations in multiplicative form. For example, when the pattern generalization task shown in Fig. 25.14 was presented to both elementary and middle school student groups after the teaching experiment, sixth-grade student Tamara initially abducted the recursive relation  $+4$ , which enabled her to deduce the explicit rule  $s = n \times 4 + 1$ . She then used her combined abductive-deductive inference to perform deductive closure, in which case she induced the given stages and predicted the correct number of squares for any stage in her pattern. Tamara's empirical justification of her explicit rule for the total number of squares  $s$  involves seeing a fixed square and four copies of the same *leg* that grew according to the stage number  $n$ . In the case of third-grade Anna, her multiplicative-driven abductive processing enabled her to both construct and justify the same explicit rule that Tamara established for the pattern. However, she needed to express her answers inductively, as follows

$$4 \times 1 + 1, 4 \times 2 + 1, 4 \times 3 + 1, \dots, 4 \times 100 + 1, \dots$$

## 25.4 Enacting Abductive Action in Mathematical Contexts

We close this chapter by providing four suggestions for assisting students to enact meaningful, structured, and productive abduction action. Together the suggestions target central features in abductive cognition, that is, thinking, reasoning, processing, and disposition. Empirical research in mathematics education along these features is needed to fully assess the extent and impact of their power in shaping mathematical knowledge construction.

### 25.4.1 Cultivate Abductively-Infused Guesses with Deduction

Students will benefit from knowing how to generate *new* guesses and conjectures that can explain a problem and occur “within the wider scope of the process of inquiry” [25.20, p. 116]. That is, while abductions certainly emerge from perceptual judgments, in actual practice the more useful ones are usually constrained

and logical as a consequence of knowing the problem context and being “compounds of deductions from general rules” (i. e., hypothetico-deductivist) that individual knowers are already familiar with (Peirce, quoted in [25.20, p. 119]). *Tschaepé* writes, “(w)e guess in an attempt to address the surprising phenomenon that has led to doubt; it is our inchoate attempt to provide an explanation” [25.20, p. 118]. Viewed in this sense [25.20, p. 122],

“[a]bduction is a logical operation, and guess is logical insofar as it is a type of reasoning by which an explanation of a surprising phenomenon is first created, selected, or dismissed [...] Guessing is the creative component of abductive inference in which a new idea is first suggested through reasoning.”

### 25.4.2 Support Logically-Good Abductive Reasoning

Students will benefit from knowing how to develop abductions that are logically good, that is, they are: clear (i. e., can be confirmed or disconfirmed); can explain the facts; are capable of being tested and verified; and can lead to true explanations that establish “sustainable belief-habits” [25.2, p. 163]. Such explanations may be new and may emerge from guesses and instincts, but, *Khachab* writes [25.2, pp. 171–172],

“logical goodness is the reason for *abduction*, under its diverse meanings. No matter *how* abduction *actually* generates *new* ideas – whether it is abductive inference, strategic inference, instinctive insight, etc. – its purpose is, ultimately, to provide true explanatory hypotheses for inquiry. And, in this regard, *new* hypotheses should always be evaluated in reference to their goodness.”

### 25.4.3 Foster the Development of Strategic Rules in Abductive Processing

*Paavola* [25.12] distinguishes between definitory and strategic rules. While definitory rules focus on logic and logical relationships, strategic rules pertain to “goal-directed activity, where the ability to anticipate things, and to assess or choose between different possibilities, are important” [25.12, p. 270]. Thus, abductive strategies produce justifications for given explanatory hypotheses, including justifications for “why there cannot be any further explanation” [25.12, p. 271]. Hence, all generated abductive inferences conveyed in the form of discoveries provide an analysis or explanation of

the underlying conceptual issues and are not merely reflective of mechanical recipes or algorithms for generating ideas and discoveries. Furthermore, the analysis or explanation should present “a viable way of solving a particular problem and that it works more generally (and not only in relationship to one, particular anomalous phenomenon)” [25.12, p. 273] and fit the “constraints and clues that are involved in the problem situation in question” [25.12, p. 274].

### 25.4.4 Encourage an Abductive Knowledge-Seeking Disposition

*Sintonen*’s [25.45] interrogative model of inquiry that employs an explicit logic of questions demonstrates the significance of using certain strategic principles and why-questions as starting points in abductive processing. Questions as well as answers drive discoveries and the scientific process. Questions, especially, “pick out something salient that requires special attention, and that it also gives heuristic power and guidance in the search for answers” [25.45, p. 250]. Furthermore, [25.45, p. 263],

“principal questions are often explanation-seeking in nature and arise when an agent tries to fit new phenomena to his or her already existing knowledge. Advancement of inquiry can be captured by examining a chain of questions generated. By finding answers to subordinate questions, an agent approaches step by step toward answering the big initial question, and thus changes his or her epistemic situation.”

Students will benefit from situations and circumstances that engage them in a knowledge-seeking game in which they “subject a source of information [...] to a series of strategically organized questions. This Sherlock Holmes method therefore is at the heart of abductive reasoning” [25.45, p. 254]. Furthermore, the interrogative model allows conclusions (i. e., answers) to emerge. “For abductive tasks”, *Sintonen* writes [25.45, p. 256],

“the goal must be understanding and not just knowledge. A rational inquirer who wants to know why and not only that something is the case must, after hearing the answer, be in the position to say *Now I know (or rather understand) why the (singular or general) fact obtains*. Obviously this condition is fulfilled only if she or he knows enough of the background to be able to insert the offered piece of information into a coherent explanatory account.”

Jonathan Waskan, Urbana, USA

Model-based reasoning refers to the kinds of inferences performed on the basis of a knowledge-context that guides them. This context constitutes a model of a domain of reality, that is, an approximative and simplifying to various degrees representation of the factors that underlie, and the interrelations that govern, the behavior of the entities in this domain. Model-based reasoning is ubiquitous in the human (and not only the human) brain. Various studies have shown that most likely we do not draw inferences by applying some abstract, formal rules; instead inference rules are applied within concrete-knowledge contexts that determine which rules should be used and when.

Model-based reasoning is not limited to the cognitive functions of the brain but it is likely that it extends to perceptual functions that retrieve information from the environment. [Chapter 26](#) defends the view that the processes of visual perception constitute a case of model-based reasoning. It discusses, first, the problem of whether vision involves model-based inferences and, if so, what kind. Secondly, it discusses the problem of the nature of the context that guides visual inferences. It finally addresses the broader problem of the relation between visual processing and thinking; various modes of inferences, the most predominant conceptions about visual perception, the stages of visual processing, the problem of the cognitive penetrability of perception, and the logical status of the processes involved in all stages of visual processing are discussed and assessed.

Reasoning is usually considered to consist of actions that occur exclusively within the brain of the agent that reasons. Reasoning is a mental activity in which various inference rules are applied to mentally represented sentences. This is not always true, however. On many occasions agents use external representations to enhance their inferential capabilities by overcoming limitations in working memory capacities, by simplifying the problem space, etc. In the second chapter, [Bechtel](#) argues that humans often reason by constructing, manipulating, and responding to external representations, whether the reasoning be deductive, abductive, or inductive. These representations are not only linguistic expressions (symbols on a piece of paper, for instance) but also include diagrams. Although diagrams are used in everyday reasoning, they are particularly important in science; diagrams, for example, figure in the processes through which scientists analyze data and construct their explanations. In [Chap. 27](#) [Bechtel](#) discusses what is known about how people, including scientists, reason with diagrams.

Another consequence of the assumption that reasoning takes place within the human mind is that reasoning

depends only on the mental properties of the reasoning agent and is independent of the agent's body. More generally, cognition is limited within the mind of the cognitive agent. This assumption has been recently challenged on many grounds and the argument has been made that reasoning is embodied in that it constitutively and not merely causally involves the body of the reasoning agent. In this vein, [Chap. 28](#) focuses on the role of the concept of mental imagery as a fundamental cognitive capability that enhances the performance of cognitive robots. The authors discuss the embodied imagery mechanisms applied to build artificial cognitive models of motor imagery and mental simulation to control complex behaviors of humanoid platforms that represent the artificial body.

If reasoning is model based, the reasoning agent draws from a variety of sources in order to choose the more salient and useful rules in a particular problem context, to choose the information that will be brought to bear on the problem at hand, to determine how to update her knowledge basis in view of the outputs of the rule, etc. The complexity of the task paves the way for dynamic approaches to cognition, as they are better suited to handle complexities of this magnitude and explain animals' intelligent behavior more adequately. Dynamical models of cognition put emphasis on time and complexity, both of which relate context to behavior. In [Chap. 29](#), [Metzger](#) argues that temporal processes allow memory, feedback, the effects of non-linear recursion, and the generation of expectation to be brought to bear on cognitive activities, whereas complexity allows stable patterns of coordination to emerge from the interaction of sub-processes. [Metzger](#) reviews several models of cognition, and their dynamical features. She focuses on the manner in which each model deals with time and complexity, thought, and action.

Dynamical models could also be used to model the ways that humans continuously adapt their behavior to changes in their environment, and the way their cognitive abilities continuously develop over time. In [Chap. 30](#), [P. van Geert](#), [R. den Hartigh](#), and [R. Cox](#) argue that an important question for psychologists in this direction has been the discovery of the (cognitive) mechanism that underlies the control of human behavior in real time, as well as the process of cognitive development in the long term. Their chapter discusses two kinds of general approaches, namely, the reductionist approach and the complex dynamic systems (CDS) approach. The reductionist approach, on the one hand, assumes that separate components, such as brain areas or cognitive processing mechanisms, are the main determinants of behavior and development, by processing (and responding to) specific environmental inputs.

---

The CDS approach, on the other hand, assumes that cognition, and, hence, the control of behavior and development, are distributed over the brain, the body, and the environment, all three continuously interacting over time.

Thus, dynamic system theory proposes ways in which embodied cognition (that is, the view that cognitive processes constitutively involve the body) and extended cognition (that is, the view that cognitive processes constitutively involves the environment and, in this sense, are extended to the world breaking the boundaries of the mind/brain) could be brought together with the received view that cognition is restricted to what happens within the boundaries of the brain, and provide a more adequate account of animal cognition. To substantiate this claim, the authors compare the two approaches with respect to their assumptions, research strategies, and analyses. Furthermore, they discuss the extent to which current research data in the cognitive domain can be explained by the two

different approaches. They conclude that the CDS approach provides the most plausible approach to cognition.

In *Chap. 31*, *Waskan* argues that model-based reasoning in science is often carried out in an attempt to understand the kinds of mechanical interactions that might give rise to particular occurrences. Scientists do that by constructing and using mental models that are like scale models in crucial respects. Behavioral evidence points to the existence of these mental models, but the neural plausibility of this hypothesis is still questioned. *Waskan* provides an overview of the psychological literature on mental models of mechanisms, focusing on the problem of how representations that share the distinctive features of scale models might be realized by neural machinations. He argues that lessons brought together from the computational simulation of mechanisms and from neurological research on mental maps in rats, could be applied to explain how neurophysiological processes might realize mental models.

## 26. Vision, Thinking, and Model-Based Inferences

Athanasios Raftopoulos

Model-based reasoning refers to the sorts of inferences performed on the basis of a knowledge context that guides them. This context constitutes a model of a domain of reality, that is, an approximative and simplifying to various degrees representation of the factors that underlie, and the interrelations that govern, the behavior of this domain.

This chapter addresses both the problem of whether vision involves model-based inferences and, if yes, of what kind; and the problem of the nature of the context that acts as the model guiding visual inferences. It also addresses the broader problem of the relation between visual processing and thinking. To this end, the various modes of inferences, the most predominant conceptions about visual perception, the stages of visual processing, the problem of the cognitive penetrability of perception, and the logical status of the processes involved in all stages of visual processing will be discussed and assessed.

The goal of this chapter is, on the one hand, to provide the reader with an overview of the main broad problems that are currently debated in philosophy, cognitive science, and visual science, and, on the other hand, to equip them with the knowledge necessary to allow them to follow and assess current discussions on the nature of visual processes, and their relation to thinking and cognition in general.

*Helmholtz* [26.1] famously maintained that perception is a form of inference; the brain uses probabilistic knowledge-driven inferences to induce the causes of the sensory input from this input, that is, to extract from the bodily effects of the light emanating from the objects in a visual scene as it impinges on our transducers the various aspects of the world that cause the input. The brain integrates computationally the retinal properties of the image of an object with other relevant sources of information to determine the object's intrinsic properties. *Rock* [26.2] claimed that the perceptual system combines inferential information to form the percept. From visual angle and distance information, for example, the perceptual system infers and perceives size. This inference may be automatic and outside the authority of the viewer who does not have control over it, but is an inference nevertheless.

Similarly, *Spelke* [26.3] suggests "perceiving objects may be more akin to thinking about the physical world than to sensing the immediate environment". The reason is that the perceptual system, to solve the underdetermination problem of both the distal object from the retinal image and of the percept from the retinal image, employs a set of object principles (the Spelke principles) that reflect the geometry and the physics of our environment. Since the principles can be thought of as some form of knowledge about the world, perception engages in inferential processes from some pieces of worldly knowledge and visual information to the percept, that is, the object of our ordinary visual encounters with the world.

Recently *Clark* [26.4] argued that:

"To perceive the world just is to use what you know to explain away the sensory signal across multiple spatial and temporal scales. The process of perception is thus inseparable from rational (broadly Bayesian) processes of belief fixation [...] As thought, sensing, and movement here unfold, we discover no stable or well-specified interface or interfaces between cognition and perception. Believing and perceiving, although conceptually distinct, emerge as deeply mechanically intertwined."

The aim of this conglomeration of faculties that constitute perception is, therefore, to enable perceivers to respond, modify their responses, and eventually adapt their responses as they interact with the environment so as to tune themselves to the environment in such a way that this interaction be successful; success in such an endeavor relies on inferring correctly (or nearly so) the nature of the source of the incoming signal from the signal itself.

In all these views, the visual system constructs the percept in the way thinking constructs new thoughts on

the basis of thoughts that are already entertained. In this sense, vision is a cognitive, that is, thought involving, process.

If perception is to be thought of as some sort of thinking, its processes must necessarily first include transformations of states that are expressed in symbolic or propositional form, and, second, these transformations must be inferences from some states that function as premises to a state that is the conclusion of the inference. That is to say, visual processes must be inferences or arguments, exactly like the processes of rational belief formation. These two conditions follow directly from the claim that perception is some sort of thinking, since the characteristic trait of thinking is drawing inferences (whether it be deductive, abductive, or inductive) operating on symbolic forms by means of inference rules that are represented in the system, although thinking is not reduced to drawing inferences this way. In view of these considerations, the principles guiding the transformations of perceptual states, that is, the principles (such as Spelke's principles) acting as the inference rules in perceptual inferences, must be expressed in the system and, specifically, must be represented in a symbolic form. Whenever the system needs some of the principles to draw an inference, it simply activates and uses them. In addition, the premises and the conclusion of a visual argument be represented in the viewer in a propositional-like, symbolic form.

If these conditions are met, perception involves discursive inferences, that is, drawing propositions or conclusions from other propositions acting as premises by applying (explicitly or implicitly) inferential rules that are also represented in the system. Clark's view quoted above seems to echo this thesis in so far as Clark conceives the processes of visual perception as a rational process of belief fixation. It follows that the inferences used in perception are no different from the inferences used in thought. That is, they are discursive inferences.

A short digression is needed here, however, lest we attribute to Clark intentions that he may not have. The previous analysis assumes the standard view of the brain as a physical machine that processes symbols in purely formal or syntactic way on the basis of the physical properties of the symbols; the brain performs digital computations. These symbols have meaning, of course, and so do the transformations of these symbols, but the processes in the brain are independent of any meaning. To put it differently, the brain is a syntactic machine that processes symbols that have meaning. The standard view can be modified by adding the thesis that digital computations are not merely formal syntactic manipulations but also involve semantics, that is, the contents of the states that participate in computations

are causally relevant in the production of the computations' outputs [26.5].

Although this is the standard, algorithmic, view of cognition, it is by no means unequivocally endorsed. There is another, competing view of cognition, according to which the brain is not a syntactic machine that processes symbols through algorithms. The brain represents information in a nonsymbolic, analogue-like form, as activation patterns across a number of units. Furthermore, the processes in the brain do not assume the form of algorithmic but of algebraic transformations; this is the connectionist view of cognition, of which Clark is a stern proponent. This is not the place to expand and explain connectionism, but I wish to stress that in this view of cognition, the brain does not use at all discursive inferences, although some of its behavior certainly simulates the usage of discursive inferences. If this is so, Clark's thesis that perception is inseparable from the rational processes of belief fixation does not commit him to the view that perception employs discursive inferences for the simple reason that thinking itself does not implicate such inferences.

Furthermore, given the propositional or symbolic form of the format in which the states of the visual system must be represented if vision is akin to thinking, the contents of these states, that is the information carried by the states, consists of concepts that roughly correspond to the symbols implicated; it is conceptual content. If vision is some sort of thinking, therefore, its contents must be conceptual contents. This means two things. Either the visual circuits store conceptual information that they use to process the incoming information, or they receive from the inception of their function such information from the cognitive areas of the brain while they are processing the information impinging on the retina. Spelke's principles that guide visual processing and render the percept possible are examples of conceptual content.

It should be noted that discursive inferences are distinguished from *inferences* as understood by vision scientists according to whom any transformation of signals carrying information according to some rule is an inference [26.6]:

"Every system that makes an estimate about unobserved variables based on observed variables performs inference [...] We refer to such inference problems that involve choosing between distinct and mutually exclusive causal structures as causal inference."

One could claim, therefore, that although inferences, in this liberal sense, occur in the brain during visual perception, they are not like the inferences used

in thought. One might even go further than that and claim that these inferences, or rather state transformations, do not involve representational states at all [26.7]. Although the percept is certainly a representational state, the processes that lead to its formation are not representations. It follows that visual perception is not a cognitive process, if *cognitive* is taken to entail the use of mental representations; "a system is cognitive because it issues mental representations" [26.7].

In this chapter, I examine vision and its processes and discuss the relation of vision with thinking. I do not have the space here to discuss the problem of whether visual processes involve representations. I proceed by assuming that they do although, first, as I will argue, the state transformations do not presuppose the application of inference rules that are represented in the system, and, second, not all visual states are representational.

In Sect. 26.1, in view of the close relationship between thinking and inference, I chart and briefly discuss inference and its modes, namely, deduction, induction, and abduction or inference to the best explanation.

In Sect. 26.2, I sketch an overview of the main conceptions concerning vision, to wit constructivism, direct or ecological theory of vision, and the more recent proposals that view vision as inseparable from action.

In Sect. 26.3, I present the two stages of which visual perception consists, namely early vision and late vision.

In Sect. 26.4, I discuss the problem of the cognitive penetrability (CP) of perception, because if vision is akin to thinking, visual processes necessarily involve concepts and are thus cognitively penetrated. If it turns out that some stage of vision is cognitively impenetrable (CI) and conceptually encapsulated, the status of the logical characterization of the visual processes of that stage remains open since, being nonconceptual in nature, they cannot be discursive inferences. I am going to argue that a stage of vision, early vision, is CI and has nonconceptual content. This content is probably iconic, analogue-like and not symbolic. By not being symbolic, the contents of the states of early vision cannot be transformed to some other contents by means of discursive inferences in so far as the latter operate on symbolic forms. The second main visual stage, namely late vision, is CP and implicates concepts. I also address in this section two problems with my claim that early vision is conceptually encapsulated. The first is raised by the existence of some general regularities that seem to guide the functioning of the perceptual system, of which the Spelke principles are a subset, and which operate at all levels of visual processing. The problem is, first, whether the existence of such principles entails that at least some part of the information

processed in early vision is inherently conceptual, and, second, whether the existence of such principles entails that vision in general is theory-laden. The second concerns the effects of perceptual learning, since one might argue that through perceptual learning some concepts are embedded in the perceptual circuits of early vision. If either of these two is correct, the states of early vision have conceptual contents and thus the processes of early vision may involve discursive inferences rendering early vision akin to thought and belief formation. I argue, however, that neither the principle nor the effects of perceptual learning entail that early vision has conceptual content.

## 26.1 Inference and Its Modes

Let us grant that vision is like thinking and, therefore, involves discursive inferences. The question that arises concerns the nature of the inferences involved; are they deductive, inductive, or abductive? (Appendix 26.A for a definition of deductive, inductive, and abductive inference).

I think it is safe to assume that the whole visual process fits better the description of an abductive inference. The main reason for this thesis is that vision constructs a representation, (i. e., the percept) that best fits the visual scene. Specifically, given that the retinal image is sparse and thus underdetermines both the distal object and the percept, the visual system has to fill in the missing information to arrive at the best explanation, that is, the percept that best fits the retinal information. In essence, given the sparsity of the incoming information in the retinal image, the brain attempts to construct a representation that consists of the properties that an object should have in order to produce the specific retinal image. That is, the brain works back from the information that the retinal image contains to the object that could produce such a retinal image. Many objects could produce this image and the brain attempts to figure out which one of them best fits the retinal image. This is the trait par excellence of an abductive inference. Recent work (see [26.4] for an overview) suggests that this abductive inference or inference to the best explanation is a Bayesian inferences in which the brain constructs the percept that best explains the visual input by selecting the hypothesis that has the highest probability given the visual input.

It follows that the inference is ampliative, that is, the conclusion has a wider content than that of the premises and thus is not implicitly included in the premises; as such, the inference is not deductive. This is easy to grasp if we consider that the only information im-

In Sect. 26.5, I examine the logical status of the processes of early and late vision and argue that the processes of early vision are abductive nondiscursive inferences that do not involve any concepts, while the processes of late vision despite the fact that they are abductive inferences guided by concepts, are not discursive inferences either. I argue that the abductive inferences involved in visual perception are not sentential inferences but, instead, they rely on pattern-matching mechanisms that explore both iconic, analogue-like information and symbolic information. In this sense, visual abduction could be construed as consisting of a series of model-based inferences.

pinging on the retina consists of differences of light intensities and electromagnetic wavelengths. The percept that which the visual processes output (and since we have assumed that vision is a complex inference, the premises of the inference consist in the impinging information and the percept is the conclusion of this inference), however, is the object of our ordinary experience with its shape, size, color, motion, texture, etc. All these properties far exceed the impinging information concerning light intensities and wavelengths.

Moreover, and related to the first consideration, even if the premises of a visual inference that outputs the percept are correct, that is, even if the principles that guide perception reflect correctly the physical and geometrical regularities, and the impinging information being what it is, the percept may still not be a correct representation of the object in the environment that emanated the light rays and caused the perception. In other words, the conclusion may be wrong even though the premises are correct. This is why vision should be better understood as an abductive process or as an inference to the best explanation. Traditionally, abduction is thought as synonymous to the inference to the best explanation (for a recent reaffirmation see [26.8]). Recently, however, this thesis has come under attack mainly on the ground that abduction is for the generation of theories, whereas the inference to the best explanation is for their evaluation [26.9, 10]. Although I agree with Lipton, I will not dwell on this issue here any further. I will continue to use *abduction* as synonymous to *inference to the best explanation* because nothing important in the discussion in this chapter hinges on the outcome of this debate.

One may wonder why this ampliative, non-truth-preserving inference should be construed as an abductive inference and not as an inductive inference. One

might argue that all inductions are abductions or inferences to the best explanation [26.11]. Most authors, however, think that abduction is a subspecies of induction since it bears the basic marks of induction as it is ampliative and does not preserve truth. However, it is more specific than induction since it aims exclusively to pinpoint the cause or causes for some phenomena, that is, it aims to yield an explanation of a set of phenomena. Not all inductions are focused towards this aim. Several times a good induction leads to a generalization that subsumes a set of phenomena under the heading of a generalization, which, however, does not explain the phenomena. Consider the following induction.

Bird  $\alpha$  is a crow and is black ( $Ca&Ba$ )  
 Bird  $\beta$  is a crow and is black ( $Cb&Bb$ )  
 ...  
 Bird  $\kappa$  is a crow and is black ( $C\kappa&B\kappa$ )  
 Therefore (inductively)  
 All crows are probably black ( $(x)(Cx \rightarrow Bx)$ )

Under certain conditions this is a good induction in which from the colors of specific specimens of crows

one infers the color of all crows. This is hardly a good explanation though. A good explanation seeks to explain, that is, make us or the scientific community understand why crows  $\alpha$  and  $\beta$  are black. The generalization *All crows are probably black* fails to accomplish this since all that it does is gather together all instances of black crows in a generalization. Moreover, a good explanation of a set of phenomena is expected to have a wider range than these specific phenomena in the sense that it can be used as a springboard to explain a wider class of phenomena. In our case, a good explanation of why crows  $\alpha$  and  $\beta$  are black should certainly involve genetics. Such an account not only would provide understanding of the correlation of crows with the color black, but it could also be used to explain the colors of other species. Now, it is widely agreed that the discovery of the relevant laws of genetics would fall within the purview of abduction. To put this point differently, all abductions are inductive inferences but not all inductions are abductions.

When I examine in Sects. 26.3 and 26.5 the visual processes in some detail, I shall adduce more evidence supporting the claim that visual processing is an abductive inference.

## 26.2 Theories of Vision

I have claimed that vision is a complex process that starts when light impinges on the retina and culminates with the formation of the percept, that is, the object of our ordinary experience and its properties. If vision as a whole is a complex process, it consists of a series of processes, or, in other words, in a series of state transformations in which one state containing some information is transformed via the visual mechanisms to a state containing some other sort of information. According to this view, vision is a process in which the visual system constructs the percept from the incoming visual information. All these processes take place within the visual system and although information from the other modalities and the actions of the viewer may either facilitate or inhibit the visual processing, vision in principle is autonomous from the other modalities and action.

This thesis can be assaulted from at least two fronts. The first is to deny that vision is a complex process involving information processing. It may be the direct retrieval of visual information from the environment without any need for mediating processes. The proponents of this view are divided into two camps. The first maintain that the retrieval of information from the environment is mediated by representations, while the

second deny the necessity of invoking representations to explain how visual perception works. The second is to claim that although vision necessarily involves inferences, vision cannot be separated from action in that actions figure inherently and constitutively in vision. In this section, I present the three different conceptions of vision.

### 26.2.1 Constructivism

Visual perception begins with information impinging on the retina, this is the stimulation of the sensory organs, and culminates with the construction of the percept, which is a visual representation of the worldly objects (they are called *distal objects*) that emanate the light that stimulates the sensory organs. This is made possible through a series of transformations whereby the information impinging on the retina is progressively transformed into a final visual representation, the percept. The construction of the final visual representation is preceded by the construction of a host of intermediate visual representations of increasing complexity.

The transformation from one visual representation to the other, which are both mental representations being located in the brain, is effectuated through the

processes of vision that consist of the application of transformational rules that take as input representation  $r_1$  at time  $t_1$  and output representation  $r_{t+1}$  at time  $t_2$ . These rules could be construed as abductive inferences since the brain is called upon to fill in the gaps in the information contained in the retinal image in order to construct a representation of the distal object that is the most likely candidate for being the object that could have produced the retinal image. It could be argued, hence, that the brain guesses which object is the best fit to explain the retinal image.

Since visual perception consists of a series of constructions of visual representations, vision is a constructive process. Let us call this construal of visual perception *constructivism*. According to one of the most influential visual scientists that espouse constructivism, Marr [26.12], there are three levels of representation. The initial level of representation involves Marr's *primal sketch*, which consists of the *raw primal sketch* and the *full primal sketch*. The *raw primal sketch* provides information about the edges and blobs present in a scene, their location and their orientation; this information is gathered by locating and coding individual intensity changes. Grouping procedures applied to the edge fragments formed in the *raw primal sketch* yield the *full primal sketch*, in which larger structures with boundaries and regions are recovered. Through the *primal sketch* contours and textures in an image are captured. The primal sketch can be thought of as a description of the image of a scene but not as a description of the real scene. This latter involves the relative distances of the objects and their motions. This information is provided by the viewer-centered representation, which is Marr's  $2^{1/2}$  *sketch*. At this level information about the distance and layout of each surface is computed using various depth cues and by means of analysis of motion and of shading. This information describes only the parts of the object that are visible to the viewer and thus is relative to the viewer.

The computations leading to the formation of the  $2^{1/2}$  *sketch* are determined by three factors:

1. The input to the visual system, that is, the optical array
2. The physiological mechanisms involved in vision, and the computations they allow, and
3. Certain principles that restrict and guide the computation.

These principles are constraints that the system must satisfy in processing the input. These constraints are needed because perception is underdetermined by any particular retinal image; the same retinal image could lead to distinct perceptions. Thus, unless the

observer makes some assumptions about the physical world that give rise to the particular retinal image, perception is not feasible.

It is important at this juncture to stress that according to Marr, all the processes that lead to the formation of the  $2^{1/2}$ D sketch are data-riven; they are driven solely by the input.

One of the aims of vision is the recognition of objects. This requires the matching of the shape of a structure with a particular object, a matching that requires an object-centered representation. This is Marr's *three-dimensional (3-D) model*. The recovery of the objects present in a scene cannot be purely data-driven, since what is regarded as an object depends on the subsequent usage of the information, and thus is task dependent and cognitively penetrable. Most computational theories of vision [26.12, 13] hold that object recognition is based on part decomposition, which is the first stage in forming a structural description of an object. It is doubtful, however, whether this decomposition can be determined by general principles reflecting the structure of the world alone, since the process appears to depend upon knowledge of specific objects [26.14]. Object recognition, which is a top-down process and requires knowledge about specific objects, is accomplished by the high-end vision. The construction of the percept, which is the end product of visual perception, therefore requires the synergy of both top-down and bottom-up transfer of information between the visual circuits and the cognitive centers of the brain. Object recognition requires matching the internal representation of an object stored in memory against the representation of an object generated from the image. In Marr's model of object recognition the 3-D model provides the representation extracted from the image that will be matched against the stored structural descriptions of objects (perceptual classification). (It should be emphasized that these *object recognition* units are not necessarily semantic, since we may recognize an object that we had seen before, even though we have no idea of its name, of what it does and how it functions, that is, even if we have no semantic and lexical information about it. Ref. [26.15] introduces a distinction between the *perceptual classification* and *semantic classification* and *naming*. These processes are independent one of the other. ). See Appendix 26.B for an overview of constructivism.

Marr's and Biederman's hypothesis that object recognition occurs through part decomposition is based on the conception of three-dimensional objects as arrangements of some set of primitive 3-D shapes. According to Marr, these primitive 3-D shapes are generalized cylinders (Fig. 26.1) that are defined in terms of major axes and radii of objects.

According to Biederman, the primitive 3-D shapes are the so-called geons (Fig. 26.2). All objects can be decomposed into a set of 36 specific geons related in various ways. The properties that identify geons and allow them to function as volumetric perceptual primitives are viewpoint invariant, that is, they do not change as the angle of view changes. As such, they are called nonaccidental features since they are features not only of the image but also of the worldly objects (that is, they are properties that exist in the environment outside the viewer) that do not depend on what the viewpoint may be accidentally. Examples of nonaccidental properties are parallel lines and collinearity. If an object has parallel lines many rotations of this object yield an image in which these lines are still nearly parallel; that is to say, parallelism is a property that is rotation- or perspective-invariant.

Let me close the account of constructivism by reminding the reader that the theories of visual perception presented in this part of the chapter are some among the many different theoretical accounts of visual processing. The differences between the various theories notwithstanding, all constructivist theories share a common core, namely that visual perception involves state transformations in the course of which visual representations of increasing complexity are being gradually constructed by the visual system. The visual processes start from the meager information contained in the retinal image and which consists of local distributions of light intensities and wavelengths. These transformations can also be construed as computations in which the brain computes an output state given an input state. Many of these transformations (but not all of them) act on and therefore essentially involve mental representations that are within the brain of the viewer, and can be independent of any other activities on the part of the viewer. The transformations are made possible through the application of transformational rules, such as, for example, the rule that abrupt changes in light intensity signify the presence of edges that is used by the perceptual system to construct the raw primal sketch. Such a rule takes as input states that carry information about various light intensities distributed in space and delivers states that carry information about edges. It follows that the transformations taking place in visual processing are information-processing operations. (I said that not all of the transformations operate on representations because many of these transformations operate on states that are not representational. It would require another chapter to discuss the conditions under which a state is representational or not and, of course, much depends on how one defines the term *representation*. I confine myself to pointing out

Fig. 26.1 Marr's generalized cylinders

Fig. 26.2 Biederman's geons

that many of the earlier visual states are probably not representational because they do not meet the criteria that an adequate definition of representation posits, and to referring the reader to the discussion in Chap. 4. As we shall see in Sect. 26.4, one could claim that there is a sharp distinction between internal probabilistic dependencies between states that can be explained by internal causal connections between the circuits of the brain and those that cannot; only those that cannot be explained internally carry information about the external world and thus involve representational states.)

The fact that the visual brain transforms states to other states through the usage of some rules means that the function of the brain can be understood as a series of inferences from some state/premises to some other states/conclusion. In view of our discussion in the beginning of this section, as well as in the previous one, the inferences most likely are abductive in nature.

### 26.2.2 Theory of Direct Vision or Ecological Theory of Visual Perception

Gibson [26.16] started from a very different assumption than that of constructivism. In contradistinction to the latter, Gibson argued that perception begins not with the informationally sparse retinal image but with the informationally rich *optic array*. The spatial pattern of light intensities and the mixture of wavelengths that impinge on the receptors of the retina form the optic array. This light, however, carries a lot of information about the solid objects in the environment (the distal objects) because the intensities of light and its wavelengths vary from one solid visual angle to another (as the rays of light emanating from solid objects travel in space and between the surfaces of the objects that fill the space, given that at any point in space light converges from all directions, at each point in space there is a nested set of solid visual angles). As a result, the optical array is determined by, and therefore carries information about, the nature and location of the three-dimensional worldly surfaces from which it is being reflected.

Unlike the retinal image, the optic array is an external source of information, or, better, an external information-bearing structure since it exists outside the viewer, is independent of the constitution of the brain of the viewer, and carries information about the environment. Gibson's central claim is that the information contained in the optic array suffices to allow perceivers to specify the visual scene that causes the optic array, that is, to specify the solid surfaces that surround them, and to use the information included in the optic array to interact with their environment.

When perceivers move in their environment, moreover, the entire optic array is transformed to reflect the new environment since it depends exclusively on it. As perceivers move around, they sample different optic arrays and therefore receive a variety of information about the changing environment, since the transformations of the optic array as perceivers move contain information about the layout of the objects in the environment as well. As in realistic situations perceivers are not static, motion enriches the visual information that the perceivers receive from the environment enabling them to recover the visual scene much easier than if they were static. Furthermore, this motion by effecting transformations of the optic array allows the perceivers to identify those aspects of objects that remain invariant under movement (the nonaccidental properties that we have discussed). It goes without saying that this information is made available only to perceivers that move in their environment and effect a change in the optic array that they receive from the environment; a static perceiver would never be able to detect the properties

of objects that remain invariant under motion. Note that information about the invariant properties is available in the environment, but viewers can retrieve or detect it only as they move. This entails that perception becomes entangled with action, since moving around is a form of action.

The richer the information that the light impinging on the retina carries, the less information processing the visual brain is required to do in order to form the percept. Taking this view to its extreme end, one might claim that if the optic array suffices all by itself to enable viewers to recover the visual scene, there is no need to posit any internal information processing on information-bearing states. Visual perception involves no information processing and no inferences of any sort; it just recovers the visual scene directly from the information contained in the optic array (which explains coining this theory a theory of direct vision). This interpretation of the theory received a devastating criticism in Fodor and Pylyshyn's [26.17] paper entitled *How Direct is Visual Perception*. I think it safe to assume that the radical interpretation that excludes information processing from visual perception has not recovered from this critique since most of the counterarguments raised in that paper have not been adequately answered. Whether, however, Gibson subscribed to this radical view is debatable. Be that as it may, the radical interpretation is not the only possible interpretation of direct vision.

The fact that the input to the visual system may contain more information than that envisaged by constructivism does not entail that visual perception does not involve any internal information processing. It only entails that the internal information processing needed for the formation of the percept is less than in constructivist theories since a part of it is being replaced by the manipulation through motion and transformation of the optic array, which as you recall is an external information-bearing structure. Nor does the richness of the information in the input entail that no representations are needed; it entails that visual perception allows positing less representations than those required in constructivist theories. As Rowlands [26.18] remarks:

“Here is nothing in Gibson's theory itself – as opposed, perhaps, to his statements about his theory – that entails or even suggests that all of the role traditionally assigned to manipulation and transformation of internal information-bearing structures can be taken over by the manipulation and transformation of external information-bearing structures.”

In this moderate interpretation of Gibson's theory of direct vision, the need for some information processing over internal representational states still persists, except

that, in view of the fact that the information contained in the visual input is richer than previously thought, this need is attenuated. Therefore, visual perception involves some sort of inferences.

Gibson's theory was coined the *theory of direct perception* because it relinquished the need for internal information processing; instead, the viewers retrieve all the information they need to detect the environment directly from the environment without any internal processing of any sort mediating the process of information retrieval. If, however, some information processing over internal representations is needed as well, as a moderate form of Gibson's theory asserts, can the qualification *direct* be salvaged?

There is a sense in which it might. Suppose that *direct* is construed so as to emphasize not the lack of information processing operating on internal representations, but the fact that the information processing is entirely data-driven, that is, guided by environmental input and some principles that reflect regularities in the environment, and the whole process is not influenced by other internal nonvisual states of the viewer, such as the viewer's cognitive or emotional states. If this supposition is borne out, then visual perception is direct in the sense that the whole process is data-driven and, as such, the information processing used operates over information retrieved exclusively from the environment. Note that this presupposes that the principles guiding visual processing do not constitute some form of intervention on the part of the viewer whose contribution exceeds what is given in the environment.

This assumption is borne out if visual perception or at least some stage of it, is purely data-driven, that is, cognitively and emotionally impenetrable. If cognitive states penetrate and thus influence perceptual processing, the viewer's cognitive states actively contribute to the formation of the percept and the visual processing does not retrieve information directly from the environment but only through some cognitive intervention; visual perception, in this case, is not direct. Norman [26.19] has argued along this line that the processing along the dorsal visual pathway that guides our on-line interactions with the environment, owing to the fact that when it operates immediately on the visual input it is entirely data-driven, is a visual function that conforms very closely to Gibson's *direct* theory. The ventral visual pathway, in contradistinction that is responsible for object recognition and categorization is clearly affected by cognition and, in this sense, is not a *direct* visual function. Since both visual pathways are found in the brain, the constructivist and the ecological theories of perception can be reconciled.

Even though it seems abundantly clear that visual perception requires a significant amount of information

processing, and in this sense one of Gibson's main insights is considered to be wrong, several of Gibson's insights have been incorporated in the constructivist information-processing research program. For example, most, if not all, information-processing theories hold that most of the ambiguities that occur during the information processing of the retinal input cannot be resolved by that input alone and need top-down assistance only when information comes from a static monocular image. When additional information can be derived from stereopsis and motion of real scenes, then the information-processing program can resolve the ambiguity without the need of a top-down flow of information. If one takes into account the real input to human vision, which is binocular and dynamic, there are few ambiguities that cannot be resolved through a full consideration of the products of the early visual processing *modules* [26.20]. This shows that the dynamic and interactive character of vision solves several problems encountered within the information-processing research program.

Our discussion about direct vision revealed an aspect of visual processing that traditional constructivist theories did not initially consider, namely the interaction of perception and action. The next kind of theory of perceptual processing that we will examine views visual perception as inextricably linked with action and uses the most recent neuropsychological evidence, vision science research, and computer modeling to both substantiate this claim, and draw the details of how the active visual brain works in order to provide a fully fledged unifying model of perception and action. Although this model aims to cover all modalities, for the purpose of this chapter I will restrict the presentation and discussion to visual perception.

### 26.2.3 Predictive Visual Brain: Vision and Action

The basic tenet of the theory of ecological or direct vision is that all the information viewers need to recover the visual scene that causes the retinal image is already included in the incoming information in the optic array. Little or no information processing is required for the construction of the percept. The constructivist theories of visual perception, in contradistinction, underline the necessity of information processing and state transformations in the brain. The flow of information in the brain is bidirectional; both top-down and bottom-up signals are transmitted and the ensuing percept is the result of the synergy between top-down and bottom-up processing. This class of theories assumes that the representation constructed at some level is transmitted bottom-up to the neuronal assembly at the next

immediate level where it is further processed. Moreover, recurrent signals return top-down to earlier levels mainly to test hypotheses concerning aspects of the visual scene (recall that visual perception aims to recover the visual scene that causes the retinal image and does that by constructing increasingly more complex representations of the probable aspects of the visual scene at various spatial and temporal scales) until the percept is constructed.

Recent empirical findings and modeling shed light on the way the brain actually effectuates these processes. These details, as we shall see, entail certain deviations from the traditional constructivism image, which concern (a) the sort of information transmitted bottom-up; only prediction errors are transmitted to the next level, (b) the nature of the representations constructed; they are distributions of probabilities rather than having a unique value (note that this new approach emphasizes the indispensable role of representations in visual processing), and (c) the interaction between perception and cognition. This last trait is very important has important repercussions for our discussion on the relation between visual processing and thinking.

According to this view of visual perception, brains are predictive machines [26.4]:

“They are bundles of cells that support perception and action by constantly attempting to match incoming sensory inputs with top-down expectations or predictions. This is achieved using a hierarchical generative model that aims to minimize prediction error within a bidirectional cascade of cortical processing.”

A hierarchical generative model as applied to visual processing is a model of perceptual processes according to which the brain uses top-down flow of information (enabled by top-down neural connections) in an attempt to generate a visual (meaning, in the brain) representation of the visual scene (in the environment) that causes the light pattern impinging on the transducers and the low-level visual responses to this light pattern. The brain attempts to recover gradually the causal matrix (the various aspects of a visual scene) that causes and thus is responsible, for the retinal image seen as a data-structure (i. e., the sensory data). The brain does that by capturing the statistical structure of the sensory data, that is, by discovering the deep regularities underlying the retinal structure, on the very plausible assumption that the deep structure underneath the sensory data reflects, so to speak, the causal structure of the visual scene.

Hierarchical generative models attempt to achieve this by constructing, at each level, hypotheses about the probable cause of the information represented in

the immediately previous level, and testing these hypotheses by matching their predictions with the actual sensory data at the preceding processing level. Suppose, for example that a neuronal assembly at level  $l$  receives from level  $l-1$  information concerning differences in light intensities. The higher level attempts to recover the probable edges that cause the variation in light intensity and forms a hypothesis involving such edges. Now, and this is the crucial part, if this hypothesis were correct, that is, if the edges as represented in the hypothesis were present in the environment, then a certain pattern of variation of light intensities at the appropriate local scale would have been present in the sensory data. This prediction is transmitted top-down to level  $l-1$  and matched against the actual pattern of variations in light intensities. If there is a match (with an acceptable degree of error deviation due to the inherent noise of the signal, of course) no further action is needed since the perceptual system *assumes* that it has constructed the correct, at this spatial scale, representation of the relevant environmental input. If the match reveals a discrepancy, that is, if an error in the prediction is detected, this prediction error is transmitted bottom-up to level  $l$  so that a new hypothesis be formulated and tested until, eventually, no unacceptable prediction error persists. If one thinks of the discovered error as a surprise for the system, the system strives to correct its hypotheses so that by making correct predictions, the testing of the hypotheses yields no surprises; this is a typical error-driven learning process where a system learns, i. e., constructs a correct representation, by gradually reducing error. The hierarchical generative models hence generate, in essence, low-level states (the predictions they make about the activities at the lower levels) from high-level causes (the hypotheses that would, if correct, explain the activity at the lower levels).

Bidirectional hierarchical structure allows the system to [26.4]:

“infer its own priors (the prior beliefs essential to the predicting routines) as it goes along. It does this by using its best current model at one level as the source of the priors for the level below, engaging in a process of *iterative estimation* that allows priors and models to coevolve across multiple linked layers of processing so as to account for the sensory data.”

To form hypotheses concerning the probable cause of the sensory data at a certain level, at a specific spatial and temporal scale, the neuronal assembly at the next level, say level  $l$ , uses information not only about the sensory data at the previous level (or, to be precise, information regarding its prediction error) that is transmitted bottom-up, but also higher-level information that

is transmitted to *l* either laterally, that is, from neuronal assemblies at the same level (neurons in V1 processing wavelengths inform other neurons in V1 processing shape information, for example), or top-down from levels higher in the hierarchy (neurons in V4, for instance, are informed about the color of incoming information from neurons in the inferotemporal cortex in the brain (IT) as a result of precueing – that is, when a viewer has been informed about the color of an object that *will* appear on a screen). This higher-level information may and usually does concern general aspects of the world (such as *solid objects do not penetrate each other, or solid objects do not occupy exactly the same space at the same time, etc.*), and may also reflect knowledge about specific objects learned through experience. All this lateral and top-down flow of information provides the context in which each neuronal assembly constructs the most probable hypothesis that would explain the sensory data at the lower level. Thus, context-sensitivity is a fundamental and pervasive trait of the processing of hierarchical predictive coding; the contextualized information significantly affects, and on occasions (as in hallucinations) may override, the information carried by the input.

The hierarchical predictive processing model can be naturally extended to include action and thus closely ties perception with action [26.4]. This is the action-oriented predictive processing. Action-oriented predictive processing extends the standard hierarchical predictive model by suggesting that motor intentions actively elicit, via the motor actions they induce, the ongoing streams of sensory data at various levels that our brains predict. In other words, once a prediction is made about the state in the world that causes the transduced information, the action-oriented predictive processes engage in a search in the environment of the appropriate worldly state. Suppose, for example, that owing to bad illumination conditions, a perceiver is unsure about the identity of an object in view. Its brain makes a prediction about the putative object that causes the sensory data the perceiver receives, and the perceiver moves around the object in order to acquire a better view that will confirm the prediction. By moving around, the perceiver's expectations about the proprioceptive consequences of moving and acting directly cause the moving and acting since where and when the perceiver moves is guided by the aim that the perceiver's action brings the object into a better view.

It is worth pausing at this point to discuss briefly the problem of nature of the relation between visual perception and action and, specifically, motion. Is this relation constitutional, which means that if someone cannot or does not move they cannot visually perceive anything? This claim was initially made by *Noe* although,

in view of vehement criticism, *Noe* has attempted to modify it without compromising the main tenets of his views [26.21]:

“When you experience an object as cubical merely on the basis of its aspect, you do so because you bring to bear, in this experience, your sensorimotor knowledge of the relation between changes in cube aspects and movement. *To experience a figure as a cube, on the basis of how it looks, is to understand how it looks changes as you move* (emphasis added).”

The sensorimotor knowledge consists of the expectations of how our perception of an object changes as we move around it, or as this object moves with respect to us. These expectations constitute a form of practical knowledge, a *knowing how* as opposed to a *knowing that*. Thus, to be able to experience visually an object, one needs to have the ability to move around the object and explore it. Visually experiencing the object literally consists of grasping the relevant sensorimotor contingencies, that is, the sensorimotor knowledge associated with this specific object. There are two ways to read this claim. According to the first reading, which *Noe* seems to espouse judging from the previously cited passage, to be able to visually perceive requires the actual exercise of the ability to probe the world. According to the second reading, visually perceiving an object only requires the ability to probe the world but not the actual exercise of this ability. The first reading entails immediately that prior to exercising this ability, one does not visually perceive the object. Since this is absurd, one has to concede that viewers do not need to exercise actually the ability to probe the environment, it suffices that they take recourse to their experience with similar objects and retrieve the requisite sensorimotor contingencies from experience. Even if one takes this line, however, the problem remains that at the time of a first encounter with an object to be able to see its, say, shape, one should be able to probe the object either by moving around the object, or by having the object move around them. Thus, when stationary viewers perceive a stationary novel object, lacking any knowledge of sensorimotor contingencies, they do not see its shape or its other properties.

It follows that infants upon opening their eyes for the first time and facing the world, by lacking any sensorimotor knowledge and by not probing the environment, they do not see anything. This claim flies to face of countless empirical evidence, which shows that there is something fundamentally wrong with equating visual perception with understanding sensorimotor contingencies and deploying the relevant practical knowledge. This entails, in turn, that the relation between visual

perception and action, no matter how important it is, is not a constitutional relation; one gets to see the world even if both they and the world are stationary, although it goes without saying that their experience will be restricted compared to other viewers who can probe the environment. They could not visually experience, for example, Marr's 3-D sketch because they lack knowledge of the unseen surfaces of objects.

This unity between perception and action emerges most clearly in the context of *active inference*, where the agent moves its sensors in ways that amount to actively seeking or generating the sensory consequences that their brains expect. "Perception, cognition, and action work closely together to minimize sensory prediction errors by selectively sampling, and actively sculpting, the stimulus array" [26.4]. Their synergy moves a perceiver in ways that fulfill a set of expectations that constantly change in space and time. Accordingly, perceptual inference is necessary to induce prior expectations about how the sensorium unfolds and action is engaged to resample the world to fulfill these expectations.

Since the construction of the representations of the putative causes of the sensory inputs is made possible through a synergy of bottom-up processing transmitting the prediction errors and top-down processing transmitting for testing the hypotheses concerning the probable causes of the input and in so far as the processes constructing these hypotheses are informed by high-level knowledge of the sort discussed above, visual perception unifies cognition and thinking with sensation; these two become intertwined. This means that perception inextricably involves thinking. Notice that this account of visual perception necessarily involves representations; it requires that each level retain a representation of the data represented at this level so that the top-down transmitted predictions of the hypotheses formed at subsequent higher levels be matched against the information represented at the lower level in order for the hypothesis to be tested. It also requires the representation of the putative causes of the sensory data at the preceding level; these are called the representation-units, which operate along the error units (the units that compute the error signal, that is, the discrepancy between prediction and actual data) in a hierarchical generative system.

Furthermore, testing hypotheses and altering them as a result of any prediction errors until the prediction error is minimized and thus until the most probable cause of the sensory data has been discovered, is an inference. Being a probabilistic inference that aims to

discover the most probable hypothesis that explains away a set of data, it is most likely a Bayesian inference. It is very plausible, therefore, that the computational framework of hierarchical predictive processing realizes a Bayesian inferential strategy (see Appendix 26.C for an analysis of Bayes' theorem). Indeed, recent work on Bayesian causal networks [26.22] presents the brain as a Bayesian net operating at various space and time scales.

What Bayes' theorem, on which this strategy is based, ensures is that a hypothesis is eventually selected that makes the best prediction about the sensory data minimizing thereby the prediction error and thus best explains them away; that is a hypothesis that by having the highest posterior probability provides the best fit for the sensory data. The construction of this hypothesis crucially and necessarily involves the context, as it is clearly expressed in Bayes' equation in the form of the prior probability for the hypothesis  $P(A)$ , whose value depends on the context. That is to say, it is the context that provides the initial plausibility of a hypothesis before the hypothesis is tested.

This enables Clark [26.4] to claim that in the framework of predictive brains that use hierarchical generative processing perception becomes theory-laden in the specific sense that what viewers perceive depends crucially on the set of priors (that is, the hypotheses that guide the predictions about the matrix of the sensory data at the lower processing levels, which the hypothesis projects) that the brain brings to bear in its attempt to predict the current sensory data. This remark brings us back to the main theme of this chapter, namely, the relation between perceiving and thinking. If thinking necessarily implicates discursive inferences and deploying concepts, as it usually does, Clark's claims entail that perception employs from its onset concepts and draws discursive inferences. To assess this dual claim, we must examine the processes of vision to determine first whether concepts are used and if the answer is affirmative the extent to which they are being used, and second, whether the inferences that are undoubtedly used in perception must necessarily be discursive. I hasten to note that, with respect to this last problem, nowhere in his account does Clark suggest that the inferences must be discursive. In fact, the sources he refers to, especially those concerning connectionist neural networks, suggest that the inferences on which perception relies may take another form and need not necessarily involve propositionally structured premises and conclusions.

## 26.3 Stages of Visual Processing

I said above that we must examine the processes of vision with a view to determine whether and, depending on the answer to this question, the extent to which, cognition penetrates visual perception in the sense that perceptual processing uses conceptual information that is either transmitted top-down to perceptual circuits, or is inherently embedded in visual circuits. In the literature, visual processing is divided into two main stages, to wit, early vision and late vision.

### 26.3.1 Early Vision

Early vision is a term used to denote the part of perceptual processing that is preattentive, where attention means top-down, cognitively driven attention. *Lamme* [26.23, 24] argues for two kinds of processing that take place in the brain, the feedforward sweep (FFS) and recurrent processes (RP). In the FFS, the signal is transmitted only from the lower (hierarchical) or peripheral (structural) levels of the brain to the higher or more central ones. There is no feedback; no signal can be transmitted top-down as in RP. Feedforward connections in conjunction with lateral modulation and recurrent feedback that occurs and is restricted within the early perceptual areas (local recurrent processing – LRP) extract high-level information that is sufficient to lead to some initial categorization of the visual scene and selective behavioral responses.

When a visual scene is being presented, the feedforward sweep reaches *V1* in about 40 ms. Multiple stimuli are all represented at this stage. The unconscious FFS extracts high-level information that could lead to categorization, and results in some initial feature detection. LRP produces further binding and segregation. The representations formed at this stage are restricted to information about spatiotemporal and surface properties (color, texture, orientation, motion, and perhaps to the affordances of objects), in addition to the representations of objects as bounded, solid entities that persist in space and time. (*Affordances* is the term *Gibson* [26.16] used to refer to the functional properties of objects (an object affords eating to an organism, grasping to an organism, etc.). *Clark* [26.25] defines *affordance* as “the possibilities for use, intervention and action which the physical world offers a given agent and are determined by the *fit* between the agent’s physical structure, capacities and skills and the action-related properties of the environment itself”. Affordances are directly perceivable by an organism in the sense that an object does not have to be classified as a member of a certain category in order for the organism to draw the conclusion, or use the relevant knowledge, that this object can be

used in a certain way by the organism; the organism just perceives the affordance, that is, the opportunity of action on this specific object. Affordances have two important properties. First, they are determined by the functional form of an object, that is, a combination of the object’s visible properties should suffice to determine whether this object has an affordance relative to some viewer. Affordances are based on certain invariant characteristics of the environment. Second, the affordance is always relative to the viewing organism; this is a consequence of the fact that affordances provide organisms with the opportunity to interact with objects in their environment. This interaction depends on the objects’ properties but it also depends on the needs and the constitution of the organism. A fly, for instance, affords eating to a frog but not to a human.)

At this level there are nonattentional selective mechanisms that prevent many stimuli from reaching awareness, even when attended to. Such stimuli are the high temporal and spatial frequencies, physical wavelength (instead of color), crowded or masked stimuli and so forth. FFS results in some initial feature detection. Then this information is fed forward to the extrastriate areas. When it reaches area *V4* recurrent processing occurs. Horizontal and recurrent processing allows interaction between the distributed information along the visual stream. At this stage, features start to bind and an initial coherent perceptual interpretation of the scene is provided. Initially, RP is limited to within visual areas; it is local. At this level one can be phenomenally aware of the content of perceptual states. At these intermediate levels there is already some competition between multiple stimuli, especially between close-by stimuli. The receptive fields that get larger and larger going upstream in the visual cortical cannot process all stimuli in full and crowding phenomena occur. Attentional selection intervenes to resolve this competition. Signals from higher cognitive centers and output areas intervene to modulate processing; this is global RP and signifies the inception of late vision.

*Lamme* [26.23, 24] discusses the nature of information that has achieved local recurrent embedding. He suggests that local RP may be the neural correlate of binding or perceptual organization. However, it is not clear whether at this preattentional stage the binding problem has been solved. The binding of some features, such as its color and shape, may require attention, while other feature combinations are detected preattentively. So, before attention has been allocated, the percept consists of only tentatively but uniquely bound features that form the proto-objects [26.26]. *Lamme* [26.24] argues that Marr’s  $2\frac{1}{2}$ D surface representation of objects and

their surface properties are extracted during the local RP stage. Other research [26.27] suggests that spatial relations are extracted at this recurrent stage. In addition motion and size are represented in cortical areas in which local RP take place.

It should be added that Marr thought of the 2½D sketch as the final product of a cognitively unaffected stage of visual processing, since, as we have seen, the formation of the 3-D sketch relies on semantic, conceptual knowledge. If, as is usually thought, cognitive effects on perception are mediated by cognitively-driven top-down attention, Lamme's proposal that early vision is not affected by this sort of attention echoes Marr's view that early vision is not affected by cognition and is thus CI, a view shared by *Pylyshyn* [26.28].

Current research (see [26.4] for a discussion) sheds light on the nature of inferences involved in the hypothesis testing implicated in early vision. Specifically, the top-down and lateral effects within early vision aim to test hypotheses concerning the putative distal causes of the sensory data encoded in the lower neuronal assemblies in the visual processing hierarchy. This testing assumes the form of matching predictions made on the basis of this hypothesis about the sensory information that the lower levels should encode assuming that the hypothesis is correct, with the current, actual sensory information encoded at the lower levels. Eventually, the hypothesis that best matches the sensory data is selected and the whole process of hypothesis selection can be construed as an abductive inference or inference to the best explanation, which could very well be carried through by Bayesian nets. One should note that this account of early vision shows that the standard constructivist theories of visual processing can be reconciled and greatly benefit from the recent conceptions of the brain as a generative, predictive machine.

There seems to be, however, a crucial discrepancy between the account of early vision presented here and Clark's account of generative hierarchical predictive models. It concerns the role of context, or previously acquired knowledge, in the formation of the working hypotheses and its direct consequence that because of this trait, visual perception and discursive thinking are inseparable. If early vision is restricted to processes occurring within the visual cortex and excludes any cognitive influences, then first, previous knowledge seems to play no role in the formation of the working hypotheses, and second, early vision does not involve any thinking since the latter requires the participation of the cognitive centers of the brain. Moreover, the representations in early vision are analogue-like, iconic and not symbolic and this entails that early vision cannot be some sort of discursive thinking since the latter operates on symbolic forms.

With respect to the first point, there is actually no real discrepancy. Recall that lateral and local recurrent processes play a fundamental role in the formation of the hypotheses that are constructed in early vision. Moreover, as we shall see in the next section, all visual processes including those of early vision, are restricted by certain principles, or better constraints, that reflect general regularities about the world and its geometry. Now, one could say that these constraints constitute a body of knowledge that informs early vision processing and affects early vision from the within and not in a top-down manner, since as we saw there are no cognitive top-down effects in early vision. This as we shall see, however, is misleading because these constraints do not constitute some form of knowledge that by affecting early vision renders it theory-laden, as Clark claims. Finally, early vision is also affected by associations of object properties that reflect statistical regularities in the environment and are stored in the early visual circuits through perceptual learning. I argue in the next section that these associations do not constitute a body of knowledge that affects early vision rendering it theory-laden. The lateral and local recurrent processes, the constraints, and the associations built in the early visual circuits constitute a rich context that contributes significantly to the formation of the working hypotheses that early vision neuronal assemblies construct to explain the sensory data at the lower processing levels. This context, however, does not involve any body of knowledge that renders perception theory-laden, as theories are traditionally understood.

As far as the second point is concerned, there is indeed a discrepancy because the account of early vision and Clark's views. Early vision, by being CI and conceptually encapsulated does not involve thinking and is radically different from thinking. In fact, as I argue in Sect. 26.5, not even late vision that involves concepts and is affected by the viewers' knowledge about the world is like thinking.

### 26.3.2 Late Vision

The conceptually modulated stage of visual processing is called late vision. Starting at 150–200ms, signals from higher executive centers including mnemonic circuits intervene and modulate perceptual processing in the visual cortex and this signals the onset of global recurrent processing (GRP). In 50ms low spatial frequency (LSF) information reaches the IT and in 100ms high spatial frequency (HSF) information reaches the same area. (LSF signals precede HSF signals. LSF information is transmitted through fast magnocellular pathways, while HSF information is transmitted through slower parvocellular pathways.)

Within 130 ms, parietal areas in the dorsal system but also areas in the ventral pathway (IT cortex) semantically process the LSF information and determine the gist of the scene based on stored knowledge that generates predictions about the most likely interpretation of the input. This information reenters the extrastriate visual areas and modulates (at about 150 ms) perceptual processing facilitating the analysis of HSF, for example by specifying certain cues in the image that might facilitate target identification [26.29–31]. Determining the gist may speed up the FFS of HSF by allowing faster processing of the pertinent cues, using top-down connections to preset neurons coding these cues at various levels of the visual pathway [26.32].

At about 150 ms, specific hypotheses regarding the identity of the object(s) in the scene are formed using HSF information in the visual brain and information from visual working memory (WM). The hypothesis is tested against the detailed iconic information stored in early visual circuits including V1. This testing requires that top-down signals reenter the early visual areas of the brain, and mainly V1. Indeed, evidence shows that V1 is reentered by signals from higher cognitive centers mediated by the effects of object- or feature-centered attention at 235 ms post-stimulus [26.33, 34]. This leads to the recognition of the object(s) in the visual scene. This occurs, as signaled by the P3 event-related-potentials (ERP) waveform, at about 300 ms in the IT cortex, whose neurons contribute to the integration of LSF and HSF information. (The P3 waveform is elicited about 250–600 ms and is generated in many areas in the brain and is associated with cognitive processing and the subjects' reports. P3 may signify the consolidation of the representation of the object(s) in working memory.)

A detailed analysis of the form that the hypothesis testing might take is provided by *Kosslyn* [26.35]. Note that one need not subscribe to some of the assumptions presupposed by Kosslyn's account, but these disagreements do not undermine the framework. Suppose that one sees an object. A retinotopic image is formed in the visual buffer, which is a set of visual areas in the occipital lobe that is organized retinotopically. An attentional window selects the input from a contiguous set of points for detailed processing. This is allowed by the spatial organization of the visual buffer. The information included in the attention window is sent to the dorsal and ventral system where different features of the image are processed. The ventral system retrieves the features of the object, whereas the dorsal system retrieves information about the location, orientation, and size of the object. Eventually, the shape, the color, and the texture of the object are registered in anterior portions of the ventral pathway. This information is transmitted to the

pattern activation subsystems in the IT cortex where the image is matched against representations stored there, and the compressed image representation of the object is thereby activated. This representation (which is a hypothesis regarding the identity, that is, class membership of an object) provides imagery feedback to the visual buffer where it is matched against the input image to test the hypothesis against the fine pictorial details registered in the retinotopical areas of the visual buffer. If the match is satisfactory, the category pattern activation subsystem sends the relevant pattern code to associative or WM, where the object is tentatively identified with the help of information arriving at the WM through the dorsal system (information about size, location, and orientation). Occasionally the match in the pattern activation subsystems is enough to select the appropriate representation in WM. On other occasions, the input to the ventral system does not match well a visual memory in the pattern activation subsystems. Then, a hypothesis is formed in WM. This hypothesis is tested with the help of other subsystems (including cognitive ones) that access representations of such objects and highlight their more distinctive feature. The information gathered shifts attention to a location in the image where an informative characteristic or an object's distinctive feature can be found, and the pattern code for it is sent to the patternactivation subsystem and to the visual buffer where a second cycle of matching commences.

Thus, the processes of late vision rely on recurrent interactions with areas outside the visual stream. This set of interactions is called *global recurrent processing* (GRP). In GRP, standing knowledge, i. e., information stored in the synaptic weights is activated and modulates visual processing that up to that point was conceptually encapsulated. During GRP the conceptualization of perception starts and the states formed have partly conceptual and eventually propositional contents. Thus, late vision involves a synergy of perceptual bottom-up processing and top-down processing, where knowledge from past experiences guides the formation of hypotheses about the identity of objects. This is the stage where the 3-D sketch (that is, the representation of an object as a volumetric structure independently of the viewer's perspective) is formed. This recovery cannot be purely data-driven since what is regarded as an object depends on the subsequent usage of the information and thus depends on the knowledge about objects. Seeing 3-D sketches is an instance of amodal completion, i. e., the representation of object parts that are not visible from the viewer's standpoint. (Amodal completion is the perception of the whole of an object or surface when only parts of it affect the sensory receptors. An object will be perceived as a complete volumetric structure even if

only part of it, namely, its facing surface, projects to the retina and thus is viewed by the viewer; it is perceived as possessing internal volume and hidden rear surfaces despite the fact that only some of its surfaces are exposed to view. Whether this perception involves visual awareness, in which case the brain completes the missing features through mental imagery, or visual understanding only, which means that the hidden features are not present in the phenomenology of the visual scene but are thought of, is a matter of debate. In amodal completion, one does not have a perceptual impression of the object's hidden features since the perceptual system does not fill in the missing features as happens in modal perception; the hidden features are not perceptually occurrent (see Appendix 26.D for a discussion of modal and amodal perception or completion).

One readily notices that Kosslyn's account of hypothesis testing naturally fits the schema of hierarchical generative predictive models as discussed in Clark [26.4]. The main themes of this schema are present in Kosslyn's account. These are: the generation of hypotheses at a higher level of visual processing, the crucial role of context or previously acquired knowledge in the formation of these hypotheses, and the testing of these hypotheses through their predictions against the rich iconic information stored in the lower

levels in the visual hierarchy. The whole process fits the scheme of an abductive inference or inference to the best explanation that could be carried out by means of Bayesian networks.

There is a marked difference between the abductive inferences involved in early vision and those involved in late vision; the latter but not the former are informed by knowledge properly speaking, that is, by information that is articulated in thought and thus contains concepts. This might tempt one to think that late vision may be akin to thought and thus that there is a stage of visual processing that has the most crucial traits of thinking, i. e., it involves discursive inferences justifying thus in part Clark's, Spelke's and others' belief to that effect. Against this, I am going to argue in Sect. 26.5, that late vision despite its being informed by conceptually articulated knowledge, differs in significant ways from thinking, the most important difference being that late vision does not engage in discursive inferences.

I have claimed that late vision constructs gradually a representation that best matches the visual scene through a set of processes that test a series of hypotheses by matching these hypotheses against stored iconic information. In other words, the output of late vision, a recognitional belief, is the result of an abductive inference.

## 26.4 Cognitive Penetrability of Perception and the Relation Between Early Vision and Thinking

In assessing claims relating perception to thinking and cognition, it is of paramount importance to examine the role that concepts play in modulating perceptual processing. This is so because if the processes of visual perception are the same as those that lead to belief formation, which means that perception and thinking are of the same nature and cannot be separated, then since belief formation is a process that requires the deployment of concepts, so should perception; perception should be conceptual through and through.

I have argued elsewhere [26.36] that early vision, the first stage of visual processing, is CI and conceptually encapsulated in the sense that its processes are not affected directly, that is, in an on-line manner from cognitive states. There are, as a matter of course, many indirect cognitive effects on early vision, such as precueing effects and the effects of spatial attention in its capacity as a determinant of the focus of gaze, but these effects do not constitute cases of genuine CP [26.36] because, first, concepts do not enter the content of the states of early vision although they causally affect it, and second, because of the preceding fact, these sorts

of cognitive effects can be mitigated and thus do not threaten the epistemological role of early vision as a neutral arbiter of perceptual judgments. If this view is correct, early vision being CI does not employ any concepts and thus it cannot be like thinking, which necessarily involves concepts.

One might object that this claim overlooks the possibility that concepts are embedded in the circuits subserving early vision, rendering it conceptual from the within as it were and not because of any top-down cognitive influences. Being conceptually affected and by using inferences, there is no obstacle in thinking of early vision as akin to thinking. This objection is reinforced by two empirical facts. First, as we have seen, all stages of visual processing are restricted by a set of principles or constraints that aim to solve the various problems of underdetermination. These principles contain concepts and exemplify some form of knowledge that renders early vision theory-laden; it follows that early vision can be like thinking owing to its inherent structure. Second, as a result of perceptual learning, many an environmental regularity are

learned and stored in the early visual circuits to facilitate the processing of familiar input. Since these associations could arguably be construed as involving concepts, a claim could be made that early vision is affected by concepts.

In what follows, I examine these two objections and argue that both sorts of phenomena do not signify the CP and theory-ladenness of perception. This is so because, first, they do not entail that there are any concepts embedded in early vision, and second, because it is doubtful whether they contain any representations. This is also important for the wider claim that visual perception is like thinking, since thinking necessarily involves inferences driven by representations of both premises and the rules of inferences. If it turns out, as I argue here, that the transformation rules that visual perception employs to process its states are not represented anywhere in the system, this would severely undermine the claim that perceptual inferences are the same as the inferences used in belief formation.

### 26.4.1 The Operational Constraints in Visual Processing

There is extensive evidence that there is an important *body of information* that affects perception not in a top-down manner but from within and this might be construed as evidence for the CP of visual perception from its inception. The perceptual system does not function independently of any kind of internal restrictions. Visual processing at every level is constrained by certain principles or rather operational constraints that modulate information processing. Such constraints are needed because distal objects are underdetermined by the retinal image, and because the percept itself is underdetermined by the retinal image. Unless the processing of information in the perceptual system is constrained by some *assumptions* about the physical world, perception is not feasible. Most computational accounts hold that these constraints substantiate some reliable generalities of the natural physical world as it relates to the physical constitution and the needs of the perceiving agents. There is evidence that the physiological visual mechanisms reflect these constraints. Their physical making is such that they implement these constraints, which are thus hardwired in perceptual systems (see Appendix 26.E for a list of some of these constraints).

These are Raftopoulos' [26.36] *operational constraints* and Burge's [26.37] *formation principles*. The operational constraints reflect higher-order physical regularities that govern the behavior of worldly objects and the geometry of the environment and which have been incorporated in the perceptual system through causal interaction with the environment over the evolu-

tion of the species. They allow us to lock onto medium size lumps of matter, by providing the discriminatory capacities necessary for the individuation and tracking of objects in a bottom-up way; they allow perception to generate perceptual states that present worldly objects as cohesive, bounded, solid, and spatiotemporally continuous entities.

The constraints are not available to introspection, function outside the realm of consciousness, and cannot be attributed as acts to the perceiver. One does not believe implicitly or explicitly that an object moves in continuous paths, that it persists in time, or that it is rigid, though one uses this information to parse and index the object. These constraints are not perceptually salient but one must be *sensitive* to them if one is to be described as perceiving their world. The constraints constitute the *modus operandi* of the perceptual system and not a set of rules used by the perceptual system as premises in perceptual inferences even though the *modus operandi* of the visual system consists of operations determined by laws describable in terms of computation principles. They are reflected in the functioning of the perceptual system and can be used only by it. They are available only for visual processing, whereas *theoretical* constraints are available for a wide range of cognitive applications. These constraints cannot be overridden since they are not under the perceiver's control; one cannot decide to substitute them with another body of constraints even if one knows that they lead to errors.

Being hardwired, the constraints are not even contentful states of the perceptual system. A state is formed through the spreading of activation and its modification as it passes through the synapses. The hardwired constraints specify the processing, i. e., the transformation from one state to another, but they are not the result of this processing. They are computational principles that describe transitions between states in the perceptual system. Although the states that are produced by means of these mathematical transformations have contents, there is no reason to suppose that the principles that specify the mathematical transformation operations are states of the system or contents of states in the system. If they are not states of the visual system, the principles that express them linguistically cannot be contents of any kind. Even though the perceptual system uses the operational constraints to represent some entity in the world and thus operates in accord with the principles reflected in the constraints (since the constraints are hardwired in the perceptual system, physiological conditions instantiate the constraints), the perceiver does not represent these principles or the constraints in any form. By the same token, these principles cannot be thought of as implicating concepts, since concepts are

representational. For this reason, perceptual operations should not be construed as inference rules, although they are describable as such, and they do not constitute either a body of knowledge or some theory about the world.

Recent work on Bayesian causal networks [26.4] draws a picture of the brain as a Bayesian net operating at various space and time scales, and suggests that there is a sharp distinction between internal probabilistic dependencies that can be explained by internal causal connections and those that cannot. Only those that cannot be explained internally carry information about the external world. Applying this to the case of the neuronal mechanisms that implement the operational constraints at work in visual processing, one could say that these mechanisms perform transformations that depend entirely on the internal probabilistic dependencies in the system as they are determined by the hardwired circuitry that realizes the internal causal connections and thus there is nothing representational about them.

These considerations allow us to address *Cavanagh's* [26.38] claim that the processes that lead to the formation of a conscious percept constitute *visual cognition* in virtue of their use of inferences. The construction of a percept is “the task of visual cognition and, in almost all cases, each construct is a choice among an infinity of possibilities, chosen based on likelihood, bias, or a whim, but chosen by rejecting other valid competitors” [26.38]. This process is an inference in that “it is not a guess. It is a rule-based extension from partial data to the most appropriate solution”; in the terminology of this chapter, the selection process is an abduction.

According to *Cavanagh* [26.38], for inference to take place the visual system should not rely to purely bottom-up analyses of the image that use only retinal information, such as sequences of filters that underlies facial recognition, or the cooperative networks that converge on the best descriptions of surfaces and contours. Instead, the visual system should use some object knowledge, which is nonretinal, context-dependent information. By *object knowledge* *Cavanagh* means any sort of nonretinal information that may be needed for the filling in that leads to the construction of the percept. This knowledge consists of rules that guide or constrain visual processing in order to solve the underdetermination problem that I mentioned above; they provide the rule-based extension from partial data that constitutes an inference. These rules do not influence visual processing in a top-down way, since they reside within the visual system; they are “from the side” [26.39].

The discussion concerning the nature of the operational constraints suggests that, their crucial role

in perceptual processing notwithstanding, these constraints do not justify *Cavanagh's* characterization of visual perception as *visual cognition*, if cognition is thought of as involving discursive inferences.

## 26.4.2 Perceptual Learning

Evidence from studies showing early object classification effects suggests that to the extent that object classification presupposes object knowledge, this knowledge affects early vision in a top-down manner rendering it theory-laden. Moreover, even if one could show that these effects do not entail the CP of early vision, one could argue that since perceptual learning affects the way one sees the world, some experiences are learned and form memories that are stored in visual memory and affect perceptual processing from its inception. Our experiences shape the way we see the world.

Indeed, visual memories affect perception. Familiarity with objects or scenes that is built through repeated exposure to objects or scenes (sometimes one presentation is enough), or even repetition memory [26.40] facilitate search, affect figure from ground segmentation, speed up object identification and image classification, etc. [26.41–43].

Familiarity can affect visual processing in different ways. It may facilitate object identification and categorization, which are processes that take time since their final stage occurs between 300–600 ms after stimulus onset as is evidenced by the P3 responses in the brain, but their earlier stage starts about 150 ms after stimulus onset [26.44–46]. One notices that familiarity intervenes during the latest stage of visual processing (300–360 ms). These effects involve the higher cognitive levels of the brain at which semantic information and processing, both being required for object identification and categorization, occur [26.30]. In this sense, these sort of familiarity effects do not threaten the CI of early vision, which has ended about 120 ms after stimulus onset.

Familiarity, including repetition memory, also affects object classification (whether an image portrays an animal or a face), a process that occurs in short latencies (95–100 ms and 85–95 ms respectively) [26.47–49]. These early effects may pose a threat to the CI of early vision since they cannot be considered post-sensory. The threat would materialize should the classification processes either require semantic information to intervene or require the representations of objects in working memory to be activated, since that would, too, mean conceptual involvement.

Researchers however unanimously agree that the early classification effects in the brain result from the FFS and do not involve top-down semantic information,

nor do they require the activation of object memories. The brain areas involved are low-level visual areas (including the FEF – front eye fields) from V1 to no higher than V4 [26.48] or perhaps a bit more upstream to posterior IT [26.42] and lateral occipital complex (LOC) [26.49].

The early effects of familiarity may be explained by invoking contextual associations (target-context spatial relationships) that are stored in early sensory areas to form unconscious perceptual memories [26.50] which, when activated from incoming signals that bear the same or similar target-context spatial relationships, modify the FFS of neural activity resulting in the facilitating effects mentioned above. Thus, what is involved in the phenomenon are certain associations built in the early visual system that once activated speed up the feedforward processing. This is a case of rigging-up the early visual processing; it is not a case of top-down cognitive effects on early visual processing.

The early effects may also be explained by appealing to configurations of properties of objects or scenes. Currently, neurophysiological research [26.40, 49], psychological research [26.42], and computation modeling [26.51] suggest that what is stored in early visual areas are implicit associations representing fragments of objects and shapes, or *edge complexes*, as opposed to whole objects and shapes. One of the reasons that have led researchers to argue that it is object and shape fragments that are used in rapid classifications instead of whole objects and shapes is the following: If these associations reflecting some sort of object recognition can affect figure-ground segmentation as we have reasons to believe [26.42] in view of the fact that figure-ground segmentation occurs very early (80–100 ms) [26.52] these associations must be stored in early visual areas (up to V4, LO and posterior IT) and cannot be the representations stored in, say, anterior IT. The earlier visual areas store object and shape fragments and not holistic figures and shapes [26.40, 51].

The associations that are built in, through learning, in early visual circuits reflect in essence the statistical distribution of properties in environmental scenes [26.32, 53]. The statistical differences in physi-

cal properties of different subsets of images are detected very early by the visual system before any top-down semantic involvement as is evidenced by the elicitation of an early deflection in the differential between animal-target and nontarget ERP's at about 98 ms (in the occipital lobe) and 120 ms (in the frontal lobe). The low-cues could be retrieved very early in the visual system from a scene by analyzing the energy distribution across a set of orientation and spatial frequency-tuned channels [26.54]. This suggests that the rapid image classification may rely on low-level, or intermediate-level cues [26.51] that act diagnostically, that is, they allow the visual system to predict the gist of the scene and classify images very fast. These cues may be provided by coarse visual information, say by low-level spatial frequency information and thus the visual system does not have to rely on high-level fully integrated object representations in order to be able to classify rapidly visual scenes.

It follows that the classification of an object that occurs very early during the fast FFS at about 85–100 ms is due to associations regarding shape and object fragments stored in early visual areas and does not reflect any top-down cognitive effects on, that is, the CP of, early vision. Thus, early object classification is not a sign of the theory-ladenness of early vision, since the knowledge about the world does not affect it in a top-down manner.

To recapitulate the results of our discussion in this section, I have argued that neither the operational constraints operating in visual perception, nor perceptual learning entail that concepts affect early vision. Moreover, they do not entail that visual processing in general is theory-laden because of the role of these constraints, since they are not representational elements and any theory constitutively implicates representational elements. On the other hand, both the operational constraints and the effects of perceptual learning provide the context in which early vision constructs its hypotheses, and part of the context in which late vision operate, the other part being the viewer's knowledge of the world, which, as I have said, affects late vision but not early vision.

## 26.5 Late Vision, Inferences, and Thinking

*Jackendoff* [26.55] distinguishes visual awareness from visual understanding. There is a qualitative difference between the experience of a 3-D sketch and the experience of a  $2\frac{1}{2}$ -D sketch. Although one is in some sense aware of the 3-D sketch or of category-based representations, however, this is not visual awareness but some

other kind of awareness. Visual awareness is awareness of Marr's  $2\frac{1}{2}$ -D sketch, which is the viewer-centered representation of the visible surfaces of objects, while the awareness of the 3-D sketch is visual understanding. Thus, the 3-D sketch, which includes the unseen surfaces that are not represented in the  $2\frac{1}{2}$ -D sketch,

is a result of an inference. These views belong to the belief-based account of amodal completion: the 3-D sketch is the result of beliefs abductively inferred from the object's visible features and other background information from past experiences (see Appendix 26.D for an explanation of amodal and modal completion or perception).

The problem is whether the object identification that occurs in late vision (which, as we have seen most likely constitutes in essence an abductive inference) and depends on concepts should be thought of as a purely visual process or as a case of discursive understanding involving discursive inferences. If late vision involves conceptual contents and if the role of concepts and stored knowledge consists of providing some initial interpretation of the visual scene and in forming hypotheses about the identity of objects that are tested against perceptual information, one is tempted to say that this stage relies on inferences and thus differs in essence from the purely perceptual processes of early vision. Perhaps it would be better to construe late vision as a discursive stage involving thoughts, in the way of epistemic seeing, where *seeing* is used in a metaphorical nonperceptual sense, as where one says of his friend whom she visited *I see he has left*, based on perceptual evidence [26.56]. It is, also possible that Dretske [26.57, 58] thinks that seeing in the doxastic sense is not a visual but rather a discursive stage.

One might object, first, that abandoning this usage of *to see* violates ordinary usage. A fundamental ingredient of visual experience consists of meaningful 3-D solid objects. Adopting this proposal would mean that one should resist talking of seeing tigers and start talking about seeing viewer-centered visible surfaces. "By this criterion, much of the information we normally take to be visually conscious would not be, including the 3-D shape of objects as well as their categorical identity" [26.59].

More to the point, I think that one should not assume either that late vision involves abductive inferences construed as inferential discursive-state transformations that constitutively involve thoughts in the capacity of premises in inferences whose conclusion is a recognitional belief, or that late vision consists of discursively entertaining thoughts; if thinking is construed as constitutively implicating discursive argumentation, visual perception is different from thinking in some radical ways. The reason is twofold. First, seeing an object is not the result of a discursive inference, that is, a movement in thought from some premises to a conclusion, even though it involves concepts and intrastate transformations. Second, late vision is a stage in which conceptual modulation and perceptual processes form an inextricable link that differentiates late vision from

discursive stages and renders it a different sort of a set of processes than understanding, even though late vision involves implicit beliefs regarding objects that guide the formation of hypotheses concerning object identity, and an explicit belief of the form *that O is F* eventually arises in the final stages of late vision. Late vision has an irreducible visual ingredient that makes it different from discursive understanding.

Let me clarify two terminological issues. First, judgments are occurrent states, whereas beliefs are dispositional states. To judge that *O is F* is to predicate *F*-ness to *O* while endorsing the predication [26.60]. To believe that *O is F* is to be disposed to judge under the right circumstances that *O is F*. This is one sense in which beliefs are dispositional items. There is also a distinction between standing knowledge (information stored in long term memory, LTM) and information that is activated in working memory (WM). The belief that *O is F* may be a standing information in LTM, a memory about *O* even though presently one does not have an occurrent thought about *O*. Beliefs need not be consciously or unconsciously apprehended, that is, activated in the mind, in order to be possessed by a subject, which means that beliefs are dispositional rather than occurrent items; this is a second sense in which beliefs are dispositional. When this information is activated, the thought that *O is F* emerges in WM; all thoughts are occurrent states.

It follows that a belief qua dispositional state may be either a piece of standing knowledge, in which case it is dispositional in the sense that when activated it becomes a thought, or a thought that awaits endorsement to become a judgment, in which case the belief is dispositional in the sense that it has the capacity to become a judgment. In the first case, beliefs differ from thoughts. In the second case, a belief is a thought held in WM, albeit one that has not been yet endorsed. In what follows, I assume that beliefs are either pieces of standing information or thoughts that have not been endorsed and thus are not judgments. Finally, by *implicit belief* I mean the belief held by a person who is not aware that she is having that belief.

As I said in the introduction, this chapter examines whether the abductive processes that take place in late vision should be construed as discursive inferences. Specifically, my claim is that the processes in late vision are not inferential processes where *inference* is understood as discursive, that is, as a process that involves drawing propositions or conclusions from other propositions, that are represented in the system, acting as premises by applying (explicitly or implicitly) inferential rules that are also represented. As we saw, these inferences are distinguished from *inferences* as understood by vision scientists according to whom

any transformation of signals carrying information according to some rule is an inference.

### 26.5.1 Late Vision, Hypothesis Testing, and Inference

I think that the states of late vision are not inferences from premises that include the contents of early vision states, even though it is usual to find claims that one infers that a tiger, for example, is present from the perceptual information retrieved from a visual scene. An inference relates some propositions in the form of premises with some other proposition, the conclusion. However, the objects and properties as they are represented in early vision do not constitute contents in the form of propositions, since they are part of the nonpropositional, iconic nonconceptual content of perception. In late vision, the perceptual content is conceptualized but the conceptualization is not a kind of inference but rather the application of stored concepts to some input that enters the cognitive centers of the brain and activates concepts by matching their content. Thus, even though the states in late vision are formed through the synergy of bottom-up visual information and top-down conceptual influences, they are not inferences from perceptual content.

Late vision involves hypotheses regarding the identity of objects and their testing against the sensory information stored in iconic memory. One might think that inferences are involved since testing hypotheses is an inferential process even though it is not an inference from perceptual content to a recognitional thought. It is, rather, an argument of the form of: if  $A$  and  $B$  then (conclusion)  $C$ , where  $A$  and  $B$  are background assumptions and the hypothesis regarding the identity of an object respectively, and  $C$  is the set of visual features that the object is likely to have.  $A$  consists of implicit beliefs about the features of the hypothesized visual object. If the predicted visual features of  $C$  match those that are stored in iconic memory in the visual areas, then the hypothesis about the identity of the object is likely correct. The process ends when the best possible fit is achieved. However, the test basis or evidence against which these hypotheses are tested for a match, that is, the iconic information stored in the sensory visual areas, is not a set of propositions but patterns of neuronal activations whose content is nonpropositional.

There is nothing inference-like in this matching. It is just a comparison between the activations of neuronal assemblies that encode the visual features in the scene and the activations of the neuronal assemblies that are activated top-down from the hypotheses. If the same assemblies are activated then there is a match. If they are not, the hypothesis fails to pass the test.

This can be done through purely associational processes of the sort employed, say, in connectionist networks that process information according to rules and thus can be thought of as instantiating processing rules, without either representing these rules or operating on language-like symbolic representations. Such networks perform vector completion and function by satisfying soft constraints in order to produce the best output given the input into the system and the task at hand. Note that the algebraic and thus continuous nature of state transformations in neural networks, as opposed to the algorithmic discrete-like operations of classical AI (which assumes that the brain is a syntactic machine that processes discrete symbols according to rules that are also represented in the system) suits best the analogue nature of iconic representations.

In perceptual systems construed as neural networks, the fundamental representational unit is not some linguistic or linguistic-like entity but the activation pattern across a proprietary population of neurons. If one wishes to understand the workings of the visual brain, one should eschew sentences and propositions as bearers of representations and meanings and reconceptualize representations as activation patterns. This does not mean, of course, that the brain does not have symbolic representations but only that, first, these are a subset of the representations that the brain uses in its various functions, and, second and most importantly, the symbolic representations are constructed somehow out of the more fundamental context-dependent representations that the brain uses and are, consequently, a later construct, phylogenetically speaking. This has an important corollary for any theory of cognition that employs activation patterns as the fundamental units of representation, namely, that it must be able to explain the existence and usage of symbolic representations. This means also that the processing at work in the brain, that is, the transformation of the representational units to other representational units is not exclusively the transformation of complex or simple symbols by means of a set of syntactic rules as in the algorithms that, according to the classical view, the brain is supposed to run. Instead, it can be the algebraic transformation of activation patterns (in essence the algebraic transformations from one multidimensional matrix or tensor to another). The transformation is effected by the synaptic connections among the neurons as the signal passes from one layer to another. These connections have weights that constitute a filter through which the signal is transformed as it passes through.

The above also explain the holistic nature of the abductive visual processes that classical cognitive theories (the family of theories that assume that the brain is a syntactic machine that processes symbols that are

constant, context independent, and freely repeatable elements) have failed to capture. It is interesting that if I am right, Fodor's attempt to differentiate the perceptual systems from cognitive functions in order to protect the former from the abductive holistic reasoning implicated in the latter fails since late vision is abductive and holistic as well.

Since discursive inferences are carried out through rules that are represented in the system and operate on symbolic structures, the processing in a connectionist network does not involve discursive inferences, although it can be described in terms of inference making. Thus, even though seeing an object in late vision involves the application of concepts that unify the appearances of the object and of its features under some category, it is not an inferential process.

I have said that the noninferential process that results in the formation of a recognitional thought or belief can be recast in the form of an argument from some premise to a conclusion. However, this does not entail that the formation of the perceptual thought is a piece of reasoning, that is, a transition from a set of premises that act as a reason for holding the thought to the thought itself. Admittedly, the perceiver can be asked on what grounds she holds the thought that *O* is *F*, in which case she may reply *because I saw it or I saw that O is F*. However, this does not mean that the reason she cites as a justification of her thought is a premise from which she inferred the thought. The perceiver does not argue from her thought *I saw it to be thus and so* to the thought *It is thus and so*. She just forms the thought on the basis of the evidence included in her relevant perceptual state in the noninferential way I described above. What warrants the recognitional thought *O is F* is not the thought held by the perceiver that she sees *O* to be *F* but the perceptual state that presents to her the world as being such and such. "When one knows something to be so by virtue of seeing to be so, one's warrant for believing it to be so is that one sees it to be so, not one's believing that one sees it to be so" [26.57].

*Spelke* [26.3] who echoes *Rock's* [26.2] views that the perceptual system combines inferential information to form the percept (for example, from visual angle and distance information, one infers and perceives size) – argues "perceiving objects may be more akin to thinking about the physical world than to sensing the immediate environment". The reason is that the perceptual system, to solve the underdetermination problem of both the distal object from the retinal image and of the percept from the retinal image, employs a set of object principles and that reflect the geometry and the physics of our environment. Since the contents of these principles consist of concepts, and thus the principles can be thought of as some form of knowledge about the world,

perception engages in discursive, inferential processes. Against this, I argued above that the processes that constrain the operations of the visual system should not be construed as discursive inferences. They are hardwired in the perceptual circuits and are not represented in it. Thus, perceptual operations should not be construed as inference rules, although they are describable in terms of discursive inferential rules. It follows that the abduction that takes place in late vision is not an Aristotelian inference; it is better described by the ampliative vector completion of connectionism.

### 26.5.2 Late Vision and Discursive Understanding

Even if I am right that seeing in late vision is not the result of a discursive abductive inference but the result of a pattern-matching process that ensures the best fit with the available data, it is still arguable that late vision should be better construed as a stage of discursive understanding rather than as a visual stage. If object recognition involves forming a belief about class membership, even if the belief is not the result of an inference, why not say that recognizing an object is an experience-based belief that is a case of understanding rather than vision?

#### Late Vision Is more than Object Recognition

A first problem with this view is that late vision involves more than a recognitional belief. Suppose that *S* sees an animal and recognizes it as a tiger. In the parallel preattentive early vision, the proto-object that corresponds to the tiger is being represented amongst the other objects in the scene. After the proto-objects have been parsed, the object recognition system forms hypotheses regarding their identity. However, for the subject's confidence to reach the threshold that will allow her to form beliefs about the identity of the objects and report it, these hypotheses must be tested [26.61].

For this to happen, the relevant sensory activations enter the parietal and temporal lobes, and the prefrontal cortex, where the neuronal assemblies encoding the information about the objects in the scene are activated and the relevant hypotheses are formed. To test these hypotheses, the visual system allocates resources to features and regions that would confirm or disconfirm the hypotheses. To accomplish this, activation spreads through top-down signals from the cognitive centers to the visual areas of the brain where the visual sensory memory and the fragile visual memory store the proto-objects extracted from the visual scene. This way, conceptual information about the tiger affects visual processing and after some hypothesis testing the animal is recognized as a tiger through the synergy of

visual circuits and WM. At this point the explicit belief *O is F* is formed. This occurs after 300 ms, when the viewer consolidates the object in WM and identifies it with enough confidence to report it, which means that beliefs are formed at the final phases of late vision.

However, semantic modulation of visual processing and the process of conceptualization that eventually leads to object recognition starts at about 130–200 ms. There is thus a time gap between the onset of conceptualization and the recognition of an object, which is a prerequisite for the formation of an explicit recognitional belief. As *Treisman* and *Kanwisher* [26.62] observe, although the formation of hypotheses regarding the categorization of objects can occur within 130–200 ms after stimulus onset, it takes another 100 ms for subsequent processes to bring this information into awareness so that the perceiver could be aware of the presence of an object. To form the recognitional belief that *O is F*, one must be aware of the presence of an object token and construct first a coherent representation. This requires the enhancement through attentional modulation of the visual responses in early visual circuits that encode rich sensory information in order to integrate them into a coherent representation, which is why beliefs are delayed in time compared with the onset of conceptualization; not all of late vision involves explicit beliefs.

#### Late Vision as a Synergy of Bottom-Up and Top-Down Information Processing

A second reason why the beliefs formed in late vision are partly visual constructs and not pure thoughts is that the late stage of late vision in which explicit beliefs concerning object identity are formed constitutively involves visual circuits (that is, brain areas from LGN to IT in the ventral system). Pure thought, on the other hand, involves an amodal form of representation formed in higher centers of the brain, even though these amodal representations can trigger in a top-down manner the formation of mental images and can be triggered by sensory stimulation. The point is that amodal representations can be activated without a concomitant activation of the visual cortex. The representations in late vision, in contrast, are modal since they constitutively involve visual areas. Thus, what distinguishes late vision beliefs from pure thoughts is mostly the fact that the beliefs in late vision are formed through a synergy of bottom-up and top-down activation and their maintenance requires the active participation of the visual circuits. Pure thoughts can be activated and maintained in the absence of activation in visual circuits.

The constitutive reliance of late vision on the visual circuits suggests that late vision relies on the presence of the object of perception; it cannot cease to function

as a perceptual demonstrative that refers to the object of perception, as this has been individuated through the processes of early vision. As such, late vision is constitutively context dependent since the demonstration of the perceptual particular is always context dependent. Thought, on the other hand, by its use of context independent symbols, is free of the particular perceptual context. Even though recognitional beliefs in late vision and pure perceptual beliefs involve concepts, the concepts function differently in the two contexts [26.37]:

“Perceptual belief makes use of the singular and attributive elements in perception. In perceptual belief, pure attribution is separated from, and supplements, attributive guidance of contextually purported reference to particulars. Correct conceptualization of a perceptual attributive involves taking over the perceptual attributive’s range of applicability and making use of its (perceptual) mode of presentation.”

The attributive and singular elements in perception correspond to the perceived objects and their properties respectively. The attributive elements or properties guide the contextual reference to particulars or objects since the referent in a demonstrative perceptual reference is fixed through the properties of the referent as these properties are presented in perception.

Concepts enter the game in their capacity as pure attributions that make use of the perceptual mode of presentation. Burge’s claim that in perceptual beliefs pure attributions supplement attributions that are used for contextual reference to particulars may be read to mean that perceptual beliefs are hybrid states involving both visual elements (the contextual attributions used for determining reference to objects and their properties) and conceptualizations of these perceptual attributives in the form of pure attributions. In this case, the role of perceptual attributives is ineliminable. In late vision, unlike in pure beliefs, there can be no case of pure attribution, that is, of attribution of features in the absence of perceptually relevant particulars since the attributions are used to single out these particulars.

The inextricable link between thought and perception in late vision explains the essentially contextual [26.63, 64] character of beliefs in late vision. The proposition expressed by the belief cannot be detached from the perceptual context in which it is believed and cannot be reduced to another belief in which some third person or objective content is substituted for the indexicals that figure in the thought (in the way one can substitute via Kaplan’s characters the indexical terms with their referents and get the *objective* truth-evaluable content of the belief); the belief is tied to a idiosyncratic

viewpoint by making use of the viewer's physical presence and occupation of a certain location in space and time; the context in which the indexical thought is believed is essential to the information conveyed.

The discussion on late vision and the inferences it uses to construct the percept suggests that late vision, its conceptual nature notwithstanding, does not involve discursive inferences and in this sense is fundamentally different from thinking, if the latter is thought to implicate constitutively discursive inferences. Late vision employs abductive inferences, in that it constructs the representation that best fits the sensory image, but these inferences are not the result of the application of rules that are represented in the system. Even the operational constraints that restrict visual processing in late vision and could be thought of as transformation rules that the system follows to make inferences, are not, as we have seen, propositional structures or even representations in the brain. The inferences involved are informed and guided by conceptual information in pattern-matching processes but fall short of being discursive inferences.

## 26.6 Concluding Discussion

I have argued in this chapter that visual processing involves abductive inferences that aim to construct a representation, namely, the percept, that best matches the sensory information. To achieve this, the brain probably uses Bayesian strategies since abductive inferences are probabilistic in nature. I also argued that these inferences are not discursive inferences and since the latter are the characteristic trait of thinking, visual processing is not akin to thinking despite its usage of abductive inferences; my claim applies to both early vision and late vision.

The discussion in this chapter, and especially the view on the relation between perceptual inference and perceptual judgments, is in agreement with *Magnani's* [26.65] elaboration on *Peirce's* [26.66, 67] views on visual perception, which Peirce also conceived of perception as an abductive inference. In particular, I have tried to defend the thesis eloquently expressed by Peirce that the transition between abductive inferences and perceptual judgment is a continuous one without any sharp line of demarcation between them despite their many differences that I elaborated on in the previous section. My discussion also reinforces *Magnani's* view that "judgments in perception are fallible but indubitable abductions we are not in any condition to psychologically conceive that they are false, as they are unconscious habits of inference" [26.65]. Most importantly, my account of the abductive inferences in-

The fact that both conceptual and nonconceptual representations are in essence activation patterns allows us to understand how conceptual, symbolic information and nonconceptual iconic information could interact. The main difference between the two forms of representations is that the former are not homogeneous and have a syntactic structure that has a canonical decomposition, whereas the latter are homogeneous and lack a canonical decomposition. To appreciate the difference think of it in following way: the fact that a symbolic representation has a canonical decomposition means that not every subpart of the representation is a representation; only those subparts that satisfy the syntactic rules of the representational systems are symbols or representations. The expression (p&Q), for instance, is a symbol or a representation, but the expression (p(&q)) is not. Any subpart of an image, on the other hand, is an image and thus a representation.

The output of late vision, namely the percept, enters the space of reasons and participates in discursive inferences and thus in thought.

Involved in visual perception fully justifies *Magnani's* claim that visual abduction is not sentential, that is, it does not employ symbolic, or discursive as I have called them, inferences. Instead it relies on pattern matching in which activation patterns that take on continuous values are compared. Thus, the representational medium employed is analogue and not symbolic in nature and the usage of stored knowledge in drawing inferences resembles more the use of models that put the incoming information in a context so that conclusions could be drawn rather than the recruitment of sentences and inference rules. In other words, visual abduction is model-based.

In constructing the percept, the brain uses a set of operational constraints that aim to solve the various underdetermination problems that the visual perception encounters in order to construct the percept. I have argued that these constraints should not be thought of as rules that are represented in the system or that have some representational contents and guide the perceptual inferences rendering them discursive. Instead, they are hardwired in the visual system and are not representations.

I also suggested, although I did not discuss this issue in full, that the recent developments in vision studies tend to bring together the different theories of vision by showing the points of contact between them, rather than to underline their differences.

To recapitulate, the main conclusion of this chapter is, first, that to the extent that thinking is associated with the use of discursive inferences, perception differs radically from thinking. If the meaning of thinking is extended to comprise nondiscursive inferences, the claim may be made that perception is thinking. In this case, however, a distinction should be drawn between discursive thinking that characterizes cognition and nondiscursive thinking that characterizes perceptual processes. Second, if thinking also necessarily involves the deployment of concepts, then there is a stage of visual processing, namely, early vision, which is not akin to thinking since its contents are nonconceptual. The other stage of visual processing, namely late vision, uses conceptual information. Since, as I will argue, the processes of late vision are not discursive inferences,

**Table 26.1** Visual perception and thinking

Perception	Thinking	
	Thinking narrow	Thinking wide
Early vision	No	Yes/no concepts
Late vision	No	Yes/yes concepts

if thinking is conceived as necessarily implicating discursive inferences late vision is not akin to thinking, notwithstanding the conceptual involvement. If the concept of thinking is extended to include other sorts of inferences, such as the model-based abductive inferences discussed in this chapter, late vision could be thought of as a sort of thinking, which, unlike early vision, implicates concepts (see Table 26.1 for a taxonomy).

## 26.A Appendix: Forms of Inferences

These are the three forms of inferences in which all syllogisms can be categorized.

### 26.A.1 Deduction

An inference is deductive if its logical structure is such that the conclusion of the inference is a logical consequence of the premises of the inference. This entails that if the premises of a deductive argument are true then its conclusion is necessarily true as well. In this sense, deductive arguments are truth preserving. This is equivalent to saying that in any interpretation of the inference in which the premises are true, the conclusion is true too. Differently put, if an argument is deductively valid, there is no model under which the premises are true but the conclusion is false. This is why deductive inferences are sometimes characterized as conclusive.

A typical example of a deductive argument is this: All men are mortal; Socrates is a man. Therefore Socrates is mortal.

### 26.A.2 Induction

An argument is inductive if its conclusion does not follow logically from the premises. The premises of an inductive argument may be true and still its conclusion false. The premises of an inductive argument provide epistemic support or epistemic warrant for its conclusion; they constitute evidence for the conclusion. By definition, inductive arguments are not truth preserving.

A typical example of an inductive argument is the following: Bird  $\alpha$  is a crow and is black; bird  $\beta$  is a crow and is black; . . . bird  $\kappa$  is a crow and is black. Therefore: All crows are probably black.

If the examined specimens are found in a variety of places and under different environmental conditions, the premises of the inference provide solid evidence for the conclusion. Yet, the conclusion may still be wrong since the next crow that we will examine may not be black. This example shows that the conclusion does not follow logically from the premises. It is still possible, no matter how good the premises, that is the evidence, are that the conclusion be false, which explains the qualification *probably* in the conclusion of an inductive argument. The world could be such that even crows  $\alpha$  through  $\kappa$  are black, crow  $\kappa + 1$  is white. For this reason inductions are considered to be nonconclusive but tentative [26.68].

### 26.A.3 Abduction or Inference to the Best Explanation

It is an inference in which a series of facts, which are either new, or improbable, or surprising on their own or in conjunction, are used as premises leading to a conclusion that constitutes an explanation of these facts. This explanation makes them more probable and more comprehensible in that it accounts for their appearance. As such, with abductive inferences the mind reaches conclusions that go far beyond what is given. For this reason, abductions are the main theoretical tools for building models and theories that explain reality. Ab-

duction is inductive since it is ampliative, does not preserve truth and is thus probabilistic in that the conclusion is tentative.

#### 26.A.4 Differences Between the Modes of Inference

##### Induction versus Deduction

Induction is an ampliative inference, whereas deduction is not ampliative. This means that the information conveyed by the conclusion of an inductive argument goes beyond the information conveyed by the premises and, in this sense, the conclusion is not implicitly contained in the premises. In deduction, the conclusion is implicitly contained in the premises and the inference just makes it explicit. If all men are mortal and Socrates is a man, for example, the fact that Socrates is mortal is implicitly contained in these two propositions. What the deduction does is to render it explicit in the form of the conclusion. When we deduce that Socrates is mortal, our knowledge does not extend that which we already knew; it only makes it explicit. When, on the other hand, we inductively infer that all crows are probably black from the premise that all the specimens of crows that we have examined thus far are black, we extend the scope of our knowledge because the conclusion concerns all crows and not just the crows thus far examined.

The above discussion entails the main difference between deductive and inductive arguments. Deductive arguments are monotonous, while inductive arguments are not. This means that a valid deductive argument remains valid no matter how many premises we add to the argument. The reason is that the validity of the deductive argument presupposes that the conclusion is a logical conclusion of its premises. This fact does not change by the addition of new premises, no matter what these premises stipulate and thus the deductive argument remains valid. Things are radically different in induction. A new premise may change the conclusion even if the previous premises strongly supported the conclusion. For example, if we discover that crow  $\kappa + 1$  is white, this undermines that previously drawn and well-supported conclusion that all crows are black.

### 26.B Appendix: Constructivism

Some of Marr's particular proposals of his model have been criticized on many grounds (see, for example, [26.59]). In particular, against Marr's model of object recognition, it has been argued by several researchers that object recognition may be more image-based than based on object-centered representations,

##### Induction versus Abduction

Both abduction and induction are tentative forms of inference in that they do not warrant the truth of their conclusion even if the premises are true. They are, also, both ampliative in that the conclusion introduces information that was not contained implicitly in the premises. As we have seen, in abduction one aims to explain or account for a set of data. Induction is a more general form of inference. When, for instance, one successfully tests a hypothesis by making predictions that are borne out, the predicted data provide inductive, but not abductive, support for the hypothesis. In general, the evaluation phase in hypothesis, or theory, construction is considered to be inductive. Conceiving the explanatory hypothesis, on the other hand, is an abductive process that may assume the form of a pure, educated guess that need not have involved any previous testing. In this case, the abductively produced hypothesis is not, a priori, the best explanation for the set of data that need explanation; this is one of the occasions in which abduction can be distinguished from the inference to the best explanation. However, it should be stressed, although I do not have the space to elaborate on this problem, that in realistic scientific practice abduction as theory construction could not be separated from the evaluative inductive phase since they both form an inextricable link. This justifies the claim that abduction is an inference to the best explanation.

A further difference between abduction and induction is that even though both kinds of inference are ampliative, in abduction the conclusion may, and usually does, contain terms that do not figure in the premises. Almost all theoretical entities in science were conceived as a result of abduction. The nucleus of an atom, for example, was posited as a way of explaining the scattering of particles after the bombardment of atoms. Nowhere in the premises of the abductive argument was the notion of an atom present; the evidence consisted in measurements of the deviation of the pathways particles from their predicted values after the bombardment. The conclusion *all crows are probably black*, on the other hand, contains only terms that are available in the premises.

which means that the latter may be less important than Marr thought them to be. Neurophysiological studies [26.69] also suggest that both object-centered and viewer-centered representations play a substantial role in object recognition. Nevertheless, his general ideas about the construction of gradual visual representations

remain useful. According to this form of constructivism, vision consists of four stages, each of which outputs a different kind of visual representation:

1. The *formation of the retinal image*; the immediate stimulus for vision, that is the first stimulus that affects directly the sensory organs (this is called the proximal stimulus) is the pair of two-dimensional (2-D) images projected from the environment to the eyes. This representation is based on a 2-D retinal organization. At this stage, the information impinging on the retina (which as you may recall concerns intensity of illumination and wavelengths, and which is captured by the retinal receptors) is organized so that all of the information about the spatial distribution of light (i. e., the light intensity falling on each retinal receptor) be recast in a reference frame that consists of square image elements (*pixels*), each indicating with a numerical value the light intensity falling on each receptor. Sometimes, the processes of this stage are called *sensation*.
2. The *image-based stage*; it includes operations that receive as input the retinal image (that is, the numerical array of values of light intensities in each pixel) and process it in order to detect local edges and lines, to link these edges and lines in a more global scale, to match up corresponding images in the two eyes, to define 2-D regions in the image, and to detect line terminations and blobs. This stage outputs 2-D surfaces at some particular slant that are located at some distance from the viewer in 3-D space.

In general, the image-based representation has the following properties: First, it receives as input and thus operates first on information about the 2-D structure of the retinal image rather than on information concerning the physical, distal, objects. Second, its geometry is inherently two-dimensional. Third, the image-based representation of the 2-D features is cast in a coordinate reference system that is defined with respect to the retina (as a result, the organization of the information is called *retino-topic*). This means that the axes of the reference system are aligned with the eye rather than the body or the environment. This stage is the first stage of *perception* proper:

3. The *surface-based*; in this stage, vision constructs representations of the intrinsic properties of sur-

faces in the environment that might have produced the features constructed in the image-based model. At this stage, and in contradistinction to the preceding stage, the information about the worldly surfaces is represented in three dimensions. Marr's two-and-a-half-dimensional (2.5-D) sketch is a typical example of a surface-based representation. Note that the surface-based representation of a visual scene does not contain information about all the surfaces that are present in the scene, but only those that are visible for the viewer's current viewpoint.

In general, the surface-based representation has the following properties: First, The elements that the surface-based stage outputs consist of the output of the image-based stage, that is, in 2-D surfaces at some particular slant that are located at some distance from the viewer in 3-D space. Second, these 2-D surfaces are represented within a 3-D spatial framework. Third, the aforementioned reference framework is defined in terms of the direction and distance of the surfaces from the observer's standpoint (it is egocentric):

4. The *object-based*; this is the stage in which the visual system constructs 3-D representations of objects that include at least some of the occluded surfaces of the objects, that is, the surfaces that are invisible from the standpoint of the viewer, such as the back parts of objects. In this sense, this is the stage in which explicit representations of whole objects in the environment are constructed. It goes without saying that in order for the visual system to achieve this aim, it must use information about the whole objects that viewers have stored from their previous visual encounters with objects of the same type. The viewer retrieves from memory this information and fills in with it the surface-based image constructed at the previous stage.

In general, the object-based representation has the following properties: First, this stage outputs volumetric representations of objects that may include information about unseen surfaces. Second, the space in which these objects are represented is three-dimensional. Third, the frame of reference in which the object-based representations are cast is defined in terms of the intrinsic structure of the objects and the visual scene (it is scene-based or allocentric).

## 26.C Appendix: Bayes' Theorem and Some of Its Epistemological Aspects

Bayes' theorem is the following probabilistic formula (in its simple form because there is another formulation when one considers two competing hypotheses), where  $A$  is a hypothesis purporting to explain a set of data  $B$

$$P(A/B) = P(B/A)P(A)/P(B),$$

where  $P(A)$  is the prior probability, that is, the initial degree of belief in  $A$ ;  $P(A/B)$  is the conditional probability of  $A$  given  $B$ , or posterior probability, that is, the degree of belief in  $A$  after taking into consideration  $B$ ;  $P(B)$  is the probability of  $B$ .  $P(B/A)$  is the likelihood of  $B$  given  $A$ , that is, the degree of belief that  $B$  is true given that  $A$  is true. The ratio  $P(B/A)/P(B)$  represents the degree of support that  $B$  provides for  $A$ .

Suppose that  $B$  is the sensory information encoded by a neuronal assembly at level  $l-1$ , and  $A$  is the hypothesis that the neuronal assembly at level  $l$  posits as an explanation of  $B$ . Bayes' theorem tells us that the probability that  $A$  is true, that is, the probability that level  $l$  represent a true pattern in the environment given the sensory data  $B$ , depends first on the prior probability of hypothesis  $A$ , that is the probability of  $A$  before the predictions of  $A$  are tested. This prior probability depends on both the incoming signal to  $l$  but, also and most crucially because many different causes could have caused the incoming signal, on the contextual effects because these are the factors that determine which is the most

likely explanation of the data among the various possible alternative accounts.

The probability of  $A$  also depends on the  $P(B/A)$ , that is, the probability that  $B$  be true given  $A$ . This reflects a significant epistemological insight, namely, that since a correct account of a set of data explains away, these data are a *natural consequence* of the explaining hypothesis, or naturally fit into the conceptual framework created by the hypothesis. The various gravity phenomena, for instance, become very plausible in view of the law of gravity; they are not so much so if the hypothesis purporting to explain these same phenomena involves some accidents of nature, even if they are systematic. To put in a reverse way, if gravity exists, then the probability that unsupported objects will fall down is greater than the probability of these objects falling down if some other hypothesis is postulated to explain the fall of unsupported objects.

The probability of the hypothesis  $A$  depends inversely on the probability of the data  $B$ . Since probabilities take values from (0 to 1), the smaller the probability in the denominator, that is, the more surprising and thus improbable  $B$  is, the greater the probability that  $A$  be true given  $B$ . This part of the equation also reflects an important epistemological insight, namely that the more surprising a set of data is, the more likely is to be true a hypothesis that successfully explains them. Finally, the ratio  $P(B/A)/P(B)$  expresses the support  $B$  provides to  $A$  in the sense that the greater this ratio, the greater the probability that the hypothesis  $A$  is true.

## 26.D Appendix: Modal and Amodal Completion or Perception

There are two sorts of completion. In modal completion the viewer has a distinct visual impression of a hidden contour or other hidden features even though these features are not occurrent sensory features. The perceptual system fills in the missing features, which thus become as phenomenally occurrent as the occurrent sensory features of the object.

In amodal completion, one does not have a perceptual impression of the object's hidden features since the perceptual system does not fill in the missing features as it happens in modal perception, although as we shall see mental imagery can fill in the missing phenomenology; the hidden features are not perceptually occurrent.

There are cases of amodal perception that are purely perceptual, that is, bottom-up. In these cases, although no direct signals from the hidden features impinge on the retina (there is no local information available), the

perceptual system can extract information regarding them from the global information contained in the visual scene without any cognitive involvement, as the resistance of the ensuing percepts to beliefs indicates. However, in such cases, the hidden features are not perceived. One simply has the visual impression of a single concrete object that is partially occluded and not the visual impression of various disparate image regions. Therefore, in these perceptually driven amodal completions there is no mental imagery involved, since no top-down signals from cognitive areas are required for the completion, and since the hidden features are not phenomenologically present.

There are also cases of amodal completion that are cognitively driven, such as the formation of the 3-D sketch of an object, in which the hidden features of the object are represented through the top-down acti-

vation of the visual cortex from the cognitive centers of the brain. In some of these cases, top-down processes activate the early visual areas and fill in the missing features that become phenomenologically present. In

other cases of cognitively driven amodal completion, the viewer simply forms a pure thought concerning the hidden structure in the absence of any activation of the visual areas and thus in the absence of mental imagery.

## 26.E Appendix: Operational Constraints in Visual Processing

Studies by [26.3, 70–72] show that infants, almost from the very beginning, are constrained by a number of domain-specific principles about material objects and some of their properties. As *Karmiloff-Smith* [26.72] remarks, these constraints involve “attention biases toward particular inputs and a certain number of principled predispositions constraining the computation of those inputs”. Such predispositions are the conception of object persistence, and four basic principles (boundness, cohesion, rigidity, and no action at a distance).

The *cohesion principle*: “two surface points lie on the same object only if the points are linked by a path of connected surface points”. This entails that if some relative motion alters the adjacency relations among points at their borders, the surfaces lie on distinct objects, and that “all points on an object move on connected paths over space and time. When surface points appear at different places and times such that no connected path could unite their appearances, the surface points do not lie on the same object”.

According to the *boundness principle* “two surface points lie on distinct objects only if no path of connected surface points links them”. This principle determines the set of those points that define an object boundary and entails that two distinct objects cannot interpenetrate, because two distinct bodies cannot occupy the same place at the same time.

Finally the *rigidity* and *no action at a distance* principles specify that bodies move rigidly (unless the other mechanisms show that a seemingly unique body is, in fact, a set of two distinct bodies) and that they move independently of one another (unless the mechanisms show that two seemingly separate objects are in fact connected).

Further studies shed light on the nature of these principles or constraints and on the neuronal mechanisms that may realize them. There is evidence that the physiological mechanisms underlying vision reflect these constraints; their physical making is such that they implement these constraints, from cells for edge detection to mechanisms implementing the epipolar constraint [26.73, 74]. Thus, one might claim that these principles are hardwired in our perceptual system.

The formation of the *full primal sketch* in *Marr's* [26.12] theory relies upon the principles of *local proximity* (adjacent elements are combined) and of *similarity* (similarly oriented elements are combined). It also relies upon [26.20] the more general principle of *closure* (two edge-segments could be joined even though their contrasts differ because of illumination effects).

Other principles used by early visual processing to solve the problem of the underdetermination of perception by the retinal image are those of *continuity* (the shapes of natural objects tend to vary smoothly and usually do not have abrupt discontinuities), *proximity* (since matter is cohesive, adjacent regions usually belong together and remain so even when the object moves), and *similarity* (since the same kind of surface absorbs and reflects light in the same way the different subregions of an object are likely to look similar).

The formation of the  $2\frac{1}{2}$ D *sketch* is similarly underdetermined, in that there is a great deal of ambiguity in matching features between the two images form in the retinas of the two eyes, since there is usually more than one possible match. Stereopsis requires a unique matching, which means that the matching processing must be constrained. The formation of the  $2\frac{1}{2}$ D *sketch*, therefore, relies upon a different set of operational constraints that guide stereopsis. “A given point on a physical surface has a unique position in space at some time” [26.69] and matter is cohesive and surfaces are generally smooth. These operational constraints give rise to the general constraints of *compatibility* (a pair of image elements are matched together if they are physically similar, since they originate from the same point of the surface of an object), of *uniqueness* (an item from one image matches with only one item from the other image), and of *continuity* (disparities must vary smoothly). Another constraint posited by all models of stereopsis is the *epipolar* constraint (the viewing geometry is known). *Mayhew* and *Frisby's* [26.75] account of stereopsis posits some additional constraints, most notably, the principle of *figural continuity*, according to which figural relationships are used to eliminate most of alternative candidate matches between the two images.

# Diagrammatic Reasoning

William Bechtel

Diagrams figure prominently in human reasoning, especially in science. Cognitive science research has provided important insights into the inferences afforded by diagrams and revealed differences in the reasoning made possible by physically instantiated diagrams and merely imagined ones. In scientific practice, diagrams figure prominently both in the way scientists reason about data and in how they conceptualize explanatory mechanisms.

To identify patterns in data, scientists often graph it. While some graph formats, such as line graphs, are used widely, scientists often develop specialized formats designed to reveal specific types of patterns and not infrequently employ multiple formats to present the same data, a practice illustrated with graph formats developed in circadian biology. Cognitive scientists have revealed the spatial reasoning and iterative search processes scientists deploy in understanding graphs.

In developing explanations, scientists commonly diagram mechanisms they take to be

responsible for a phenomenon, a practice again illustrated with diagrams of circadian mechanisms. Cognitive science research has revealed how reasoners mentally animate such diagrams to understand how a mechanism generates a phenomenon.

Human reasoning is often presented as a mental activity in which we apply inference rules to mentally represented sentences. In the nineteenth century, Boole presented the rules for natural deduction in logic as formalizing the rules of thought. Even as cognitive scientists moved beyond rules of logical inference as characterizing the operations of the mind, they tended to retain the idea that cognitive operations apply to representations that are encoded in the mind (e.g., in neural activity). But in fact humans often reason by constructing, manipulating, and responding to external representations, and this applies as well to deductive as to abductive and inductive reasoning. Moreover, these representations are not limited to those of language but include diagrams. While reliance on diagrams extends far beyond science, it is particularly important in science. Scientific papers and talks are replete with diagrams and these are often the primary focus as scien-

tists read papers and engage in further reasoning about them. *Zacks et al.* [27.1] determined that the number of graphs in scientific journals doubled between 1984 and 1994. One would expect that trend has continued. Although many journals now limit the number of figures that can appear in the published paper, they have increasing allowed authors to post supplemental material, which often includes many additional diagrams.

Scientists clearly use diagrams to communicate their results with others. But there is also evidence that they make extensive use of these diagrams in their own thinking – in developing an understanding of the phenomenon to be explained and in advancing an explanation of it. Diagrams also figure prominently in the processes through which scientists analyze data. Since far less attention has been paid, both in philosophy of science and in the cognitive sciences, to how diagrams figure in reasoning activities, my objec-

tive in this chapter is to characterize what is known about how people, including scientists, reason with diagrams.

An important feature of diagrams is that they are processed by the visual system, which in primates is a very highly developed system for extracting and relating information received by the eyes (approximately one-third of the cerebral cortex is employed in visual processing). I begin in Sect. 27.1 by focusing on the distinctive potential of diagrams to support reasoning by enabling people to employ visual processing to detect specific patterns and organize together relevant pieces of information and examine the question of whether images constructed in one's imagination work equally well. In this chapter, I employ the terms *diagram* in its inclusive sense in which it involves marks arranged in

a two or more dimensional layout where the marks are intended to stand for entities or activities or information extracted from them and the geometrical relations between the marks are intended to convey relations between the things represented. In Sects. 27.2 and 27.3, I will discuss separately two types of diagrams that I designate data graphs and mechanism diagrams. In each case I introduce the discussion with examples from one field of biological research, that on circadian rhythms – the endogenously generate oscillations with a period of approximately 24 h that are entrainable to the light-dark cycle of our planet and that regulate a wide range of physiological activities. I then draw upon cognitive science research relevant to understanding how people reason with each type of diagram and relate this to the diagrams used in the science.

## 27.1 Cognitive Affordances of Diagrams and Visual Images

Two different traditions have dominated cognitive science research on vision. One, associated with Marr [27.2], has emphasized how, from the activation of individual neurons in the retina, people can build up a representation of what is seen. The other, advanced by Gibson [27.3], drew attention to the rich information, often highly structured, available to the visual system. The latter is especially relevant to addressing diagrams, since they involve structured perceptual objects in the environment. A key theoretical claim Gibson advanced was that different objects of perception afford different activities for different organisms – the back of a chair affords landing for an insect but draping a garment for humans. One can extend the account of affordance to external representations, and so focus, as Zhang [27.4] does, on how different representations activate different cognitive operations [27.4, pp. 185–186]:

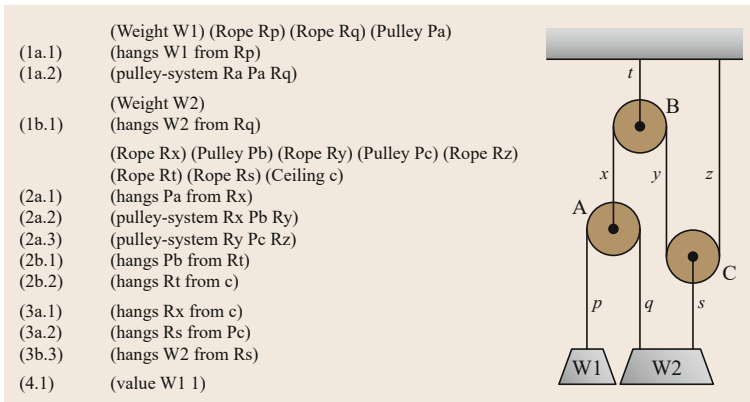

“Different representations activate different operations, not vice versa. It follows that operations are representation-specific. External representations activate perceptual operations, such as searching for objects that have a common shape and inspecting whether three objects lie on a straight line. In addition, external representations may have invariant information that can be directly perceived [...] such as whether several objects are spatially symmetrical to each other and whether one group has the same number of objects as another group. Internal representations activate cognitive operations, such as adding several numbers to get the sum.”

To investigate how diagrams afford different reasoning than other representations, Zhang compared a game formally equivalent to tic-tac-toe in which players pick

numbers from the pool 1 through 9 with the objective of being the first to pick three numbers totaling 15. Representing the numbers on a tic-tac-toe board (Fig. 27.1) shows that the two games are formally equivalent – all sequences of three numbers totaling 15 can be mapped onto a winning solution to tic-tac-toe and vice versa. Despite being formally equivalent, the tic-tac-toe board representation engages different cognitive operations than the number game represented as picking numbers from a pool. On the tic-tac-toe board, players can identify winning combinations by detecting lines but in the number variant they must perform arithmetic over many sets of numbers. In Zhang's experiments, humans played against a computer, which always made the first play and was programmed never to lose. If participants chose the best moves, however, they could always gain a tie. Participants required much longer to figure out a strategy to tie the computer when playing the number version than traditional tic-tac-toe, indicating that they deployed different operations in the two games. (See [27.5], for experiments showing similar results with variants of the Tower of Hanoi problem that placed

2	7	6

**Fig. 27.1** The game of picking three numbers that add to 15 is mapped onto a tic-tac-toe board, establishing their formal equivalence

**Fig. 27.2** Larkin and Simon's pulley problem presented in sentential form on the left and in a diagram on the right (after [27.6])

different demands on internal processes.) Zhang further claims that by limiting winning strategies to lines, traditional tic-tac-toe reduces the cognitive demands, freeing up cognitive resources for other activities.

In a provocative pioneering study addressing the question *why a diagram is (sometimes) worth 10 000 words?* Larkin and Simon [27.6] also focused on how diagrammatic representations support different cognitive operations than sentential representations. Like Zhang, they focused on representations that were equivalent in the information they provided but turned out not to be computationally equivalent in the sense that inferences that could be “drawn easily and quickly from the information given explicitly in the one” could not be drawn easily and quickly from the other. (Kulvicki [27.7] speaks in terms of information being extractable where there is a feature of a representation that is responsible for it representing a given content and nothing more specific than that. This helpfully focuses on the issue of how the representation is structured, but does not draw out the equally important point that extracting information depends on the cognitive processes that the cognizer employs.)

One of the problems Larkin and Simon investigate is the pulley problem shown in Fig. 27.2, where the task is to find the ratio of weights at which the system is in equilibrium. They developed a set of rules to solve the problem. The advantage of the pulley diagram on their analysis is that it locates information needed to apply particular rules at nearby locations in the diagram so that by directing attention to a location a person can secure the needed information. In the sentential representation the information needed for applying rules was dispersed so that the reasoner would need to conduct multiple searches. In a second example, involving a geometry proof, Larkin and Simon show how a diagram reduces both the search and recognition demands, where recognition utilizes the resources of the visual system to retrieve information. The authors also of-

fer three examples of diagrams used in economics and physics, graphs and vector diagrams, that employ not actual space but dimensions mapped to space and argue that they too provide the benefits in search and recognition.

Together, these two studies make clear that diagrams differ from other representations in terms of the cognitive operations they elicit in problem-solving situations. Most generally, diagrams as visual structures elicit pattern detection capacities whereas sentential representations require linguistic processing. Larkin and Simon note that a common response to a complex sentential description is to draw a diagram. An interesting question is whether comparable results can be obtained by mentally imagining diagrams. Pioneering studies by Shepard [27.8, 9] and Kosslyn et al. [27.10] demonstrated that people can rotate or move their attention across a mentally encoded image. But quite surprisingly Chambers and Reisberg [27.11] found that this capacity is severely limited. They presented Jastrow's duck-rabbit (Fig. 27.3) to participants sufficiently briefly that they could only form one interpretation of the figure. They then asked the participants if they could find another interpretation while imaging the figure. None were able to do so even when offered guidance. Yet, when they were allowed to draw a figure based on their mental image, all participants readily discovered the alternative interpretation.

These findings inspired numerous other investigations into the human ability to work with mental images whose results present a complex pattern. Reed and Johnsen [27.12] reached a similar conclusion as Chambers and Reisberg when they asked participants to employ imagery to determine whether a figure was contained in a figure they had previously studied. Yet when Finke et al. [27.13] asked participants to construct in imagery complex images from components, they performed well. Studies by Finke and Slayton [27.14] showed that many participants were able to generate

**Fig. 27.3** (a) The version of the duck-rabbit figure used as a stimulus in Chambers and Reisberg's experiments is shown on the left. The other two versions were drawn by participants based on their own image interpreted as a rabbit (b) and as a duck (c). From these they were readily able to discover the other interpretation, something they could not do from their mental image alone. With permission from the American Psychological Association, (after [27.11])

creative images from simple shapes in imagery (the drawings the participants produced were independently assessed for creativity). *Anderson and Helstrup* [27.15, 16] set out to explore whether drawing enhanced performance on such tasks and their conclusions were largely negative – participants produced more images, but the probability of generating ones judged creative was not increased: “These results were contrary to the initial belief, shared by most experimenters and subjects alike, that the use of pencil and paper to construct patterns should facilitate performance.”

*Verstijnen et al.* [27.17] explored whether the failure of drawing to improve performance might be due

to insufficient training in drawing. Using a task similar to that of Reed and Johnson, they compared those without formal training in drawing with design students who had 2 years of courses in drawing, and found those with training in drawing performed much better. In another study in which participants were required to create new objects from simple components, *Verstijnen et al.* [27.18] found that drawing significantly helped trained drawers create compound objects that involved restructuring the components (e.g., changing proportions within the component). One conclusion suggested by these results is that reasoning with diagrams may be a learned activity. Humans spend a great deal of time learning to read and write, and even then further education is often required to extract information from text and construct and evaluate linguistic arguments. Yet, perhaps because vision seems so natural, we assume that diagrams are automatically interpretable and except in curricula in fields like design, we provide no systematic education in constructing and reasoning with diagrams. Accordingly, it perhaps should not be a surprise that science educators have found that students often ignore the diagrams in their textbooks [27.19]. One of the challenges in teaching students how to reasoning with diagrams is identifying what cognitive operations people must perform with different types of diagrams. Cognitive scientists have begun to identify some of these operations, and I will discuss some of these in the context of data graphs and mechanism diagrams in the next two sections.

## 27.2 Reasoning with Data Graphs

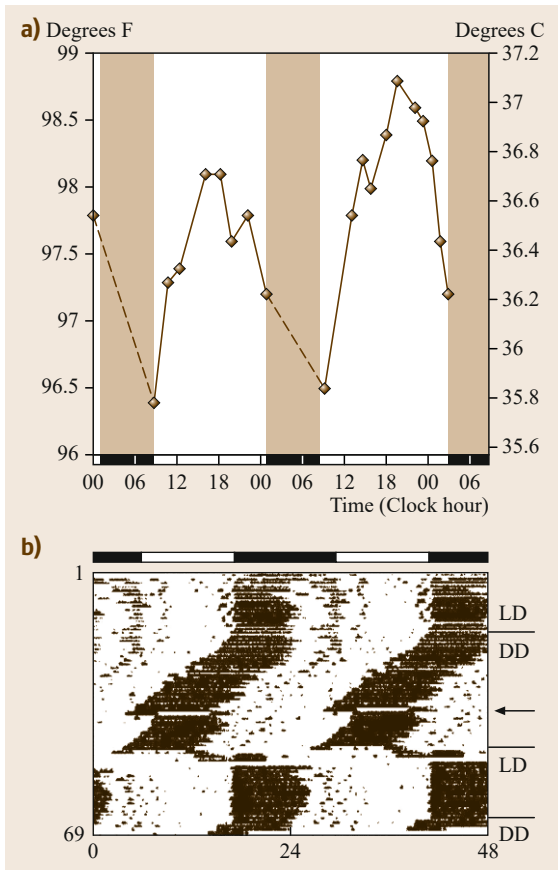

### 27.2.1 Data Graphs in Circadian Biology

By far the majority of the diagrams that figure in scientific papers are devoted to graphing data. Surprisingly, given the recognition of the roles data play both in discovering possible explanations and in evaluating them, there is little discussion in philosophy of graphing practices and how they figure in discovery and justification. Rather, the focus has been on data claims that can be represented sentimentally. Although there are common graphic formats that are highly familiar – for example, line graphs and bar graphs – in fact a wide variety of graphic formats are frequently used in science. In particular fields scientists have created their own formats, but these formats often migrate between fields. Each format elicits specific visual processing operations to identify informative patterns. In addition to different graphic formats, there are different tasks in which scientists present data. I focus on two tasks – delineating

phenomena and presenting relations between variables that are taken to be explanatory of the phenomenon.

In presenting phenomena as the target of scientific explanations, *Bogen and Woodward* [27.20] distinguish phenomena from data. They argue that phenomena, unlike data, are repeatable regularities in the world. Data provide evidence for the occurrence of phenomena. In many cases, researchers delineate phenomena by identifying patterns in data they collect. In the case of circadian rhythms, these are patterns of activity that repeat every 24 h and are often detectable by visual inspection of diagrams.

One of the most basic diagramming techniques employs a Cartesian coordinate system on which one plots values of relevant variables on the two axes. Using the abscissa to represent time and the ordinate for the value of a variable such as temperature, circadian researchers can plot each data point and then connect them by lines or a smoothed curve (Fig. 27.4a). Our visual sys-

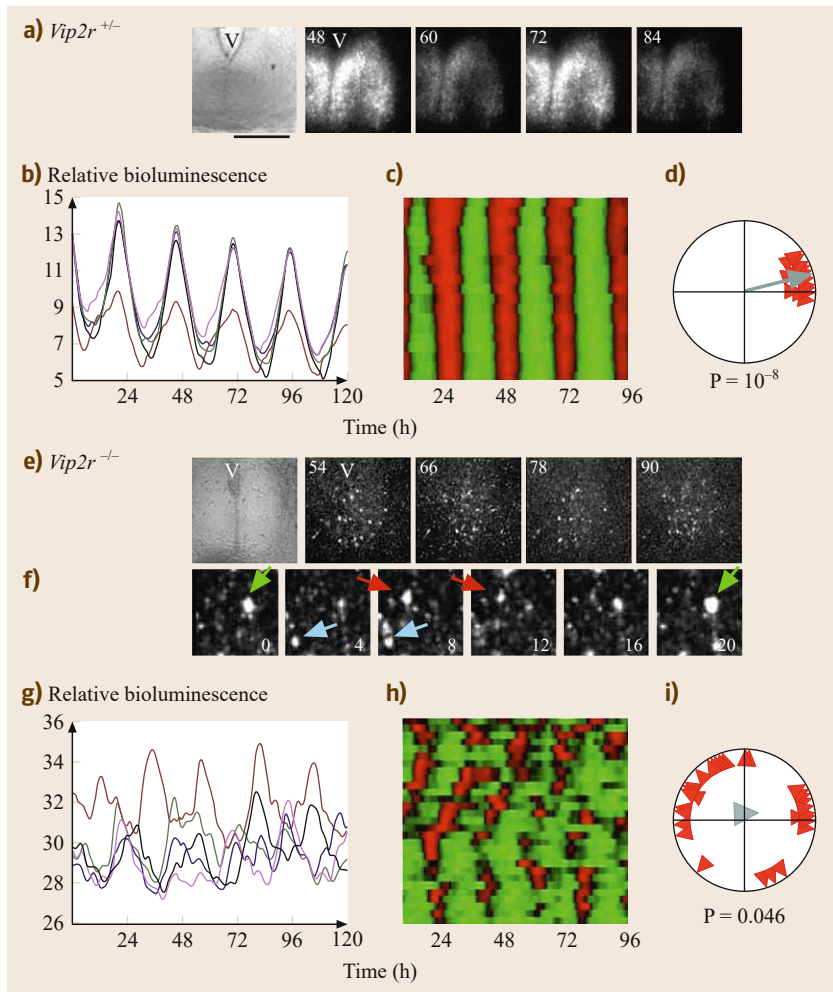

**Fig. 27.4** (a) Line graph from [27.21] showing the circadian oscillation in body temperature for one person across 48 h. (b) Example actogram showing times of running wheel activity of a wild-type mouse, reprinted with permission from Elsevier (after [27.22])

tem readily identifies the oscillatory pattern, which we can then coordinate with the bar at the bottom indicating periods of light and dark and the gray regions that redundantly indicate periods of darkness. By visually investigating the graph, one can detect that body temperature rises during the day and drops during the night, varying by about  $2^{\circ}\text{F}$  over the course of a day.

A line graph makes clear that the value of a variable is oscillating and with what amplitude, but it does not make obvious small changes in the period of activity. For this reason, circadian researchers developed actograms – a version of a raster plot on which time of each day is represented along a horizontal line and each occurrence of an activity (rotation of a running wheel by a mouse) is registered as a hash mark. Subsequent days are shown on successive lines placed below the previous one. Some actograms, such as the one shown in Fig. 27.4b, double plot the data so that each successive

24 h period is both plotted to the right of the previous 24-hour period and then again on the left on the next line. Placing adjacent times next to each other even when they wrap around a day break makes it easier to track continuous activity patterns. An actogram renders visually apparent how the phase of activity changes under different conditions such as exposure to light. In this actogram, the mouse was first exposed to a 12 : 12 light-dark cycle, as indicated by the letters LD on the right side, with the periods of light and dark indicated by the light-dark bar at the top. From day 15 to day 47, as indicated by the letters DD on the right side, the mouse was subjected to continuous darkness. On day 37, the row indicated by the arrow, the animal received a 6 h pulse of light at hour 16. It was returned to LD conditions on day 48, but returned to DD on day 67. The activity records shown on the actogram exhibit a clear pattern. During both LD periods the activity of the mouse was entrained to the pattern of light and dark so that the mouse was primarily active during the early night, with a late bout of activity late in the night (mice are nocturnal animals). On the other hand, during the DD periods the mouse began its activity somewhat earlier each day, a phenomenon known as *free running*. The light pulse reset the onset time for activity on the following day, after which the mouse continued to free run but from this new starting point. When switched back to LD the mouse exhibited a major alternation in activity the next day, but it took a couple more days to fully re-entrain to the LD pattern.

Data graphs are used not just to characterize phenomena but also to identify factors that may play a role in explaining phenomena. Figures in biological papers often contain many panels, invoking different representational formats, as part of the attempt to make visible relationship between variables that are taken to be potentially explanatory. For example, Fig. 27.5, from [27.23], employs photographs, line graphs, heat maps, and radial (Rayleigh) plots. To situate their research, in the 1970s the suprachiasmatic nucleus (SCN), a small structure in the hypothalamus, was implicated through a variety of techniques as the locus of circadian rhythms in mammals. Welsh et al. [27.24] had demonstrated that while individual SCN neurons maintain rhythmicity when dispersed in culture, they oscillate with varying periods and quickly become desynchronized. Maywood et al.'s research targeted vasoactive intestinal polypeptide (VIP), which is released by some SCN neurons, as the agent that maintains synchrony in the whole SCN or in slices from the SCN. Accordingly, they compared SCN slices from mice in which one (identified as  $\text{VIP2r}^{+/-}$ ) or both copies ( $\text{VIP2r}^{-/-}$ ) of the gene that codes for the VIP receptor are deleted. To render the rhythmicity of individual

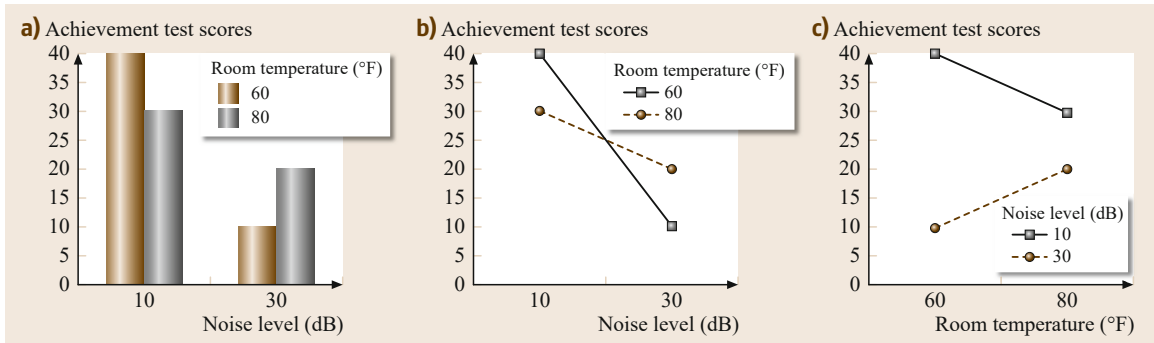

**Fig. 27.5** By using multiple graphical formats ((a,e,f) photographs of slices from the SCN, (b,g) line graphs, (c,h) raster plots (heat maps) and (d,i) radial (Rayleigh) plots) Maywood et al. make apparent in panels (a–d) that, when a receptor for VIP is present, oscillations of individual neurons are synchronized but that this is lost without VIP, panels (e–i) (after [27.23]), with permission from Elsevier

cells visible, the researchers inserted a gene coding for luciferase under control of the promoter for a known clock gene, *Per1*, so as to produce luminescence whenever PER is synthesized. The photographs in panels A are selections among the raw data. They make clear that VIP luminescence in the slice is synchronized, occurring at hour 48 and 72. Panel E reveals the lack of synchrony without the VPN receptor and panel F demonstrates that individual neurons are still oscillating without VIP but that the three neurons indicated by green, blue, and red arrows exhibit luminescence at different phases.

Although the photographs are sufficient to show that VIP is potentially explanatory of synchronous activity in the SCN, the researchers desired to characterize the relationship in more detail. They began by quantifying the bioluminescence recorded at the locus of the cell in photographs at different times. In panels B and G they displayed the results for five individual cells in each of

each type in line graphs. This makes it clear that while there is variation in amplitude, with VIP the five cells are in phase with each other while without VIP they are not. Even with five cells, though, it becomes difficult to decipher the pattern in a line graph. The raster plots in panels C and H enable comparison of 25 cells, one on each line, with red indicating periods when bioluminescence exceeds a threshold and green periods when it is below the threshold (such displays using hot and cold colors are often called *heat maps*). The raster plot enables one to compare the periodicity of individual cells more clearly, but with a loss of information about the amplitude of the oscillation at different times. The Rayleigh plots shown in panels D and I sacrifice even more information, focusing only on peak activity, but show that the peak phases are highly clustered with VIP and widely distributed without. The blue arrow shows the aggregate phase vector and indicates not only that it is oriented differently without VIP but also is

**Fig. 27.6a–c** A bar graph (a) and two line graphs (b,c), each showing the same data, but which viewers typically interpret differently (after [27.29])

extremely short, indicative of little correlation between individual neurons.

### 27.2.2 Cognitive Science Research Relevant to Reasoning with Graphs

Having introduced examples of graphs used in one field of biology, I turn now to cognitive science research that has attempted to identify aspects of the cognitive operations that figure in reasoning with graphs. *Pinker* [27.25] provided the foundation for much subsequent research on how people comprehend graphs. He differentiated the cognitive activities of creating a visual description of a graph and applying an appropriate graph schema to it. He treats the construction of a visual description as initially a bottom-up activity driven by the visual stimulus to which gestalt principles such as proximity and good continuation, among other procedures, are invoked. As explored by *Zacks* and *Tversky* [27.26], these principles differentially affect perception of bar graphs and line graphs [27.26, p. 1073]:

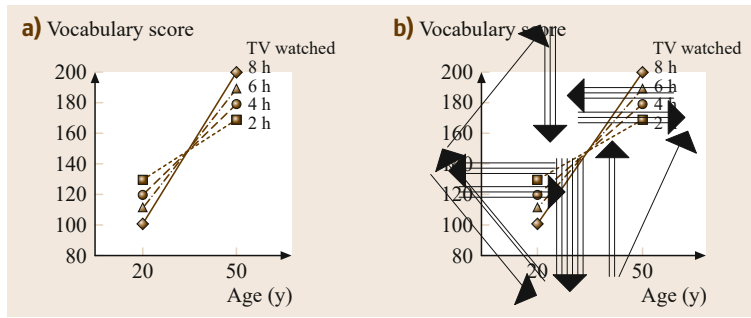

“Bars are like containers or fences, which enclose one set of entities and separate them from others. Lines are like paths or outstretched hands, which connect separate entities.”

The result, which has been documented in many studies, is that people are faster and more accurate at reading individual data points from bar graphs than line graphs but detect trends more easily in line graphs [27.27, 28]. For example, the bar graph in Fig. 27.6a makes it easy to read off test scores at different noise levels and room temperatures, and to compare test scores at the two temperatures. The line graph in Fig. 27.6b encodes the same data but the lines connecting the values at the two noise levels make that comparison more apparent. Moreover, the line graph

suggests that there are intermediate values between the two explicitly plotted. The effect is sufficiently strong that *Zacks* and *Tversky* found that when line graphs are used with categorical variables, viewers often treat them as interval variables and make assertions such as “The more male a person is, the taller he/she is” [27.26, p. 1076].

The choice of what to present on the axes also affects the information people extract. *Shah* and *Carpenter* [27.30] found that participants produce very different interpretations of the two graphs on the right of Fig. 27.6, one representing noise and the other room temperature on the abscissa. Thus, viewers of the graph in the center are more likely to notice the trend with increasing noise levels whereas those viewing the graph on the right notice the trend with increasing temperature. Further, when lines in graphs have reverse slopes, as in the rightmost graph, participants take longer to process the graph. Moreover, this difference makes the third variable, noise level, more salient since it identifies the difference responsible for the contrasting slopes.

The research reported so far focused on visual features of graphs, but one of the seminal findings about the organization of the mammalian visual processing system is that it is differentiated into two processing streams, one extracting information about the shape and identity of objects and one extracting information about location and potential for action [27.31, 32]. *Hegarty* and *Kozhevnikov* [27.33] proposed that the distinction between different processing pathways could help explain apparently contradictory results other researchers had reached about whether skill in visual imagery facilitates solving mathematics problems. They separately evaluated sixth-grade boys in Dublin, Ireland, in terms of pictorial imagery (“constructing vivid and detailed images”) and schematic imagery (“representing the spatial relationships between objects and imagining spatial transformations”). They found that good pictorial imagery was actually associated with poorer performance

**Fig. 27.7a,b** Graph (a) and superimposed eye-tracking results (b) (after [27.36]), with permission from the American Psychological Association

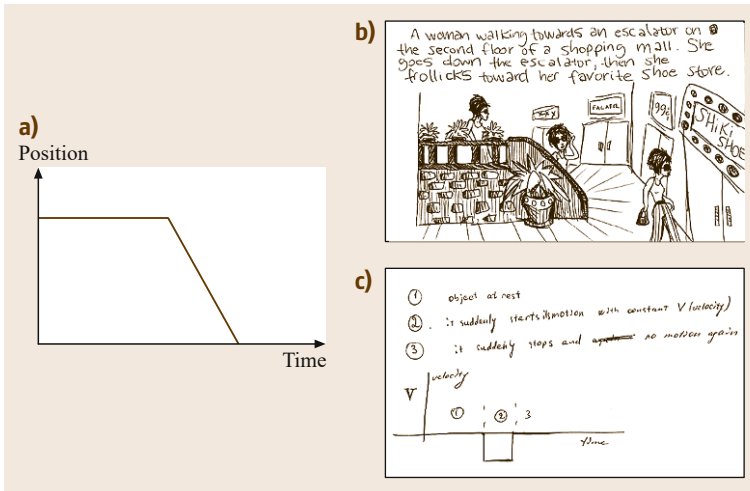

in solving mathematical problems. The following was a typical problem: *At each of the two ends of a straight path, a man planted a tree and then every 5 meters along the path he planted another tree. The length of the path is 15 meters. How many trees were planted?*

In contrast, good spatial imagery was associated with better performance. In subsequent work, Hegarty and her collaborators focused on kinetic problems involving graphs of motion and demonstrated a similar effect of pictorial versus spatial visualization. *Kozhevnikov et al.* [27.34] presented graphs such as that on the left in Fig. 27.7 to participants who, on a variety of psychometric tests, scored high or low on spatial ability. Those who scored low interpreted this graph pictorially as, for example, a car moving on a level surface, then going down a hill, and then moving again along a level surface. None of these participants could provide the correct interpretation of the graph as showing an object initially at rest, then moving at a constant velocity, and finally again at rest. On the other hand, all participants who scored high on spatial ability provided the correct interpretation. Subsequently, *Kozhevnikov et al.* [27.35] examined the differences between professionals in the arts and the sciences with respect to these graphs. They found that, except for participants who provided an irrelevant interpretation by focusing on nonpictorial features of the graph, artists tended to provide a literal pictorial interpretation of the path of movement whereas all scientists offered a correct schematic interpretation (example responses are shown on the right of Fig. 27.8).

So far I have focused on viewing a graph and extracting information from it. But an important feature of graphs in science such as those I presented in the earlier section is that they afford multiple engagements in which a user visually scans different parts of the graph seeking answers to different questions, some posed by information just encountered. *Carpenter and Shah* [27.36] drew attention to this by observing that graph comprehension is an extended activity often requiring half a minute, two orders of magnitude longer

than the time required to recognize simple patterns, including words and objects. In addition to detecting a pattern of data points along, for example, a positively sloping line, the graph interpreter must relate these points to the labels on the axes and what these represent and this is what requires processing time. Using eye tracking which participants study graphs, *Carpenter and Shah* revealed that viewers initially carve the graph into visual chunks and then cycle through focusing on different components – the pattern of the lines, the labels on the axes, the legend, and the title of the graph (Fig. 27.7). Similarly drawing attention to the prolonged engagement individuals often have with graphs, *Trickett and Trafton* [27.37] employed verbal protocols as well as eye tracking to study what people do when making inferences that go beyond what is explicitly represented in a given graph. They found that participants often employ spatial manipulations such as mentally transforming an object or extending it; they are not just passively viewing it.

Cognitive scientists have limited their focus to relatively simple graph forms such as line graphs and have not investigated the larger range of format we saw deployed in circadian research. Many of the results, however, are applicable to these other graph formats. Gestalt principles such as good continuation affect the patterns people see in actograms and raster plots (heat maps). In the actogram in Fig. 27.4, one recognizes the phase locking of activity to the light-dark cycle and daily phase advance when light cues are removed by implicitly (and sometimes explicitly) drawing a line through the starting point for each day's activity. Spatial processing is clearly important not only with the photographs in Fig. 27.5 but also with the heat map and Rayleigh plot. A skilled user of these graphs must recognize that space in the photographs corresponds to space on the slice from the brain but that space in the heat map corresponds not to physical space but an abstract space in which different cells are aligned. Finally, these diagrams are not designed to convey information in one look but rather are objects that afford shifting one's attention many times to focus on different in-

**Fig. 27.8** (a) A line graph showing an object initially at rest, then moving for a period at a constant velocity, then returning to rest that Kozhevnikov et al. [27.35] used to compare interpretations by artists and scientists. (b) A typical response from an artist, (c) response from a scientist

formation. With the Rayleigh plot, for example, one typically attends separately to the dispersal of blue arrowheads reflecting peaks of individual cells and to the vector indicating the population average. If eye tracking were performed, the pattern would likely resemble that displayed in Fig. 27.7. With panels showing the same information in multiple formats, as in Fig. 27.5, viewers are also likely to shift their focus between panels to see, for example, how the times in the line graph correspond to those in the photograph or those in the heat map. One limitation of the cognitive science studies is that the tasks participants were asked to perform were usually quite limited (e.g., interpret the graph)

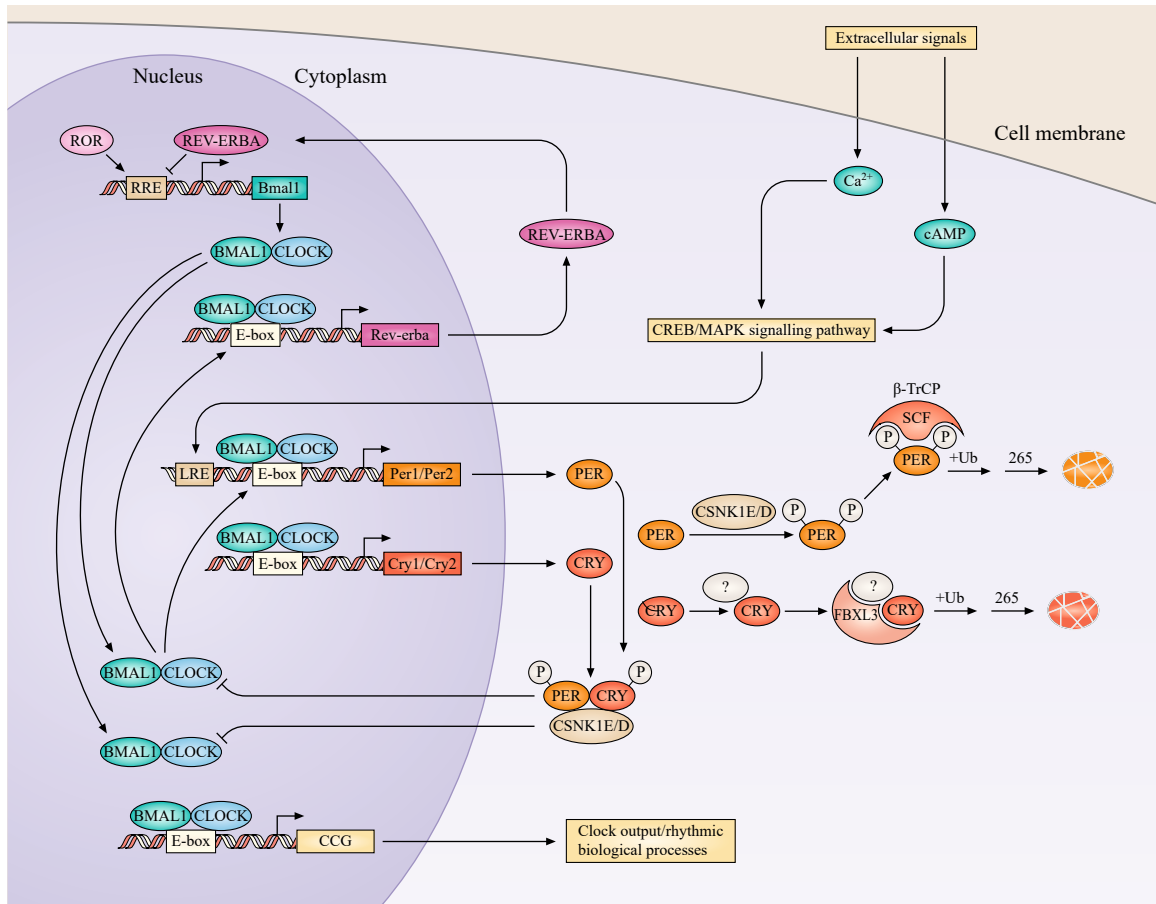

whereas scientists often use interact with graphs over multiple engagements, constructing new queries on the basis of previous ones (e.g., probing an actogram to see if the behavior really does look rhythmic or not or exploring the variability between cells revealed in a heat map). This is particularly evident when a researcher pours over a graph after producing it to determine what it means or when, in a journal club discussion, other researchers raise questions about specific features of a graph. Ultimately we need to better understand how scientists pose and address such queries over time if we are to understand the different roles graphs play in scientific reasoning.

## 27.3 Reasoning with Mechanism Diagrams

### 27.3.1 Mechanism Diagrams in Circadian Biology

Recognizing that individual activities, even if they do play a causal role in generating a phenomenon, typically do not work in isolation but only in the context of a mechanism in which they interact with other components, biologists often set as their goal to characterize the mechanism. (For discussion of the appeals to mechanism to explain biological phenomena, see [27.39–41].) The researchers' conception of the mechanism is sometimes presented in a final figure in a journal article but mechanism diagrams are even more common in review papers. Figure 27.9 is a representative sample of a mechanism diagram for the intracellular oscillator in mammalian SCN neurons. The diagram uses glyphs—"simple figures like points, lines, blobs, and arrows, which derive their meaning from geometric or

gestalt properties in context" [27.42] to represent the parts and operations of the mechanism. Tversky emphasizes the abstractness of glyphs over more iconic representations, arguing that the abstractness promotes generalization. One can abstract even more by allowing only one type of glyph (e.g., a circle) for an entity and one for an operation (an arrow), generating the sort of representations found in graph theory and used to capture general consequences of the organization of mechanisms. See Bechtel [27.43]. The parts shown in Fig. 27.9 include DNA strands, indicated by two wavy lines, on which promoter regions are indicated by lightly shaded rectangles, genes by darkly colored rectangles, and protein products, by colored ovals. Lines with arrow heads represent operations such as expression of a gene or transport of proteins to locations where they figure in other reactions, including activating gene transcription. Lines with squared

**Fig. 27.9** Takahashi et al. mechanism diagram of the mammalian circadian clock involves genes and proteins within individual cells. Reprinted with permission from Macmillan Publishers Ltd (after [27.38])

ends indicate inhibitory activity. When phosphates attach to molecules (as preparation for nuclear transport or degradation), they are shown as white circles containing a P.

The diagram is clearly laid out spatially, but only some features of the diagram convey information about spatial structures in the cell. The differentiation of the nucleus and cytoplasm is intended to correspond to these regions in the cell and lines crossing the boundary between the two parts of the cell. Beyond that, however, the distribution of shapes and arrows conveys no spatial information but only functional differentiation. The most important operations shown in this diagram are the synthesis of REV-ERBA and its subsequent transport into the nucleus to inhibit transcription of BMAL1 (shown as a loop out from and back into the nucleus in the upper left) and the synthesis of PER and CRY, the formation of a dimer, and the transport of the dimer into the nucleus to inhibit the ability of BMAL1 and

CLOCK to activate transcription of BMAL1, PER, and CRY (shown as a loop out from and back into the nucleus in the center-left of the figure). (The other operations shown are those involved in signaling from outside the cell that regulates the overall process, in the degradation of PER and CRY, and in the expression of clock-controlled genes (CCGs) that constitute the output of the clock.

For someone acquainted with the types of parts shown and the operations in which they engage, a diagram such as this provides a means of showing schematically how the various parts perform operations that affect other parts. One is not intended to take in the whole diagram at once, but to follow the operations from one part to another. To understand how the mechanism gives rise to oscillatory activity, one can mentally simulate the operations of the mechanism by starting in the middle with the *Per* and *Cry* genes. As they are expressed, more PER and CRY proteins are generated. After the proteins form a dimer and are

transported into the nucleus, they inhibit the activity of the BMAL1:CLOCK dimer and thereby stop their own expression. This reduction in expression results in reduction in their concentration and reduced inhibitory activity, which allow expression to resume. This capacity for mental animation is, however, limited, and to determine what the activity will be, especially when the other components are included, researchers often turn to computational models, generating what *Abrahamsen and I* [27.44] refer to as *dynamic mechanistic explanations*. Even here, though, diagrams provide a reference point in the construction of equations describing operation of the various parts [27.45].

Looking carefully at the lower right side of the figure, one will see two ovals with question marks in them. This indicates that the researchers suspected that something unknown binds with CRY before and potentially mediates its binding with FBXL3, which then results in its degradation. Here it is the identity of an entity that is in doubt, but sometimes question marks are employed to indicate uncertainty about the identity of an operation. In this case the diagram is from a review paper and the question mark reflects uncertainty in the discipline. On occasions when question marks appear in mechanism diagrams presented at the beginning of a researcher paper they signal that the goal of the paper is to answer a question regarding the identity of a component or its operation.

### 27.3.2 Cognitive Science Research Relevant to Reasoning with Mechanism Diagrams

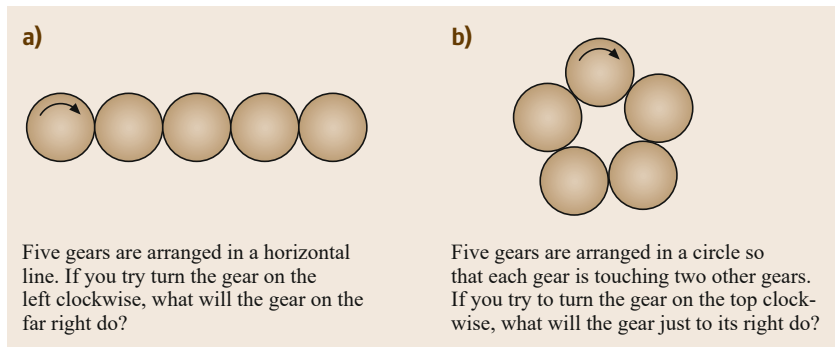

Although cognitive scientists have not explicitly focused on mechanism diagrams that figure in biology (but see *Stieff et al.* [27.46], which explores strategies used to transform diagrams of molecular structure used in organic chemistry), research on simple mechanical systems such as pulley systems (already the focus of *Larkin and Simon's* research discussed above) has highlighted one of the important cognitive activities people use with mechanism diagrams – mentally animating the operation of a mechanism when trying to figure out how it will behave. Drawing on theorists in the mental models tradition (see papers in [27.47] that explore how people answer problems by constructing and running a mental model), *Hegarty* [27.48] investigated experimentally “to what extent the mental processes involved in reasoning about a mechanical system are isomorphic to the physical processes in the operation of the system.” She measured reaction times and eye movements as participants answered questions about how various parts of a pulley system such as shown in Fig. 27.10 would behave if the rope is pulled. From the fact that

both error rates and reaction times increased with the number of operations within the mechanism the participant had to animate in order to answer the question, she inferred that people don't simulate the whole machine operating at once but rather animate individual parts in sequence. She provided further evidence for this claim by tracking the movements of the participants' eyes as they solved problems. In a follow-up experiment, *Hegarty* compared performance when participants were asked to infer the motion of a component from that of another component earlier in the causal chain or from that of a component later in the chain. Participants made more errors and required more time when they had to reason backward from events later in the chain, and still showed a preference to move their eyes forward along the causal chain.

*Schwartz and Black* [27.49] provided further insights into how people simulate mechanisms by attending to the gestures people make. In one task, shown in Fig. 27.11a, participants were asked to determine in which direction the rightmost gear would turn given the clockwise turn of the leftmost gear. They found that their participants would use their hands to indicate the direction of movement of each successive gear. (In these studies the participants never saw the diagrams but were provided with verbal descriptions of the configuration.) In this case, an alternative strategy is available: apply a simple global rule such as the parity rule: *if there are odd number of gears, the first and last will turn in the same direction* or the more local rule *if two gears are touching, they will turn in opposite directions*. *Schwartz and Black* found that as people acquired the rule, their gestures declined. But when people lack such rules or find their application uncertain, as in the gear problem in Fig. 27.11b, they again gesture. This use of gesture indicates that whatever imagery people

**Fig. 27.10** Pulley problem (after [27.48]) used to study how people employ mental animation in problem solving. With permission from the American Psychological Association

**Fig. 27.11a,b** Gear problem used by Schwartz and Black [27.49] to study when participants gesture while solving problems

employ to solve the task, it is coordinated with action. Accordingly, the researchers propose a theory of simulated doing in which [27.50]:

“the representation of physical causality is fundamental. This is because *doing* requires taking advantage of causal forces and constraints to manipulate the world. Our assumption is that people need to have representations of how their embodied ideas will cause physical changes if they are to achieve their goals.”

Animating a diagram, either mentally or with gesture, plays a crucial role in the cognitive activity of understanding how a proposed mechanism could produce the phenomenon one is trying to explain. But diagrams present not only a finished explanation of the phenomenon, they often figure in the process of discovering mechanisms. Here what matters is the ability to create and alter the glyphs and their arrangement. *Tversky* [27.42] suggests a helpful way to understand this activity – view diagrams as the “permanent traces of gestures” in which “fleeting positions become places and fleeting actions become marks and forms” [27.42, p. 500]. There is a rich literature showing how ges-

ture figures not only in communication but also in the development of one’s own understanding [27.51]. *Tversky* focuses on the activity of drawing maps, highlighting such features of the activity as selecting what features to include and idealizing angles to right angles. These findings can be extended to mechanism diagrams, which constitute a map of the functional space of the mechanism, situating its parts and operations. While *Tversky* speaks of diagrams as permanent traces and there is a kind of permanence (or at least endurance) to diagrams produced on paper or in computer files, they are also subject to revision – one can add glyphs for additional parts or alter arrows to represent different ideas of how the operations of one part affect others. In the design literature this is often referred to as *sketching*. Sketching mechanism diagrams can be motivated by evidence, but they can also be pursued in a purely exploratory manner, enabling reasoning about what would happen if a new connection were made or an existing one redirected. Sketching possible mechanisms is a common activity of scientists, and by further investigating the cognitive activities involved in this activity one can develop richer analyses of this important type of scientific reasoning.

## 27.4 Conclusions and Future Tasks

This chapter has addressed the use of diagrams by scientists in characterizing phenomena to be explained, identifying variables that figure in explaining those phenomena, and advancing proposals for mechanisms, drawing examples from circadian rhythm research. Over the last 30 years cognitive scientists have attempted to characterize cognitive activities people employ when perceiving and using diagrams in problem-solving tasks, such as making multiple scans of graphs and animating mechanical diagrams. For the most part, cognitive scientists have employed diagrams and tasks

in their studies that are simpler than those that figure in actual scientific research. But these cognitive science studies nonetheless provide insights into the cognitive processes that figure in scientists’ use of diagrams. To date the roles diagrams play in science have not figured in a major way in philosophical accounts of scientific reasoning but given the important roles diagrams play in science, there is great potential to advance our understanding of scientific reasoning by investigating further the cognitive processes involved as scientists create and use diagrams in the course of their research.

## 28. Embodied Mental Imagery in Cognitive Robots

Alessandro Di Nuovo, Davide Marocco, Santo Di Nuovo, Angelo Cangelosi

This chapter is focused on discussing the concept of *mental imagery* as a fundamental cognitive capability to enhance the performance of cognitive robots. Indeed, the emphasis will be on the embodied imagery mechanisms applied to build artificial cognitive models of *motor imagery* and *mental simulation* to control complex behaviors of humanoid platforms, which represent the artificial body.

With the aim of providing a panorama of the research activity on the topic, first we give an introduction on the neuroscientific and psychological background of mental imagery in order to help the reader to contextualize the multidisciplinary environment in which we operate. Then, we review the work done in the field of artificial cognitive systems and robotics to mimic the process behind the human ability of creating *mental images* of events and experiences, and to use this process as a cognitive mechanism to improve the behavior of complex robots. Finally, we report the detail of three recent empirical studies in which mental imagery approaches were modelled through artificial neural networks (ANNs) to enable a cognitive robot with some human-like capabilities.

The work presented in this chapter takes inspiration from the human capability to build representations of the physical world in its mind. In particular, we studied the *motor imagery*, which is considered a multimodal simulation that activates the same, or very similar, sensory and motor modalities that are activated when human beings interact with the environment in real time. This is strictly related to the embodied cognition hypothesis, which affirms that all aspects of human cognition are shaped by aspects of the body.

Similarly, when artificial intelligence was moving his first steps, *Alan Turing* argued that in order to think and speak a machine may need a human-like body and that the development of robot cognitive skills might be just as simple as teaching a child [28.1]. This is the mo-

These empirical studies exemplify how the proprioceptive information can be used by *mental imagery* models to enhance the performance of the robot, giving evidence of the embodied cognition theories in the context of artificial cognitive systems.

tivation behind a strongly humanoid design of some of the recent and most advanced robotic platforms, for example, iCub [28.2], NAO [28.3], and Advanced Step in Innovative MObility (ASIMO) [28.4]. These platforms are equipped with sophisticated motors and sensors, which replicate animal or human sensorimotor input–output streams. The sensors and actuators arrangement determine a highly redundant morphological structure of humanoid robots, which are traditionally difficult to control and, thus, require complex models implementing more sophisticated and efficient mechanisms that resemble the human cognition [28.5].

In this multidisciplinary context, improving the skill of a robot in terms of motor control and navigation capabilities, especially in the case of a complex robot

with many degrees of freedom, is a timely and important issue in current robotics research. Among the many bio-inspired mechanisms and models already tested in the field of robot control and navigation, the use of mental imagery principles is of interest in modeling mental

imagery as a complex, goal directed and flexible motor planning strategy and to go further in the development of artificial cognitive systems capable to better interact with the environment and refine their cognitive motor skill in an open-ended process.

## 28.1 Mental Imagery Research Background

Mental imagery, as the process behind the human ability of creating mental images of events and experiences, has long been the subject of research and debate in philosophy, psychology, cognitive science, and more recently, neuroscience [28.6]. Some of the main effects of mental practice on physical performance have been well established in experiments with humans as in the fields of sports science, work psychology, and motor rehabilitation. Neuropsychological research has long highlighted the complexity of brain activation in the activity of imagination. Studies have demonstrated the localization partly similar and partly different between imagery, perception, and visual memory [28.7, 8], while, in [28.9], it was demonstrated by a clinical case as visuospatial perception and imagery can be functionally separated in activating brain. In [28.10], authors proposed a revision of the constructs relevant to cognitive styles, placing them into a complex framework of heuristics regarding multiple levels of information processing, from the attentional and perceptual to metacognitive ones. These heuristics are grouped according to the type of regulatory function that they take from the automatic coding of data to the conscious use of cognitive resources. In this view, also at the cerebral area activation level, the distinction between elaboration of object properties (like shape or color) and spatial relations is better representative of a different *style* in the use of mental images than the ancient dichotomy verbal-visual [28.11].

But only quite recently a growing amount of evidence from empirical studies begun to demonstrate the relationship between bodily experiences and mental processes that actively involve body representations. This is also due to the fact that in the past, philosophical and scientific investigations of the topic primarily focused upon visual mental imagery. Contemporary imagery research has now broadly extended its scope to include every experience that resembles the experience of perceiving from any sensorial modality. From this perspective, understanding the role of the body in cognitive processes is extremely important and psychological and neuroscience studies are extremely important in this regard. *Wilson* [28.12] identified six claims in the current view of embodied cognition:

1. Cognition is situated
2. Cognition is time-pressured
3. We off-load cognitive work onto the environment
4. The environment is part of the cognitive system
5. Cognition is for action
6. Offline cognition is bodily based.

Among those six claims, the last claim is particularly important. According to this claim, sensorimotor functions that evolved for action and perception are used during offline cognition that occurs when the perceiver represents social objects, situations, or events in times and places other than the ordinary ones. This principle is reinforced by the concept of embodied cognition [28.13, 14], which affirms that the nature of intelligence is largely determined by the form of the body. Indeed, the body and every physical experience made through the body, shape the form of intelligence that can be observed in any autonomous systems. This means that even if the mind does not directly interact with the environment, it is able to apply mechanisms of sensory processing and motor control by using some innate abilities such as memory (implicit, short, and long term), problem solving, and mental imagery. These capabilities have been well studied in psychology and neuroscience, but the debate is still open on the issue of mental imagery, where mental imagery is defined as a sensation activated without sensorial stimulation.

Many evidences from empirical sciences have demonstrated the relationship between bodily experiences and mental processes that involve body representation. Neuropsychological research has demonstrated that the same brain areas are activated during seeing or recalling by images [28.15] and that areas controlling perception are needed also for maintaining mental images active in working memory. Therefore, mental imagery may be considered as a kind of biological simulation. In [28.16], author observed that the primary motor cortex M1 is activated during the production of motor images as well as during the production of active movement. Similarly, experimental studies show that neural mechanisms underlying real-time visual perception and mental visualization are the same when a task is mentally recalled [28.17]. Nevertheless, the neural

mechanisms involved in the active elaboration of mental images might be different from those involved in passive elaborations [28.18]. These studies demonstrate the tight relationship between mental imagery and motor activities (i. e., how the image in mind can influence movements and motor skills).

Recent research, both in experimental as well as practical contexts, suggests that imagined and executed movement planning relies on internal models for action [28.19]. These representations are frequently associated with the notion of internal (forward) models and are hypothesized to be an integral part of action planning [28.20, 21]. Furthermore, in [28.22], authors suggest that motor imagery may be a necessary prerequisite for motor planning. In [28.23], *Jeannerod* studied the role of motor imagery in action planning and proposed the so-called equivalence hypothesis – suggesting that motor simulation and motor control processes are functionally equivalent [28.24, 25]. These studies, together with many others (e.g., [28.26]), demonstrate how the images that we have in mind might influence movement execution and the acquisition and refinement of motor skills. For this reason, understanding the relationship that exists between mental imagery and motor activities has become a relevant topic in domains in which improving motor skills is crucial for obtaining better performance, such as in sport and rehabilitation. Therefore, it is also possible to exploit mental imagery for improving a human’s motor performance and this is achieved thanks to special mental training techniques.

Mental training is widely used among professional athletes, and many researchers began to study its beneficial effects for the rehabilitation of patients, in particular after cerebral lesions. In [28.24], for example, the authors analyzed motor imagery during mental training procedures in patients and athletes. Their findings support the notion that mental training procedures can be applied as a therapeutic tool in rehabilitation and in applications for empowering standard training methodologies. Others studies have shown that motor skills can be improved through mental imagery techniques. *Jeannerod* and *Decety* [28.18] discuss how training based on mental simulation can influence motor performance in terms of muscular strength and reduction of variability. In [28.27], authors show that imaginary fifth finger abductions led to an increased level of muscular strength. The authors note that the observed increment in muscle strength is not due to a gain in muscle mass. Rather,

it is based on higher level changes in cortical maps, presumably resulting in a more efficient recruitment of motor units. These findings are in line with other studies, specifically focused on motor imagery, which shows the enhancement of mobility range [28.28] or increased accuracy [28.29] after mental training. Interestingly, it should be noted that such effects operate both ways: mental imagery can influence motor performance and the extent of physical practice can change the areas activated by mental imagery [28.30]. As a result of these studies, new opportunities for the use of mental training have opened up in collateral fields, such as medical and orthopaedic–traumatologic rehabilitation. For instance, mental practice has been used to rehabilitate motor deficits in a variety of neurological disorders [28.31]. Mental training can be successfully applied in helping a person to regain lost movement patterns after joint operations or joint replacements and in neurological rehabilitation. Mental practice has also been used in combination with actual practice to rehabilitate motor deficits in a patient with subacute stroke [28.32], and several studies have also shown improvement in strength, function, and use of both upper and lower extremities in chronic stroke patients [28.33, 34].

In sport, beneficial effects of mental training for the performance enhancement of athletes are well established and several works are focused on this topic with tests, analysis, and in new training principles [28.35–38]. In [28.39], for example, a cognitive-behavioral training program was implemented to improve the free-throw performance of college basketball players, finding improvements of over 50%. Furthermore, the trial in [28.40], where mental imagery is used to enhance the training phase of hockey athletes to score a goal, showed that imaginary practice allowed athletes to achieve better performance. Despite the fact that there is ample evidence that mental imagery, and in particular motor imagery, contributes to enhancing motor performance, the topic still attracts new research, such as [28.41] that investigated the effect of mental practice to improve game plans or strategies of play in open skills in a trial with 10 female pickers. Results of the trial support the assumption that motor imagery may lead to improved motor performance in open skills when compared to the no-practice condition. Another recent paper [28.42] demonstrated that sports experts showed more focused activation patterns in prefrontal areas while performing imagery tasks than novices.

## 28.2 Models and Approaches Based on Mental Imagery in Cognitive Systems and Robotics

The introduction of humanoid robots had a great impact on the fast growing field of cognitive robotics, which represents the intersection of artificial cognitive modeling and robotic engineering. Cognitive robotics aims to provide new understanding on how human beings develop their higher cognitive functions. Thanks to the many potential applications, researchers in cognitive robotics are still facing several challenges in developing complex behaviors [28.43].

As exemplified in the following literature review, a key role is played by mental imagery and its mechanisms in order to enhance motor control in autonomous robots, and to develop autonomous systems that are capable of exploiting the characteristics of mental imagery training to better interact with the environment and refine their motor skills in an open-ended process [28.44]. Indeed, among the many hypotheses and models already tested in the field of cognitive systems and robotics, the use of mental imagery as a cognitive tool capable of enhancing robot behaviors is both innovative and well-grounded in experimental data at different levels.

A model-based learning approach for mobile robot navigation was presented in [28.45], where it is discussed how a behavior-based robot can construct a *symbolic process* that accounts for its deliberative thinking processes using internal models of the environment. The approach is based on a forward modeling scheme using recurrent neural learning, and results show that the robot is capable of learning grammatical structure hidden in the geometry of the workspace from the local sensory inputs through its navigational experiences.

An example of the essential role mental imagery can play in human–robot interaction was recognized by Roy et al. [28.46]. She presented a robot, called Ripley, which is able to translate spoken language into actions for object manipulation guided by visual and haptic perception. The robot maintained a dynamic *mental model*, a three-dimensional model of its immediate physical environment that it used to mediate perception, manipulation planning, and language. The contents of the robot’s mental model could be updated based on linguistic, visual, or haptic input. The mental model endowed Ripley with object permanence, remembering the position of objects when they were out of its sensory field.

Experiments on internal simulation of perception using ANN robot controllers are presented by Ziemke et al. [28.47]. The paper focuses on a series of experiments in which feedforward neural networks (FFNNs)

were evolved to control collision-free corridor following behavior in a simulated Khepera robot and predict the sensory input of next time step as accurately as possible. The trained robot is actually able to move blindly in a simple environment for hundreds of time steps, successfully handling several multistep turns.

In [28.48], authors present a neurorobotics experiment in which developmental learning processes of the goal-directed actions of a robot were examined. The robot controller was implemented with a multiple timescales recurrent neural network (RNN) model, which is characterized by the coexistence of slow and fast dynamics in generating anticipatory behaviors. Through the iterative tutoring of the robot for multiple goal-directed actions, interesting developmental processes emerged. Behavior primitives in the earlier fast context network part were self-organizing, while they appeared to be sequenced in the later, slow context part. Also observed was that motor images were generated in the early stage of development.

The study presented in [28.49] show how simulated robots evolved for the ability to display a context-dependent periodic behavior can spontaneously develop an internal model and rely on it to fulfil their task when sensory stimulation is temporarily unavailable. Results suggest that internal models might have arisen for behavioral reasons and successively exapted for other cognitive functions. Moreover, the obtained results suggest that self-generated internal states need not match in detail the corresponding sensory states and might rather encode more abstract and motor-oriented information.

Fascinatingly, in [28.50], authors explore the idea of dreams as a form of mental imagery and the possible role they might play in mental simulations and in the emergence and refinement of the ability to generate predictions on the possible outcomes of actions. In brief, what the authors propose is that robots might first need to possess some of the characteristics related to the ability to dream (particularly those found in infants and children) before they can acquire a robust ability to use mental imagery. This ability to dream, according to them, would assist robots in the generation of predictions of future sensory states and of situations in the world.

Internal simulations can help artificial agents to solve the stereo-matching problem, operating on the sensorimotor domain, with retinal images that mimic the cone distribution on the human retina [28.51]. This is accomplished by applying internal sensorimotor simulation and (subconscious) mental imagery to the

process of stereo matching. Such predictive matching is competitive to classical approaches from computer vision, and it has moreover the considerable advantage that it is fully adaptive and can cope with highly distorted images.

A computational model of mental simulation that includes biological aspects of brain circuits that appear to be involved in goal-directed navigation processes is presented in [28.52]. The model supports the view of the brain as a powerful anticipatory system, capable of generating and exploiting mental simulation for predicting and assessing future sensory motor events. The authors show how mental simulations can be used to evaluate future events in a navigation context, in order to support mechanisms of decision-making. The proposed mechanism is based on the assumption that choices about actions are made by simulating movements and their sensory effects using the same brain areas that are active during overt actions execution.

An interpretation of mental imagery based on the context of homeostatic adaptation is presented in [28.53], where the internal dynamics of a highly complex self-organized system is loosely coupled with a sensory-motor dynamic guided by the environment. This original view is supported by the analysis of a neural network model that controls a simulated agent facing sensor shifts. The agent is able to perceive a light in the environment through some light sensors placed around its body and its task is that of approaching the light. When the sensors are swapped, the agent perceives the light in the opposite direction of its real position and the control systems has to autonomously *detect* the shifting sensor and act accordingly. The authors speculate that mental imagery could be a viable way for creating self-organized internal dynamics that is loosely coupled with sensory motor dynamics. The loose coupling allows the creation of endogenous input stimulations, similar to real ones that could allow the internal system to sustain its internal dynamics and, eventually, reshape such dynamics while modifying endogenous input stimulations.

*Lalle* and *Dominey* [28.54] suggest the idea that mental imagery can be seen as a way for an autonomous system of generating internal representation and exploiting the convergence of different multimodal contingencies. That is, given a set of sensory-motor contingencies specific to many different modalities, learned by an autonomous agent in interaction with the environment, mental imagery constitutes the bridge toward even more complex multimodal convergence. The model proposed by the authors is based on the

hierarchical organization of the cortex and it is based on a set of interconnected artificial neural networks that control the humanoid robot iCub in tasks that involve coordination between vision, hand-arm control, and language. The chapter also highlights interesting relations between the model and neurophysiological and neuropsychological findings that the model can account for.

An extension of the neurocomputational model TRoPICAL (two route, prefrontal instruction, competition of affordances, language simulation) is proposed by [28.55] to implement an embodied cognition approach to mental rotation processes, a classic task in mental imagery research. The extended model develops new features that allow it to implement mental simulation, sensory prediction, as well as enhancing the model's capacity to encode somatosensorial information. The model, applied to a simulated humanoid robot (iCub) in a series of mental rotation tests, shows the ability to solve the mental rotation tasks in line with results coming from psychology research. The authors also claim the emergence of links between overt movements with mental rotations, suggesting that affordance and embodied processes play an important role in mental rotation capacities.

Starting from the fact that some evidence in experimental psychology has suggested that imagery ability is crucial for the correct understanding of social intention, an interesting study to investigate intention-from-movement understanding is presented in [28.56]. Authors' aim is to show the importance of including the more cognitive aspects of social context for further development of the optimal theories of motor control, with positive effects on robot companions that afford true interaction with human users. In the paper, the authors present a simple but thoroughly executed experiment, first to confirm that the nature of the motor intention leads to early modulations of movement kinematics. Second, they tested whether humans use imagery to read an agent's intention when observing the very first element of a complex action sequence.

A neural network model to produce an anticipatory behavior by means of a multimodal off-line Hebbian association is proposed in [28.57]. The model emulates a process of mental imagery, in which visual and tactile stimuli are associated during a long-term predictive simulation chain motivated by covert actions. Such model was studied by means of two experiments with a physical Pioneer 3-DX robot that developed a mechanism to produce visually conditioned obstacle avoidance behavior.

## 28.3 Experiments

In this section, we present three experimental studies that exemplify the capabilities and the performance improvements achievable by an *imagery*-enabled robot. Results of experimental tests with the simulator of the iCub humanoid robot platform are presented as evidence of the opportunities given by the use of artificial *mental imagery* in cognitive artificial systems.

The first study, [28.58], details a model of a controller, based on a dual network architecture, which allows the humanoid robot iCub to improve autonomously its sensorimotor skills. This is achieved by endowing the controller of a secondary neural system that by exploiting the sensorimotor skills already acquired by the robot, is able to generate additional *imaginary* examples that can be used by the controller itself to improve the performance through a simulated *mental training*.

The second study, [28.59], builds on the previous study showing that the robot could *imagine* or *mentally* recall and accurately execute movements learned in previous training phases, strictly on the basis of the verbal commands. Further tests show that data obtained with *imagination* could be used to simulate *mental training* processes, such as those that have been employed with human subjects in sports training, in order to enhance precision in the performance of new tasks through the association of different verbal commands.

The third study, [28.60], explored how the relationship between spatial mental imagery practice in a training phase could increase accuracy in sports related performance. The focus is on the capability to estimate, after a period of training with proprioceptive and visual stimuli, the position into a soccer field when the robot acquires the goal.

### 28.3.1 The Humanoid Robotic Platform: The iCub

The cognitive robotic platform used for the experiments presented here is the simulation of the iCub humanoid robot controlled by artificial neural networks. The iCub

(Fig. 28.1) is an open-source humanoid robot platform designed to facilitate cognitive developmental robotics research as detailed in [28.2]. At the current state the iCub platform is a child-like humanoid robot 1.05 m tall, with 53 degrees of freedom (DoF) distributed in the head, arms, hands, and legs. The implementation used for the experiments presented here is a simulation of the iCub humanoid robot (Fig. 28.1). The simulator, which was developed with the aim to accurately reproduce the physics and the dynamics of the physical iCub [28.61], allows the creation of realistic physical scenarios in which the robot can interact with a virtual environment. Physical constraints and interactions that occur between the environment and the robot are simulated using a software library that provides an accurate simulation of rigid body dynamics and collisions.

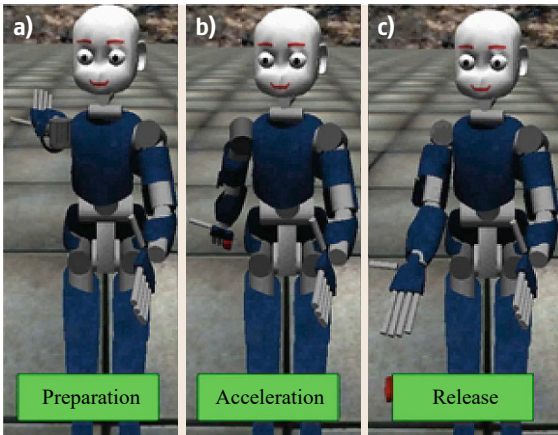

### 28.3.2 First Experimental Study: Motor Imagery for Performance Improvement

The first experimental study explored the application of mental simulation to robot controllers, with the aim to mimic the mental training techniques to improve the motor performance of the robot. To this end, a model of a controller based on neural networks was designed to allow the iCub to autonomously improve its sensorimotor skills.

The experimental task is to throw a small cube of side size 2 cm and weight 40 g as far as possible according to an externally given velocity for the movement. The task phases are shown in Fig. 28.2 and it is the realization of a ballistic action, involving the simultaneous movement of the right arm and of the torso, with the aim to throw a small object as far as possible according to an externally given velocity for the movement. Ballistic movements can be defined as rapid movements initiated by muscular contraction and continued by momentum [28.62]. These movements are typical in sport actions, such as throwing and jumping (e.g., a soccer kick, a tennis serve, or a boxing punch). In this experiment, we focus on two main features that characterize a ballistic movement: (1) it is executed by the brain with a predefined order, which is fully programmed before the actual movement realization and (2) it is executed as a whole and will not be subject to interference or modification until its completion. This definition of ballistic movement implies that proprioceptive feedback is not needed to control the movement and that its development is only based on starting conditions [28.63]. It should be noted here that since ballistic movements are

**Fig. 28.1a,b** The iCub humanoid robot platform: (a) The realistic simulator; (b) The real platform

**Fig. 28.2a–c** Three phases of the movement: **(a) Preparation:** The object is grabbed and shoulder and wrist joints are positioned at  $90^\circ$ ; **(b) Acceleration:** The shoulder joint accelerates until a given angular velocity is reached, while the wrist rotates down; **(c) Release:** the object is released and thrown away

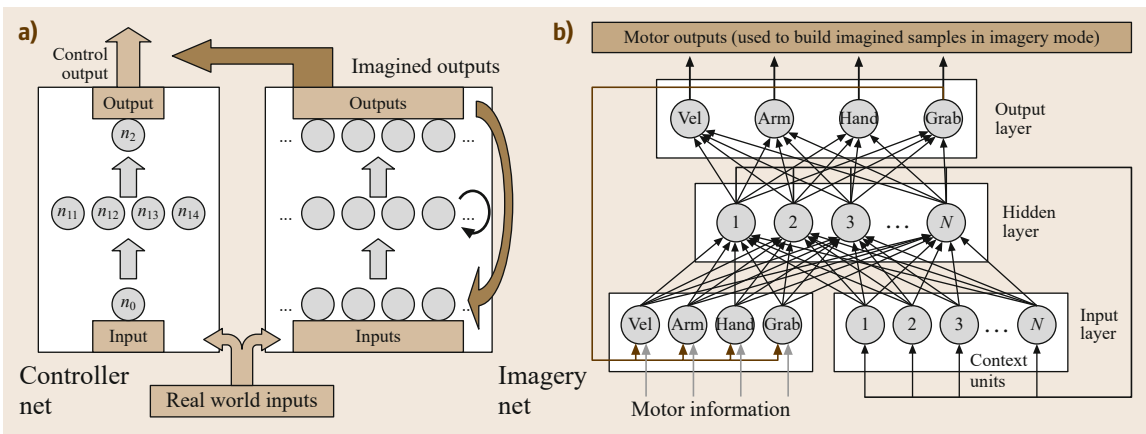

by definition not affected by external interferences, the training can be performed without considering the surrounding environment, as well as vision and auditory information.

To build the input–output training and testing sets, all values were normalized in the range  $[0, 1]$ .

To control the robot, we designed a dual neural network architecture, which can operate to improve autonomously the robot motor skills with techniques inspired by the ones that are employed with human subjects in sports training. This is achieved through two interconnected neural networks to control the robot: a FFNN that directly controls the robot’s joints and

an RNN that is able to generate additional *imaginary* training data by exploiting the sensorimotor skills acquired by the robot. The new data, in turn, can be used to generate additional *imaginary* examples that can be used by the controller itself to improve the performance through an additional learning process. We show that data obtained with artificial *imagination* could be used to simulate *mental training* to learn new tasks and enhance their performance.

The artificial neural network architecture that models the *mental training process* is detailed in Fig. 28.3a. It is a three-layer dual recurrent neural network (DRNN) with two recurrent sets of connections, one from the hidden layer and one from the output layer, which feed directly to the hidden layer through a set of context units added to the input layer. At each iteration (epoch), the context units hold a copy of the previous values of the hidden and outputs units. This creates an internal memory of the network, which allows it to exhibit dynamic temporal behavior [28.64]. It should be noted that in preliminary experiments, this architecture proved to show better performances and improved stability with respect to classical architectures, for example, *Jordan* [28.65] or *Elman* [28.66]. The DRNN comprises 5 output neurons, 20 neurons in the hidden layer, and 31 neurons in the input layer (6 of them encode the proprioceptive inputs from the robot joints and 25 are the context units). Neuron activations are computed according to (28.1) and (28.2). The six proprioceptive inputs encode, respectively, the shoulder pitch angular velocity (constant during the movement), positions of shoulder pitch and hand wrist pitch (at time  $t$ ), elapsed time, expected duration time (at time  $t$ ), and the grab/release command (0 if the object is grabbed, 1 otherwise). The five outputs encode the pre-

**Fig. 28.3a,b** Design of the cognitive architecture of the first experimental study: **(a)** The dual network architecture (FFNN + RNN). **(b)** Detail of RNN: *Brown connections* (recurrences and predicted output for the FFNN) are active only in *imagery mode*, meanwhile *light grey links* (external input–output from real world) are deactivated

dictions of shoulder and wrist positions at the next time step, the estimation of the elapsed time, the estimation of the movement duration, and the grab/release state. The DRNN retrieves information from joint encoders to predict the movement duration during the acceleration phase. The activation time step of the DRNN is 30 ms. The object is released when at time  $t_1$  the predicted time to release,  $t_p$ , is lower than the next step time  $t_2$ .

A functional representation of the neural system that controls the robot is given in Fig. 28.3a: a three-layer FFNN, which implements the actual motor controller, and of RNN. The RNN models the motor imagery and it is represented in detail in Fig. 28.3b. The choice of the FFNN architecture as a controller was made according to the nature of the problem, which does not need proprioceptive feedback during movement execution. Therefore, the FFNN sets the duration of the entire movement according to the given speed in input and the robot's arm is activated according to the duration indicated by the FFNN. On the other hand, the RNN was chosen because of its capability to predict and extract new information from previous experiences, so as to produce new imaginary training data, which are used to integrate the training set of the FFNN.

The FFNN comprises one neuron in the input layer, which is fed with the desired angular velocity of the shoulder by the experimenter, four neurons in the hidden layer, and one neuron in the output layer. The output unit encodes the duration of the movement given the velocity in input. To train the FFNN, we used a classic backpropagation algorithm as the learning process. The learning phase lasted  $1 \times 10^6$  epochs with a learning rate ( $\alpha$ ) of 0.2, without momentum (i. e.,  $\eta = 0$ ). The network parameters were initialized with randomly chosen values in the range  $[-0.1, 0.1]$ . The FFNN was trained by providing a desired angular velocity of the shoulder joint as input and the movement duration as output. After the movement duration is set by the FFNN, the arm is activated according to the desired velocity and for the duration indicated by the FFNN output.

Activations of hidden and output units  $y_i$  are calculated at a discrete time, by passing the net input  $u_i$  to the logistic function, as it is described in (28.1) and (28.2)

$$u_i = \sum_i (y_i w_{ij} - k_i) , \quad (28.1)$$

$$y_i = \frac{1}{1 - e^{-u_i}} . \quad (28.2)$$

As learning process, we used the classic backpropagation algorithm, the goal of which is to find optimal values of synaptic weights that minimize the error  $E$ , defined as the error between the teaching sequences and

the output sequences produced by the network. The error function  $E$  is calculated as follows

$$E = \frac{1}{2} \sum_{i=1}^p \|y_i - t_i\|^2 , \quad (28.3)$$

where  $p$  is the number of outputs,  $t_i$  is the desired activation value of the output unit  $i$ , and  $y_i$  is the actual activation of the same unit produced by the neural network, calculated using (28.2) and (28.3). During the training phase, synaptic weights at learning step  $n + 1$  are updated using the error calculated at the previous learning step  $n$ , which in turn depend on the error  $E$ . Activations of hidden and output units  $y_i$  are calculated by passing the net input  $u_i$  to the function, as it is described in (28.2) and (28.3). The backpropagation algorithm updates link weights and neuron biases, with a learning rate ( $\alpha$ ) of 0.2 and a momentum factor ( $\eta$ ) of 0.6, according to the following equation

$$\Delta w_{ij}(n + 1) = \eta \delta_j y_j + \alpha \Delta w_{ij}(n) , \quad (28.4)$$

where  $y_j$  is the activation of unit  $j$ ,  $\alpha$  is the learning rate, and  $\eta$  is the momentum.

To calculate the error at first step of the backpropagation algorithm, initial values of back links are initialized to one. The network parameters are initialized with randomly chosen values in the range  $[-0.1, 0.1]$ .

The experimental study is divided into two phases: in the first phase the FFNN is trained to predict the duration of the movement for a given angular velocity in input. Meanwhile, using the same movements the RNN was trained by a simple heuristic to predict its own subsequent sensorimotor state. To this end, joint angle information over time was sampled in order to build 20 input–output sequences corresponding to different directions of the movement. In addition, in order to model the autonomous throw of an object, the primitive action to grab/release was also considered in the motor information fed to the network. In the second phase, the RNN operates in *offline* mode and, thus, its prediction is made according only to the internal model built during the training phase. Normalized joint position of shoulder pitch, torso yaw, and hand wrist pitch are the proprioceptive information for input and output neurons. Another neuron implements the grab/release command, respectively, with values 1 and 0.

In this study, we intended to test the impact of mental training in action performance in a different speed range that was not experienced before. Because of this, we split both the learning and testing dataset into two subsets according to the duration of the movement:

- *Fast range* subset comprises examples that last less than 0.3 s
- *Slow range* subset comprises all the others (i. e., those that last more than 0.3 s).

A reference benchmark controller (RBC) was used to build training and testing datasets for the learning phase. The training dataset comprises data collected during the execution of the RBC with angular velocity of shoulder pitch ranging from  $-150$  to  $-850^\circ/\text{s}$  and using a step of  $-25^\circ/\text{s}$ . Thus, the learning dataset comprises 22 input–output series. Similarly, the testing dataset was built in the range from  $-160$  to  $-840^\circ/\text{s}$  and using a step of  $-40^\circ/\text{s}$ , and it comprises 18 input–output series. The learning and testing dataset for the FFNN comprises one pair of data: the angular velocity of the shoulder as input and the execution time, that is, duration, as desired output. The learning and testing datasets for the RNN comprises sequences of 25 elements collected using a time-step of 0.03 s. All data in both learning and testing datasets are normalized in the range  $[0, 1]$ . Results are shown for the testing set only.

To test the mental training, we compared results on three different case studies:

1. *Full range*: For benchmarking purposes, it is the performance obtained by the FFNN when it is trained using the full range of examples (*slow + fast*)
2. *Slow range only training*: The performance obtained by the FFNN only when it is trained using only the slow-range subset. This case stressed the generalization capability of the controller when it is tested with the fast range subset
3. *Slow range plus mental training*: In this case the two architectures operate together as a single hierarchical architecture, in which first both nets are trained

**Fig. 28.4** Comparison of the distance reached by the object after throwing with the FFNN as controller and different training approaches. Negative values represent the objects falling backward

with the slow range subset, then the RNN runs in *mental imagery mode* to build a new dataset of fast examples for the FFNN that is incrementally trained this way.

As expected, the FFNN is the best controller for the task if the full range is given as training, thus, it is the ideal controller for the task (Table 28.1). But, not surprisingly, in Table 28.2 it is shown that the FFNN it is not able to generalize with the fast range when it is trained with the slow range only.

These results show that generalization capability of the RNN helps to feed the FFNN with new data to cover the fast range, simulating *mental training*. In fact, the FFNN, trained only with the slow subset, is not able to foresee the trend of duration in the fast range; this implies that fast movements last longer than needed and, because the inclination angle is over  $90^\circ$ , the object falls backward (Fig. 28.4).

**Table 28.1** Full-range training: comparison of average results of feedforward and recurrent artificial neural nets

Test	Feedforward net				Recurrent net			
	Duration		Release point		Duration		Release point	
	<i>s</i>	Error%	Degree	Error%	<i>s</i>	Error%	Degree	Error%
Slow	0.472	1.75	-30.718	-6.46	0.482	3.60	-33.345	-11.96
Fast	0.202	0.87	-31.976	-6.34	0.194	5.67	-28.088	-22.18
Full	0.307	1.21	-31.486	-6.39	0.306	4.86	-30.132	-18.21

**Table 28.2** FFNN: Comparison of average performance improvement with artificial mental training

Test	Slow range only training				Slow range plus mental training			
	Duration		Release point		Duration		Release point	
	<i>s</i>	Error%	Degree	Error%	<i>s</i>	Error%	Degree	Error%
Slow	0.474	1.38	-30.603	-7.88	0.471	1.74	-30.774	-8.18
Fast	0.247	26.92	-64.950	-111.72	0.188	7.12	-20.901	-35.89
Full	0.335	16.99	-51.593	-71.34	0.298	5.03	-24.741	-25.11

The FFNN failure in predicting temporal dynamics is explainable by the simplistic information used to train the FFNN, which seems to be not enough to reliably predict the duration time in a faster range, never experienced before. On the contrary, the greater amount of information that comes from the proprioception and the fact that the RNN has to integrate over time those information in order to perform the movement, makes the RNN able to create a sort of internal model of the robot's body behavior. This allows the RNN to better generalize and, therefore guide the FFNN in enhancing its performance.

This interesting aspect of the RNN can be partially unveiled by analyzing the internal dynamic of the neural network, which can be done by reducing the complexity of the hidden neuron activations through a principal component analysis. Figure 28.5a, for example, presents the values of the first principal component at the last timestep, that is, after the neural network has finished the throwing movement, for all the test cases, both slow and fast showing that the internal representations are

very similar, also in the case in which the RNN is trained with the slow range only. Interestingly, the series shown in Fig. 28.8 are highly correlated with the duration time, which is never explicitly given to the neural network. The correlation is 97.50 for the full-range training, 99.41 for slow only and 99.37 for slow plus mental training. This result demonstrates that the RNN is able to extrapolate the duration time from the input sequences and to generalize when operating with new sequences never experienced before.

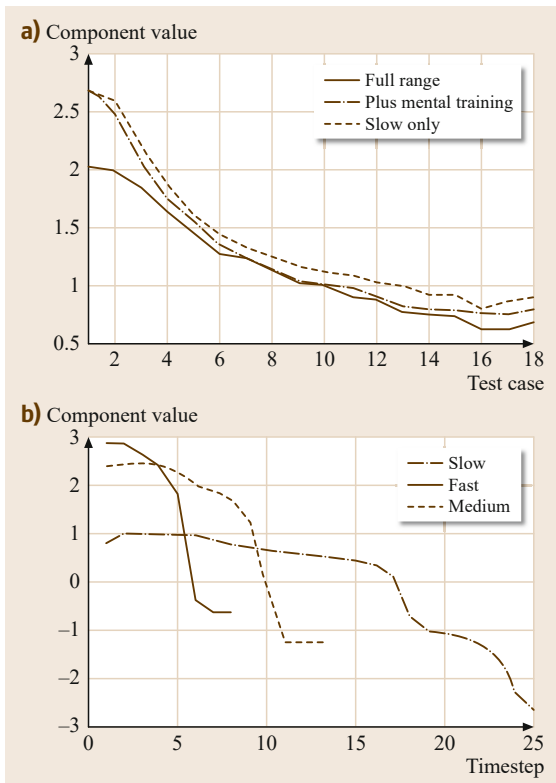

Similarly, Fig. 28.5b shows the first principal component of the RNN in relation to different angular velocities: slow being the slowest test velocity, medium the fastest within the slow range, and fast the fastest possible velocity tested in the experiment. As can be seen, the RNN is able to uncover the similarities in the temporal dynamics that link slow and fast cases. Hence, it is finally able to better approximate the correct trajectory of joint positions also in a situation not experienced before.

### 28.3.3 Second Experimental Study: Mental Training Evoked by Language

In this experimental study, we dealt with motor imagery and how verbal instruction may evoke the ability to imagine movements, already seen before or new ones obtained by combination of past experiences. These imagined movements either replicate the expected new movement required by verbal commands or correspond in accuracy to those learned and executed during training phases. Motor imagery is defined as a dynamic state during which representations of a given motor act are internally rehearsed in working memory without any overt motor output [28.67].

This study extends the first experimental study presented above, by focusing on the integration of auditory stimuli in the form of verbal instructions, to the motor stimuli already experienced by the robot in past simulations. Simple verbal instructions are added to the training phase of the robot, in order to explore the impact that linguistic stimuli could have in its processes of mental imagery practice and subsequent motor execution and performance. In particular, we tested the ability of our model to use imagery to execute new orders, obtained combining two single instructions. This study has been inspired by embodied language approaches, which are based on evidence that language comprehension is grounded in the same neural systems that are used to perceive, plan, and take action in the external world.

Figure 28.6 presents pictures of the action with the iCub simulator, which was commanded to execute the four throw tasks according to the verbal command is-

**Fig. 28.5** (a) Hidden units' activation analysis. Lines represent final values of the first principal component for all test cases; (b) hidden units' activation analysis. Lines represent the values of first principal component for a slow velocity, a medium velocity and a fast velocity

sued. The basic task is the same presented in Fig. 28.2; in this case the torso is also moving to obey to the verbal commands *left* and *right*.

The neural system that controls the robot is a three-layer RNN with the architecture proposed by *Elman* [28.66]. The Elman RNN adds in the input layer a set of *context units*, directly connected with the middle (hidden) layer with a weight of one (i. e., directly copied). At each time step, the input is propagated in a standard feedforward fashion, and then a learning rule is applied. The fixed back connections result in the context units always maintaining a copy of the previous values of the hidden units (since they propagate over the connections before the learning rule is applied). This creates an internal state of the network, which allows it to exhibit dynamic temporal behavior. To model mental imagery the outputs related with the motor activities are redirected to corresponding inputs.

Similarly to the previous experimental study, after the learning phase in which *real* data collected during simulator execution was used to train the RNN and for comparison with *imagined* data, we tested the ability of the RNN architecture to model *mental imagery*. As before, this was achieved by adding other back connections from motor outputs to motor inputs; at the same time connections from/to joint encoders and motor controllers are deactivated. This setup is presented in Fig. 28.7, where red connections are the ones active only when the *imagery mode* is on, while green connections are deactivated, including the motor controller. Specific neurons, one for each verbal instruction, were included in the input layer of the RNN in order for it to take into account these commands, while the sensorimotor information is directed to the rest of the neurons in the input layer. The RNN architecture implemented, as presented in Fig. 28.7, has 4 output units, 20 units in the hidden layer, and 27 units in the input layer, 7 of

Fig. 28.6 Examples of the iCub simulator in action: pictures of the execution of throw tasks

them encode the proprioceptive inputs from the robot's joints and 20 are the context units, that is, are back links of hidden units, they only copy the value from output of upper unit to the input of lower unit. The learning algorithm and parameters are the same as the second experiment.

As proprioceptive motor information, we take into account just the following three joints, shoulder pitch, torso yaw, and hand wrist pitch. In addition, in order to model the throw of an object, the primitive action to grab/release was also considered in the motor information fed to the network. Visual information was not computed and speech input processing was based on standard speech recognition systems.

Using the iCub simulator, we performed two experiments:

- The first experiment aimed to evaluate the ability of the RNN to model artificial mental imagery. It was divided into two phases: in the first phase the network was trained to predict its own subsequent sensorimotor state. The task was to throw in different directions (forward, left, right, back) a small object that was placed in the right hand of the robot,

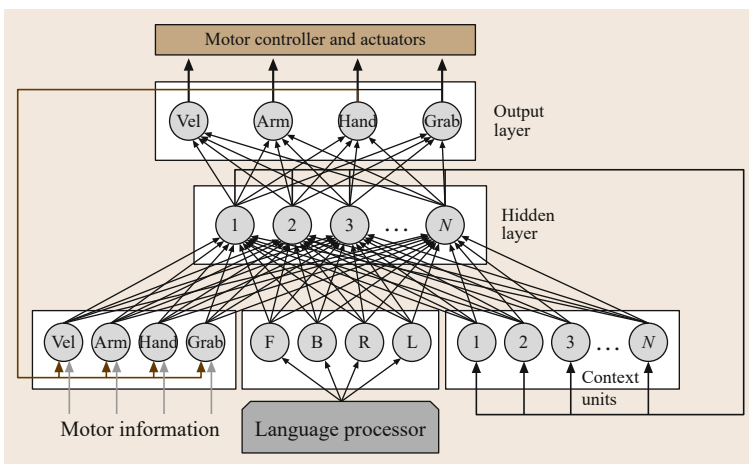

Fig. 28.7 Recurrent neural network architecture used in the second experimental study. *Brown* connections are active only in *imagery mode*, meanwhile *light grey* connections are deactivated

which is able to grab and release it. To this end the RNN was trained using the proprioceptive information collected from the robot. The proprioceptive information consisted of sensorimotor data (i. e., joint positions) and of verbal commands given to the robot according to directions. In the second phase, we tested the ability of the RNN to model mental imagery providing only the auditory stimulus (i. e., the verbal commands) and requiring the network to obtain sensorimotor information from its own outputs.

- The goal of the second experiment was to test the ability of the RNN to imagine how to accomplish a new task. In this case we had three phases: in the first phase (*real training*), the RNN was trained to throw front and just to move left and right (with no throw). In the second phase (*imagined action*), the RNN was asked to imagine its own subsequent sensorimotor state when the throw command is issued together with a side command (left or right). In the final phase (*mental training*), the input/output series obtained are used for an additional *mental training* of the RNN. After the first and third phase, experimental tests with the iCub simulator were made to measure the performance of the RNN to control the robot.

In this experiment, we tested the ability of the RNN to recreate its own subsequent sensorimotor state in absence of external stimuli. In Fig. 28.8, we present a comparison of training and imagined trajectories of learned movements according to the verbal command issued:

1. Shows results with the FRONT command
2. With the BACK command
3. With the RIGHT command
4. For the LEFT command.

Imagined trajectories are accurate with respect to the ones used to train the robot only in Fig. 28.8b, we notice a slight difference between imagined and training positions of the arm. This difference can be attributed to the fact that the BACK command is the only one that does not require the arm to stop early in throwing the object. In other words, the difference is related to the timing of the movement rather than to the accuracy. Results show that the RNN is able to recall the correct trajectories of the movement according to the verbal command issued. The trajectories are the sequence of joint positions adopted in the movements.

The second test was conducted to evaluate the ability of the RNN to build its own subsequent sensorimotor states when it is asked to accomplish new tasks not experienced before. In this case, the RNN was trained

only to throw front and to move right and left (without throwing). To allow the RNN to generalize, training examples were created using an algorithm that randomly chose joint positions not involved in the movement, that is, when throwing, the torso joint had a fixed position that was randomly chosen. The same was true for arm joints when moving right and left.

Test cases, presented in Fig. 28.9, were composed using two commands (e.g., *throw* together with *right* or *left*). In our experiments, we tested two different approaches in the language processing. In this test two commands were computed at the same time, so that input neurons associated with throw and right (or left) were fully activated at the same time with value 1.

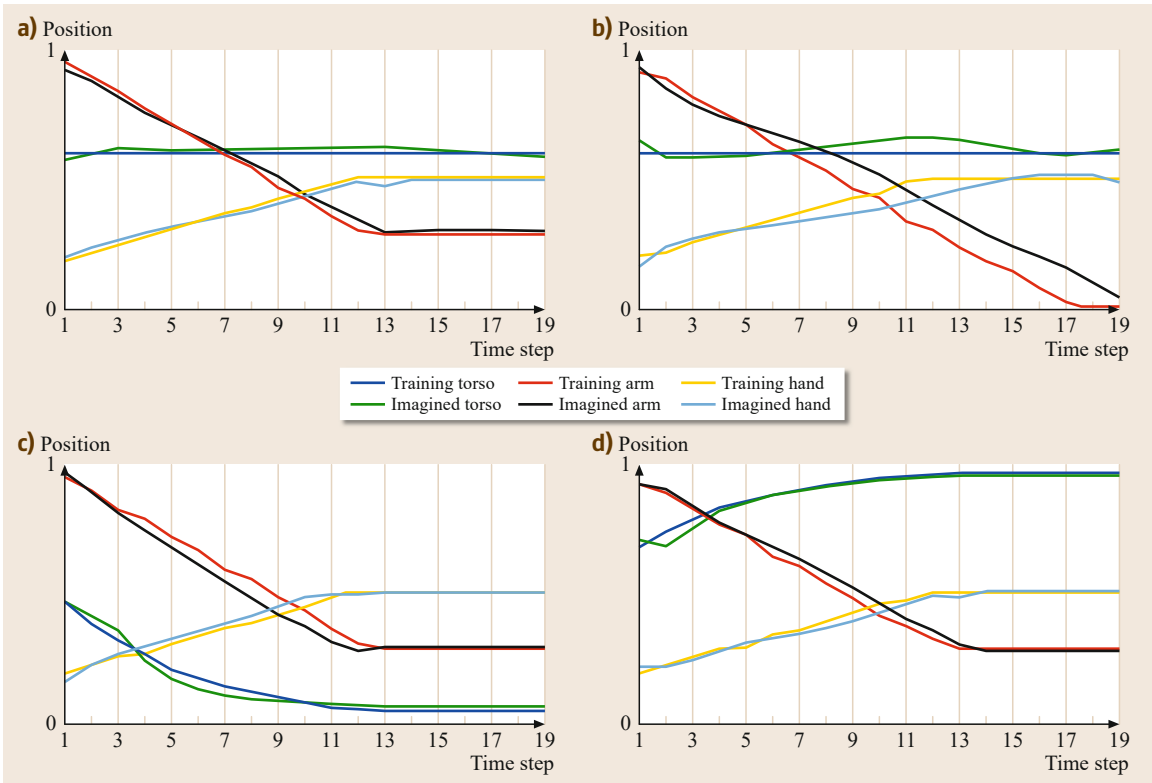

Results of the mental training experiment are presented in Fig. 28.10, which show the error of torso and arm joint position with respect to the ideal ones. The *before mental training* column presents the results of tests made without additional training, the *after mental training* column shows results after the simulated mental training, the *imagined action only* column refers to totally imagined data (i. e., when the RNN predicts its own subsequent input). Comparing results before and after mental training an improvement in precision of dual command execution could be noticed, this should be accounted to the additional training that helps the RNN to operate in a condition not experienced before.

It should be noticed also that the throw right task has worse performance compared to that of throw left with iCub simulations, but the same result is not achieved in imagined only action mode. This could be mainly explained by the influence of real proprioceptive information coming from robot joints that modifies the ideal behavior expected by the RNN, as evidenced by the comparison between imagined only and the real tests. In fact, we noticed that when a right command is issued the robot torso is initially moved on the left for few time-steps and then it turns right. Since the total time of the movement is due to the arm movement to throw, the initial error for the torso could not be recovered.

### 28.3.4 Third Experimental Study: Spatial Imagery

For this experiment the environment is a square portion of a soccer field, whose length and width are both 15 m. At one end is placed a goal 1.94 m wide, as can be seen in Fig. 28.11b, which is represented all in blue to contrast with the background and to be easily recognized. The robot can be positioned anywhere in this square and, as starting position, the ball is placed in front of his left foot (Fig. 28.11a).

The neural system that controls the robot is a fully connected RNN with 16 hidden units, 37 input units,

**Fig. 28.8** First test: A comparison of training and imagined trajectories of learned movements

**Fig. 28.9** Pictures present the execution of the two composed tasks: throw left and throw right. As test cases for autonomous learning with iCub simulator, the actions to throw left or right are now obtained by learning and then combining the basic actions of throw and move left or right

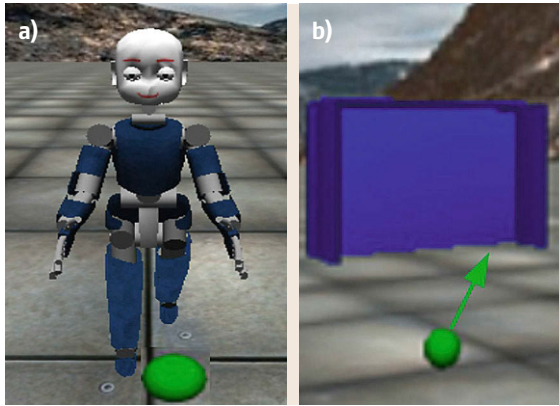

and 6 output units. The main difference between a standard feedforward neural network and the RNN is that in the latter case, the training set consists in a series of input–output sequences. The RNN architecture allows the robot to learn dynamical sequences of actions as they develop in time. The goal of the learning process is to find optimal values of synaptic weights that minimize the error, defined as the error between the teaching

**Fig. 28.10** Second test: Autonomous learning of new combined commands, error of torso and arm joint positions with respect to ideal ones

sequences and the output sequences produced by the network. Figure 28.12 presents the neural system. Input variables are as follows:

- The angle of, respectively, the neck (left–right movement), the torso (left–right movement), and

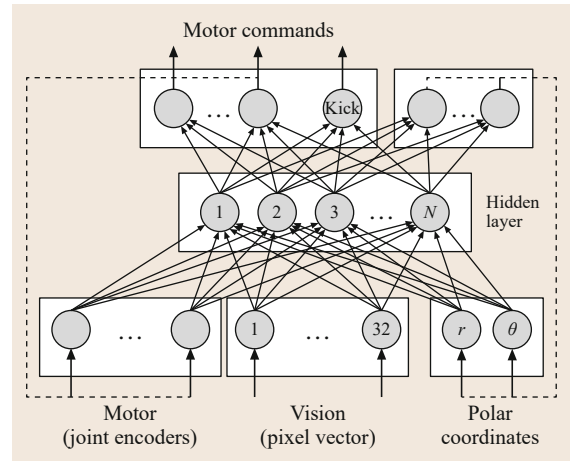

**Fig. 28.11a,b** iCub robot simulator: kicking the ball (a), the goal (b)

the body rotation joint (a joint attached to the body that allows the robot to rotate on its vertical axis).

- Visual information is provided through a vector of 32 bits, which encodes a simplified visual image obtained by the eyes and allows the robot to locate the goal in its visual field.
- Polar coordinates of the robot with respect to the goal (represented by the radius and the polar angle).

The six outputs are, respectively, the polar coordinates of the robot with respect to the goal, the desired angle of the neck, the torso and the body rotation joint, and an additional binary output that makes the robot kick the ball when its value is 1. In the learning phase, this output was set to 1 only when the motion ends and the robot must kick the ball to the goal. All input and output variables are normalized in  $[0, 1]$ . Angle ( $\theta$ ) ranges from  $-90^\circ$  to  $90^\circ$ , while radius ( $r$ ) could vary from 0 to 15 m. As angle and radius values are normalized in  $[0, 1]$ , the  $0^\circ$  (i. e., when the goal is in front of the robot) equals to 0.5.

For training the neural network, we used the *backpropagation through time algorithm* (BPTT), which is typically used to train neural networks with recurrent nodes for time-related tasks. This algorithm allows a neural network to learn the dynamical sequences of input–output patterns as they develop in time. Since we are interested in the dynamic and time-dependent processes of the robot–object interaction, an algorithm that allows to take into account dynamic events is more suitable than the standard backpropagation algorithm [28.68]. For a detailed description of the BPTT algorithm, see also [28.69]. The main difference between a standard backpropagation algorithm and the BPTT is that in the latter case the training set consists in a series of input–output sequences, rather than in a single input–output pattern. The BPTT allows the robot to learn sequences of actions. The goal of the learning pro-

**Fig. 28.12** Neural network architecture for spatial position estimation. *Dotted lines* (recurrences from output to input) are active only when the network operates in imagery mode

cess is to find optimal values of synaptic weights that minimize the error  $E$ , defined as the error between the teaching sequences and the output sequences produced by the network. The error function  $E$  is calculated as follows

$$E = \sum_s \sum_t \sum_i \left( (y_{its}^* - y_{its}) (y_{its} - (1 - y_{its})) \right)^2, \quad (28.5)$$

where  $y_{its}^*$  is the desired activation value of the output unit  $i$  at time  $t$  for the sequence  $s$  and  $y_{its}$  is the actual activation of the same unit produced by the neural network, calculated using (28.1) and (28.2). During the training phase, synaptic weights at learning step  $n + 1$  are updated using the error  $\delta_i$  calculated at the previous learning step  $n$ , which in turn depend on the error  $E$ , according to (28.4).

To build the training set, we used the iCub simulator primitives to position the robot in eight different locations of the field. For each position the robot rotated to acquire the goal by means of a simple search algorithm. During the movement, motor and visual information were sampled in input–output sequences of 20 time steps. The command to kick the ball is issued after the acquisition of the target (the middle of the goal). The kicking movement was preprogrammed. Then, the neural network was trained to predict the next sensory state (excluding the visual input) by means of a backpropagation through time algorithm for 50 000 epochs, after which the mean squared error (MSE) error in estimating the six output variables was 0.0056.

In a preliminary study the robot was first controlled by the same algorithm used for collecting the train series (*controlled condition*), the neural network was not

controlling the robot, but used only to estimate the position coordinates. In a second trial the robot was fully moved by means of the neural network (*autonomous* condition), which directly controlled the joints (i. e., network outputs were sent to neck, torso, and the body rotation actuators) as well as the kick command (moves the leg down). The result of this preliminary study shows that the *autonomous* condition performs better (i. e., 5% average error less) than the *controlled* one in terms of position estimation. For this reason, for the main experiment we employed the *autonomous* condition only, which is also more in line with the theoretical background presented so far.

The aim of the experiment was to test the generalization performance of the neural network and to evaluate the use of visual and proprioceptive information for the estimation of the robot position with respect to the goal. As testing phase, the robot was positioned in the same positions used for training (*learning set*) to verify the quality of the learning and, then, in eight new positions (*testing set*), that it did not experienced before, to evaluate the generalization capability of the model.

The structure of the experiment is divided into two phases: in the first phase the network is trained to predict its own subsequent sensorimotor state. In the second phase the network is tested on the robot, in interaction with the environment.

Table 28.3 shows the percentage error between imagined positions and real position. The error is evaluated as the percentage with respect to the real positions using the polar coordinates. All values of the imagined positions in Table 28.3 were obtained with *autonomous* control. Analyzing errors in testing position, we can see that the error is very high for position 8, this is because the robot fails to acquire the target after it makes a wrong move at the beginning and the goal goes out of sight. It should be said that the robot has not been trained to find the goal when it is not at least in part in

its visual field. The same happened when the robot was in position 2 and 7 of the learning set. The robot misses the 50% of the scores, but it is worth to mention that errors were mostly made when the goal was very distant (i. e., more than 8 m) and even a little error in the position leads the ball out of the goal.

Figures 28.13 and 28.14 graphically summarize the results showing the environment with the 8 real and imagined positions of the train set and the test set, respectively. As the figures show, overall the robot is able to estimate its position in the environment to a good extent.

Table 28.4 report the distance, evaluated using Cartesian coordinates, between the real positions and the first and last estimated positions in the imagined series. This evaluation gives further evidence that the failures on some positions are due to the fact the robot is not trained to find the target when it is out of sight. Indeed, the first imagined position is quite good, but after the wrong movement the robot is no longer able to see the goal and the visual input becomes all zeros, thus, it has no way to recover.

Figures 28.15 and 28.16 reports the entire *imagined path*, along with markers for first and last imagined positions and the actual position. The *imagined path* is the fictitious path that is composed of all positions imagined according to the movements made. The *imagined paths* for positions with very high error are not depicted to avoid confusion. It can be noted that the accuracy of imagined positions gradually improves while the robot performs the movement to aim the center of the goal and shoot. The average improvement is 0.43 m for learning set and 0.56 m for testing set. According to this result, the use of proprioceptive motor information, coming from the autonomous body movements, influences the robot imagination, and it often helps to better estimate its position in the field.

## 28.4 Conclusion

Despite the wide range of potential applications, the fast-growing field of cognitive robotics still poses several interesting challenges, both in terms of mechanics and autonomous control. Indeed, in the new humanoid platforms, sensor and actuator arrangements determine a highly redundant system, which is traditionally difficult to control, and hard-coded solutions often do not allow further improvement and flexibility of controllers. Letting those robots free to learn from their own experience is very often regarded as the unique real solution that will allow the creation of flexible and autonomous controllers for humanoid robots in the future.

In this chapter, we presented the work done so far to explain the concept of *motor imagery* and *mental simulation* as a fundamental capability for cognitive models, based on artificial neural networks, which allow the humanoid robot iCub to autonomously improve its sensorimotor skills via simulated *mental imagery* mechanisms.

Three experimental studies with the iCub platform simulator were presented to show that the application of imagery inspired mechanisms can significantly improve the cognitive behaviors of the robot, even in ranges not experienced before. The results presented, in conclusion, allow imagining the creation of novel algorithms and cognitive systems that implement even better and with more efficacy the concept of artificial mental training. Such a concept appears very useful in robotics, for at least two reasons: it helps to speed up the learning process in terms of time resources by reducing the number of real examples and real movements performed by the robot. Besides the time issue, the reduction of real examples is also beneficial in terms of costs, because

it similarly reduces the probability of failures and damages to the robot while keeping the robot improving its performance through mental simulations. In the future, we speculate that imagery techniques might be applied in robotics not only for performance improvement, but also for the creation of safety algorithms capable to predict dangerous joints' positions and to stop the robot's movements before that critical situation actually occurs.

From a technological point of view, this chapter aims to support the better understanding of mental imagery as a potential breakthrough for cognitive robot engineering principles. Such principles can be applied to go further in the development of artificial cognitive systems capable to better interact with the environment and refine their cognitive motor skill in an open-ended process. These robots will be able to reason, behave, and interact in a human-like fashion, thanks to the integration of the capabilities to mentally represent the physical and social world, resemble experiences, and simulate actions. The imagery-enabled cognitive robotic agents will be able to handle and manipulate objects and tools autonomously, to cooperate and communicate with other robots and humans, and to adapt their abilities to changing internal, environmental, and social conditions.

## 29. Dynamical Models of Cognition

Mary Ann Metzger

Models of cognition address properties of the mind by formulating cognitive processes such as memory, perception, inference, and comprehension of language. Dynamical models of cognition ascribe importance to time and complexity, both of which bring context to behavior. Temporal processes bring into the moment the possibility of memory, feedback, the effects of nonlinear recursion, and the generation of expectation. Complexity brings the possibility of stable patterns of coordination emerging from interaction of subprocesses.

In some models, time and complexity have provided a bridge between thought and action, a basis by which to characterize thought and action as inextricably combined. These models hold that action is a component of perception, or that thought and action are inseparable, or that thought and action act in concert, two sides of the same coin serving to reduce the uncertainty about the nature of events.

This chapter provides a review of several models of cognition in terms of their dynamical features, including models not generally included in the dynamical tradition, such as ART and ACT-R. It focuses on the manner in which each model treats time and complexity, thought, and action. It provides a glimpse into the methods of model development and analysis associated with the various approaches to modeling cognitive processes.

### 29.1 Dynamics

The properties of the mind are formulated and quantified by models of cognition. Examples of these will be summarized here from the dynamic point of view, which will bring in some of their points of contact with fields other than psychology, from philosophy to engineering. Models will be described in ways which highlight the manner in which they address dynamical features of mental activity.

The dynamic point of view involves two properties of cognitive models, one methodological the other substantive. The methodological aspect centers on matters of time and complexity, the question being in what way does the model incorporate concepts and methods which address temporal change as formulated in nonlinear dynamic systems theory and the science of complex systems. The substantive aspect involves the manner in

which the models address the relationship between the mental and the physical, cognition and action.

### 29.1.1 Time and Complexity

Philosophical properties of dynamical models have been considered in comparison to models which have been called computational. The former models are distinguished by elements of timing and complexity, as might characterize the production and comprehension of speech. The latter by stability, for which timing is arbitrary, as in associations among mental symbols, or application of rules of logic. Another way to express the difference is that for dynamical models of complex processes, several subprocesses act simultaneously and interactively, while for computational models, the subparts of a modeled process act as independent modules, each of which communicates with other modules by taking input prepared by a previously active module, processing it, and making the result available to the next module.

Similar distinctions have appeared in philosophical debates using related terminology as in emergent versus reductionist, dynamical versus generative, and connectionist versus artificial intelligence. Advocates for dynamical models have argued for dynamical models being superior in the sense of being more complete, perhaps more general, than their computational counterparts, as in the following quote, which refers to the computational approach as Hobbesian [29.1]:

“[...] Every cognitive process unfolds in continuous time, and the fine temporal detail calls out for scientific accounting. Moreover, many cognitive structures are essentially temporal: like utterances, they exist only as change in time. Often, getting the timing right is critical to the success of cognitive performance; this is especially so when in direct interaction with surrounding events.

Hobbesian computational models have made a bet that cognitive phenomena can be described in a way that abstracts away from the full richness of real time, replacing it with discrete orderings over formal states.”

The emphasis on continuous time is a stringent requirement for research strategies in psychology. Incorporating time as an essential component of data is something easily done, but in many areas of psychology this means not continuous time, but time-sampling, in which the process in question is measured at intervals, resulting not in a continuous signal, but in discrete time, a *time series* of observations. Much of the terminology characteristic of research related to dynamical models arises from the requirement of de-

scribing and drawing conclusions from dynamical time series.

With dynamical time-series data, the researcher can apply graphical techniques to succinctly lay out the time-course or *trajectory* of the process, the appearance of both stable patterns, called *attractors*, and the paths, *transients*, to and from attractors. The graphical techniques have mathematical counterparts and additional mathematical techniques are available to quantify and summarize features of the time series. In this way the dynamics of the process, its *rule of evolution*, may be quantified, classified, and understood.

Accepting time and time series as fundamental requirement of data emphasizes a focus not only on cognitive *entities*, symbols and rules of manipulation, but also on cognitive *performances*, *perceiving*, *remembering*, *conversing*. From this point of view, the scientific objective should be one of describing the time series of processes and correlates of cognitive behavior and discovering the rule of evolution by which the cognitive performance unfolds over time [29.2].

In an example from the production and comprehension of speech, dynamical defines the basic unit of data to be a continuous linguistic signal, while generative defines it as discrete phonetic segments. A summary of the implication of the two approaches, continuous-dynamical versus segmented generative is given in the following quotation [29.3]:

“[...] a fundamental mistake of the generative paradigm is its assumption that phonetic segments are formal symbol tokens. This assumption permitted the general assumption that language is a discrete formal system. This bias forced generative phonology to postulate a phonetic space that is closed and contains only stable symbolic objects. We show that theories of phonetics satisfying these constraints have little to no support from phonetic evidence and thus that the formal-language assumption is surely incorrect.”

There is an implication that dynamical models of cognition enjoy superior status, its associated laws being deeper and more generally applicable to behavior. That assertion has been philosophically evaluated by examining dynamical models considered examples of greater and lesser laws. Greater laws are defined to be more widely applicable than lesser. Lesser laws might be descriptive accounts of particular mental dynamics, or they might rely on concepts for which temporal factors are negligible. Dynamical models of cognition were shown to exemplify both greater and lesser laws, leading to the conclusion that time and complexity alone are not sufficient to distinguish greater versus lesser laws [29.4].

### 29.1.2 Cognition and Action

The dynamical versus computational distinction has been characterized as competing answers to the mind-body problem. In this view, dynamical theories address mind-body as a single phenomenon with cognition and action being two faces of the same process. In contrast, computational models have the dualist view that mind and body are different entities; the mind manipulates information to formulate goals and plans for the body to execute. The following is an elaboration of the dynamical view [29.5]:

“All that we know we have constructed within ourselves from the unintelligible fragments of energy impacting our senses as we move our bodies through the world. This process of intention is transitive in the outward thrust of the body in search of desired future states; it is intransitive in the dynamic construction of predictions of the states in the sensory cortices by which we recognize success or failure in achievement. The process is phenomenologically experienced in the action-perception cycle. Enactment is through the serial creation of neurodynamic activity patterns in brains, by which the self of mind-brain-body comes to know the world first by shaping the self to an approximation of the sought-for input, and then by

assimilating those shapes into cognition and meaning.”

In discussions of dynamical versus computational models of cognition, illustrations have been examples of action, for which timing of interacting subsystems is an essential feature versus cognition, for which timing enters as a secondary or negligible feature. The contrast between dynamical and computational might be illustrated as the contrast between a musical performance and the music sheet, or between a conversation and a transcript, in each case the former being action, the latter cognition. Hence, there are two conflicting points of view on the relationship between action and cognition, they are either sequentially cooperating subsystems, or they are integrated, communicating subsystems.

This chapter examines several theories of cognition focusing where possible on ways in which they characterize cognition and action and on ways in which they incorporate timing and complexity. The topic is divided into three major categories. The first concerns methods in data-oriented models, which make few general claims, but rather summarize a phenomenon or a special purpose model. The second concerns general models of cognition for which cognition and action are treated as distinct and separate processes, that is, knowledge can be developed and transformed without reference to action. The third concerns models for which cognition and action are intrinsically linked.

## 29.2 Data-Oriented Models

Data analytic methods for detecting and illustrating specific dynamical properties of a process set the stage for development of more general theories. The methods are generally derived from complexity science and nonlinear dynamic systems theory. Complexity science is the study of processes comprised of interacting subprocesses. Nonlinear dynamic systems theory is comprised of mathematical methods, usually based on differential or difference equations, used for inference about features of the trajectory of nonlinear recursive processes. A nonlinear recursive process is one for which exponential powers of previous events in the process (*feedback*) systematically determine subsequent events. In practical application, the distinction between the two methods of analysis is not always useful, since they characterize and quantify phenomena of the dynamical processes in compatible ways. Data-oriented studies aim to identify and quantify dynamical phenomena which appear during the unfolding of an objective or theoretical process. Their goal is to set data into a context which

highlights dynamical properties, thus establishing requirements for theory.

Dynamical properties of a process are revealed in a sequence of measurements on its important variables, a time series which can be used to describe and draw inferences about the trajectory of the process. Of the numerous graphical and mathematical approaches to understanding the dynamics of a process, this chapter will consider just a few central concepts related to constructing features and drawing conclusions from time series and dynamical models. More details, definitions, methods, and objectives can be found in [29.6–8].

### 29.2.1 Methods

Part of the appeal of dynamical models is they allow the modeling of complex-appearing processes, with simple, deterministic rules of evolution which generate periods of patterned behavior interwoven with transitional periods of random-seeming variation. Other dynamical

models generate simple patterns from complex systems. Three of the many methods associated with dynamical modeling will be of interest here, quantifying attractors, concepts of potential, and scale invariance.

### Quantifying Attractors

Attractors are persistent patterns which arise in a dynamical process. As an example, a whirlpool is an attractor in a flowing stream. When and how attractors are exhibited by a dynamical process often depends on the value of a quantity analogous to energy of the process. That quantity is represented by the *control parameter*. One of the ways to formalize a dynamical system is to identify the attractors, then specify manner in which the control parameter governs the trajectory of the process into and out of attractors. In the example of the flowing stream, the control parameter could be the rate of flow, when the stream flows faster or slower old whirlpools might disappear and new ones come into being. The idea is to incorporate the control parameter and nonlinear feedback into the rule of evolution.

Attractors are the most perceptible aspect of a dynamical process primarily due to their duration. Other aspects of the process are fleeting and ephemeral, but attractors can last long enough to be noticed and named. Take, for example, the process underlying the reversals of an optical illusion in which the attractors are the two possible perceptions of a staircase, rising or descending. Most of the time the perception is of one or the other, each of which is easy to describe. The time of transition between attractors is rapid and the transient ephemeral. During the transient, the staircase is neither rising nor descending, and is not easily described or named. Transient and attractor intuitively may seem two different processes, yet the dynamics of process in the visual system are presumed to be the same whether the perception is of the staircase rising, falling, or transient. It is that constant process which is captured in its rule of evolution. The assumption of dynamical systems analysis is that all phenomena arise from a rule of evolution which remains unchanged as the system evolves through attractors and transients. As the process continues through time, it visits the attractors, whose persistence constitutes the phenomenological experience of the process. While in an attractor, the system generates and maintains a pattern of increased predictability, equated with lower surprise, sometimes equated with emergent phenomena.

### Potential

Dynamical processes may be drawn into attractors and may stay in or escape from an attractor based on energetic properties. Systematic energetic properties are measured by a potential function  $V$  the basic parameter

of which is the control parameter. Thus, the dynamics, motion, and phenomenology of the system is governed by the control parameter, via the potential function at any point in time. There is a component of optimization, that is, of the system having a quality of always moving toward a lower potential.

A method for quantifying the relation between the control parameter and the attractors of a dynamical process starts with a formula for potential  $V$  associated with each point in the space possibly lying on a trajectory of the system, that is, in a space defined by the axes which correspond to the system variables and the control parameter. The rule is that systems always move in a direction to reduce  $V$ . The attractors will therefore be located at points for which the potential is at a local or global minimum which might be conceived, respectively, as a shallow or deep valley. When the system reaches a point for which  $V$  is a minimum, it tends to remain there in an attractor to be moved out of that attractor only by random or systematic fluctuation both of which might be increased by additional energy, hence the persistence of attractors. Some energy is required to keep the process in operation and drive it to its deepest attractor, but too much energy can make the system less predictable by causing it to jump in and out of attractors.

It is the essence of attractors that they persist over time and so they are perceived as patterns or entities. Local attractors last for a time comparatively shorter than global attractors. Thus, global attractors have the effect of staving off the effects of time. That is, the system remains patterned and therefore more predictable over an extended period. Comparing to transients, transients happen in time whereas attractors happen over time.

### Scale Invariance

Nonlinear dynamic systems analysis can often reveal that a process or object has the same form whether it is viewed overall or microscopically. When such a relationship occurs, it is described by the equivalent terms of fractal, self-similar, or scale invariant. Examples of scale invariance occur widely in nature, often being visual examples of trees or landscapes, but the concept of scale invariance also applies to the mathematics of the underlying processes, so a model without a visual counterpart may be described as scale invariant.

### 29.2.2 Example: Motor Coordination

Applied to bilateral motor coordination, a data-oriented method of complexity science, *coupled oscillators*, was applied specifically to bilateral coordination of hand motion [29.9]. The analysis of the purely the motor

phenomenon has served as inspiration for applying the same method of analysis to cognitive phenomena. In the hand-motion study, a participant with hands on table is instructed to start moving both index fingers in a given pattern at a given rate, then on cue, speed up or slow down. The model relies on a fundamental variable  $\phi$ , the observed phase difference between the two fingers. When in phase (toward and away from each other),  $\phi = 0$ . When out of phase (both point the same direction),  $\phi = \pi$ . With the application of complexity theory and the theory of coupled oscillators, it was possible to derive specific predictions of amplitudes and frequencies critical for the system. That is, the theory predicted accurately for individuals at what frequency in-phase or out-of-phase patterns would appear, and additionally what changes in amplitude of finger motion occurred as the process moved between out-of-phase and in-phase. The fundamental equation used to quantify the locations and depths of the attractors of the system was derived and given as

$$V = -a \cos \phi - b \cos 2\phi, \quad (29.1)$$

where potential  $V$  is a function of the phase difference  $\phi$ , and constants  $a$  and  $b$ . The trajectory of coordination of hand motion occurs predominantly in a direction which minimizes  $V$ , with small fluctuations. The function  $V$  has two distinct minima, a shallow, local minimum, and a deep global minimum. The values of  $\phi$  at which these minima occur can be found by taking the derivative of  $V$  with respect to  $\phi$ , setting it equal to zero and solving for  $\phi$ . These are the values of  $\phi$  associated with two attractors of the process. When in operation, the system generates only two attractors, a strong one at  $\phi = 0$ , associated with a global minimum of  $V$ ; a weak one at  $\phi = \pi$  associated with a local minimum. Transition between phases is governed by the control parameter, the speed of oscillation, and shows unidirectional hysteresis. That is, it is more likely to fall into the global attractor than to escape it. While the process is in an attractor, it appears patterned, either in phase or out of phase. When the trajectory takes the system between attractors, it is in a transient and appears uncoordinated. For any participant, the precise frequencies at which the two attractors occur and the ease of moving between attractors is captured by the relationship of  $|b|$  to  $|a|$ , a quantity which can independently be determined for each participant. The description so derived has been shown to be consistent with details of coordination of bilateral hand movement.

Although the application obviously concerns only coordinated motor systems, the method of coupled oscillators has come into play, at least metaphorically in theories of infant cognitive development. The develop-

mental applications rely on the emergence of patterns of phase coordination which arise naturally out of properties of motor structures. A pattern, however, gives the impression of independent existence. Some theories of cognitive development claim some of the phenomena of the infant's cognitive development, ideas about the permanence of objects, for example, may simply be emergent properties wholly a product of interaction of motor systems.

### 29.2.3 Example: Decision Under Risk

A second example of a data-oriented approach offers an integration of several theories and results in the field of decision under risk [29.10]. To summarize, using a modification of terminology: Established results begin with the concept of the subjective value ( $y$ ) of a gamble, a quantity which can be determined from a person's choices among gambles. Within a wide range, for a rational person, subjective value of a gamble is equal to the objective expected value ( $x$ ), negative for losses, positive for gains. It might be called Rational Value Theory (RVT). But much research has shown people often act as if  $y$  has been modified by additional subjective evaluations of winning and losing and other features of the gambling experience, yielding a measure of utility. When  $y$  equals utility for each value of  $x$ , it can be said choice of gambles is governed by Expected Utility Theory (EUT). In a third theory, acknowledging that losses and gains are often relative,  $y$  of the gamble can be profoundly affected, even reversed, by the context in which the gamble is presented (*framing*). When  $y$  can be reversed from a preference to an aversion by, for example, changing the framing from a context of gain to a context of loss, it is an example of Prospect Theory (PT). Each theory yields a characteristic pattern in the graph of  $y$  against  $x$ . The patterns RVT, EUT, and PT can all be observed within an individual. Deviations from RVT have been associated with emotional involvement, where least emotional involvement described by RVT, moderate by EUT, and high by PT, critical facts for dynamical systems analysis.

Dynamical systems analysis of the choices among gambles begins with the assumption that the three graphs of  $y$  against  $x$  constitute the observed attractors of the process of choice among gambles. For RVT, the graph would be a 45° line,  $y = x$  through origin. For EUT the graph is ogive shaped with varying degrees of steepness, often asymmetric. For PT, over the mid-range of  $x$ , the graph is S-shaped, also somewhat asymmetric. Taking just the upper and lower arms of the S,  $y$  is then a two-valued function of  $x$ , representing reversal of preferences due to framing. The goal

is to embed the three attractors on a surface in three dimensions by introducing a third axis, the control parameter  $a$ .

The control parameter  $a$  is defined as an indicator of amount of emotional involvement. It is included as a third dimension, placing the three  $y$  by  $x$  graphs on a surface in three-dimensional space and in a specific relation to each other. Graphs for RVT, EUT, and PT are arranged, respectively, from linear to S-shape, at  $a = 0$ ,  $a = \text{moderate-value}$ , and  $a = \text{high-value}$ . As is characteristic in nonlinear dynamic systems analysis, the control parameter is hypothesized to govern movement between the attractors; the least emotional involvement associated with linear RVT, moderate involvement with ogival EUT, and high involvement with discontinuities of PT. When the three curves are arranged along the third dimension,  $a$ , their graphs suggest the cross-sections of the folded surface of a cusp catastrophe, for which a standard quantification exists.

For processes the trajectories of which lie on a cusp-catastrophe surface, (29.2) applies. It gives the formula for finding the potential ( $V$ ) associated with any triple of points ( $y, x, a$ ). To obtain the formula for the surface, it is only necessary to find the values of ( $y, x, a$ ) which make  $V$  a minimum. This is a straightforward process of taking the partial derivative of  $V$  with respect to  $y$ , setting the derivative equal to zero and solving the result to express  $y$  as a function of  $x$  and  $a$ . The graph of the resulting function will be the cusp catastrophe surface upon which the graphs of the three theories can be fit

$$V = y^4 + ay^2 + xy. \quad (29.2)$$

The value of this analysis by cusp catastrophe is not only that it represents several types of betting choice on a single surface, describing all three with a single formula but also that it lays out a dynamics which might

take place within an agent. This suggests time-series studies of a single agent with varying levels of emotional involvement over might profitably address dynamical movement among attractors. Such an approach might reveal individual differences, intermediate attractors, a bifurcation point at which the curve becomes 2-valued, and possibly hysteresis in the 2-valued range, thus posing challenges for continued development of theories of decision under risk.

#### 29.2.4 Summary

The examples illustrate two of the many dynamical approaches of data-oriented research. In the first, the approach quantifies coordination of limb movement, applying the model of coupled oscillators, well-understood in complexity science. The model enabled predictions about both phenomenological and quantitative details of coordination of hand movement, that is, about the nature of attractors and transients. This adds to theory by clearly delineating an approach to characterize the nature of emergent phenomena. The second approach is to begin with known attractors, as in the three styles of risk-taking characterizing subjective value as a function of objective value, then propose to place the functions in a space, arranged along a dimension of a control parameter. The approach envisions a single surface on which the three attractors lie. The resulting relationships add to theory by delineating the forms of other possible attractors of the process and processes which might go on within an individual. The first theoretical analysis concerns only action. In the second, study concerns only cognition. In both types of approaches, the goal is to end up with an understanding of the attractors the nature of the transients, and the control parameter, using methods of complexity science and nonlinear dynamic systems theory.

### 29.3 Cognition and Action Distinct

The philosophical contrast between dynamical and computational theories of cognition rests to some degree on their respective theoretical link between cognition and action. For computation, the link is proposed to be a minimal relation between modules. Mental modules manipulate information and issue goals for a motor module to carry out. The claim that modular theories are not dynamical deserves examination. Consider three models, each apparently exclusively concerned with mental processes only very loosely linked to performance. The first model is of limited applicability and serves mostly to illustrate possible but unrealized links

between cognition and action. The remaining two are models that might quite reasonably be described as very large and comprehensive. Both have impressive records of empirical application and test.

#### 29.3.1 Recognition Memory Model

A theory with apparently only cognitive aspects appears in a model of recognition memory [29.11] proposed to be dynamical. The model is closely tied to a particular experimental paradigm. For a typical experiment on visual recognition memory, an agent might view either

a familiar picture or a novel one and be instructed to respond familiar or new. The model characterizes the process as a sequence of re-perceptions of the picture or re-looks at it, each look providing more information to update positive and negative accumulators for familiarity. When the positive and negative accumulators for familiarity reach sufficiently small rates of change, a judgment is generated and a response is initiated. Although the model is not presented in this way, the rates of change of the accumulators are analogs of a potential function to be minimized by re-looks. When the potential function has reached a minimum, the cognitive system has reached an attractor, namely a persistent judgment of familiar or unfamiliar. Temporal features of accumulating and looking are hypothesized to affect response time.

In the matter of the relation between cognition and action, some parts of the model are undefined. The process of re-looking, for example, is not explicitly defined. It is not clear whether re-looking is a motor function or mental re-perception without motor involvement. It is not clear whether looking is at the service of the accumulators. It is possible an accumulating module might send out a goal to a looking module, and the looking module then produce some sensations for the accumulating module to work on. Alternatively, it could be that looking and accumulating proceed in mental flux until the process reaches an attractor and initiates a response. The first would be more like a computational model, the second, dynamical.

There are additional questions about the relation of cognitive to motor. The ocular system is not the only motor function in the experimental setup. The agent must also record his judgment with a word or a press of a button. After the process has reached an attractor, presumably a command would be issued to a motor module for this purpose. So this model has the possibility of both an integrated motor process for looking and a separate motor module for executing the response. It illustrates concepts that come into play when analyzing modular models in terms of dynamic and computational features.

### 29.3.2 Adaptive Control of Thought – Rational

Adaptive Control of Thought – Rational (*ACT-R*) is a theory of cognition designed to incorporate what is known as brain function into an architecture which operates to solve problems using symbols and rules of deductive and inferential logic. Because its operations are based on symbols and rules, it can be classified as a computational model of cognition. It has focused on

higher level cognition and problem solving rather than perception or action [29.12].

In any application, ACT-R produces a simulation of the operation of a system consisting of modules of a multifaceted brain, a perceptual motor system, a goal system, a declarative memory, and a procedural system. Each module produces information in a form useful to one or more other modules. This has some dynamical aspects since there is an empirically determined characteristic timing of the operations applied to separate modules. Although it deals with symbols and rules, timing for operations of a module is not necessarily arbitrary nor altogether ignored. This model has complexity of the mental system without the additional complexity of the motor system to which it issues goals [29.12]:

“[. . .] the critical cycle in ACT-R is one in which the buffers hold representations determined by the external world and internal modules, patterns in these buffers are recognized, a production fires, and the buffers are then updated for another cycle. The assumption in ACT-R is that this cycle takes about 50 ms to complete this estimate of 50 ms as the minimum cycle time for cognition has emerged in a number of cognitive architectures [. . .]. Thus, a production rule in ACT-R corresponds to a specification of a cycle from the cortex, to the basal ganglia, and back again. The conditions of the production rule specify a pattern of activity in the buffers that the rule will match, and the action specifies changes to be made to buffers. The architecture assumes a mixture of parallel and serial processing.”

The feature of parallel processing does not imply unlimited capacity since there are two limited-capacity features built into the system. The first is the limitation on buffer contents. A buffer can hold only a single item from memory or perception. The second is a limitation on production rules, only a single one can be selected on each cycle.

ACT-R has been used along with brain imaging to identify certain brain structures with which aspects of cognition can be associated. Brain activity was imaged for participants while they learned a new artificial algebraic system, manipulated its equations, and keyed in answers, in an experiment which lasted over several days. Imaging yielded a measure of activity, the blood oxygenation level-dependent (*BOLD*) function in brain structures over the time course of the experiment and related the measure to theoretical account of steps in problem solution with the following results [29.12]:

- “1. The motor area tracks onset of keying. Otherwise, the form of the BOLD function is not sensitive to cognitive complexity or practice.
2. The parietal area tracks transformations in the imagined equation. The form of the BOLD function is sensitive to cognitive complexity but not practice.
3. The prefrontal area tracks retrieval of algebraic facts. The form of the BOLD function is sensitive to cognitive complexity and decreases with practice.
4. The caudate tracks learning of new procedural skill. The BOLD function is not sensitive to cognitive complexity and disappears with practice.”

These four results illustrate the role of timing and complexity in ACT-R theory. Although the theory can be categorized as computational, it is clear from this example that the theory addresses the dynamics of brain processes which accompany learning procedural skills of varying difficulty. Although time comes in as an index of practice, measured in days, the focus is on the end-effect of practice, to identify which brain modules and transmitter substances might be involved in developing an understanding of the algebra and skill at executing a sequence of steps to solve an algebraic problem. The objective is to match brain function and modules with their theoretical counterparts. That is, the modules and information flow represented in the architecture of the theory are matched with activities in specific brain modules, allowing the function of the brain modules to be inferred and described in terms of the theory. So, too, with complexity, which is here not taken to refer to the complexity of complexity science, but rather to the difficulty of the artificial algebra and the problems given for solution, and is also a variable to be related to the function of brain modules. Thus, ACT-R has timing and complexity, but does not address the process using methods of complexity science or nonlinear dynamic systems theory.

### 29.3.3 Artificial Neural Networks Methods

Artificial neural networks (ANNs) are a large number of theories addressing many phenomena including phenomena of cognition. ANN theories share the fundamental component of the artificial neuron ( $N$ ) an element with some similarity to physical neurons. Ns are usually lined up in layers. Artificial neurons in the lowest layer receive stimulation from an external source (*input*). The remaining layers receive weighted stimulation from other neurons usually from the next lower layer. The weights reflect variations in the strength of the connection to one N from another. The firing pattern of the highest layer (*output*) is readable in meaningful terms by some other system. Intermediate layers are

generally referred to as hidden, and their firing patterns, determined by the weights, are not necessarily easily interpreted.

Each N accumulates the weighted stimulation and transforms it according to a nonlinear function usually acting as a threshold. When the transformed value reaches the threshold, the N fires, usually stimulating at least one N in the next higher level of its next higher neighboring artificial neurons. The word *usually* appears often in the description of ANNs because the structure and operation of an ANN is subject to the ingenuity of its designer. The amount of stimulation received by one N from the firing of another is governed by their connection weight which is taken to be a measure analogous to synaptic strength. From these few properties and their numerous variations, structures can be developed which when in operation simulate thought processes associated with many brain activities thought to underlie learning, concept formation, and rational thought.

For an example of the operation, input might be of a new pattern, expressed in ones and zeros. The weighted and reweighted elements of the pattern are passed through one or more layers of artificial neurons, of each which applies a nonlinear transformation. When it reaches the output layer, the output might be ones and zeros representing a category into which the ANN has determined the new pattern falls.

Whatever the network and task, connection weights which optimize performance must be found. This is usually accomplished by minimizing a cost function during a training procedure in which the ANN learns the optimal connection weights to perform well on a particular task. Considering only supervised pattern learning, any given input pattern can be associated with a desired output, a correct classification for example. With the goal of minimizing the error over all patterns, the weights over the entire network can systematically be adjusted in a direction which reduces the cost function, which will over several trials incrementally bring the cost function to a local or global minimum. Minimizing error is similar to minimizing potential  $V$  of (29.1) and (29.2). A typical cost function is the least-squares minimization given as

$$V = \sum_i (o_i - d_i)^2, \quad (29.3)$$

where  $V$  is the cost,  $i$  indicates the  $i$ th output N,  $o$  is the output value, and  $d$  is the desired value. Minimizing the cost function is a process of reducing errors in classification by adjusting connection weights throughout the network, usually through a technique called *back-propagation*. Unlike the earlier examples, the local and

global minima for  $V$  are not usually completely known and the process of minimizing  $V$  can settle at either type of minima, arriving at a local or global attractor for the set of weights. It is a process of parameter estimation which has some analogy to the characterization of the learning process. Normally the process of parameter fitting is not part of the cognitive model, but in the case of ANNs, as the parameters are being changed trial by trial the process of parameter estimation mimics the learning process, that is, changes synaptic weights. Such changes in synaptic weights are thought to characterize learning and adaptation in biological systems.

One of the strengths of ANN models is that they can often easily incorporate substructures with known properties. ANNs are well suited to do real tasks such as those based on identification of a limited number of patterns. For example two ANNs, each of which is itself a theory of adaptation are the ANN model for Hebbian learning and the Hopfield Network for learning to classify patterns without supervision. These are examples of the power of neural network modules which can be used in sections of an ANN model of cognitive and behavioral functions.

### Hebbian Learning

In Hebbian learning when a neuron  $N$  fires, all of its connections with other  $N$ s in the layer below are affected, in particular, any  $N$  whose firing stimulated it. Each of these connections is increased in effectiveness, that is, will transmit a greater effect in the future. Hebbian learning is a dynamical model of neural modification during learning. In a Hebbian, ANN parts of the system during their normal operation create a useful learned configuration. It is a dynamical model of adaptive brain changes, which instantiates the Hebbian theory of neural correlates of learning.

### Hopfield Network

An ANN can simulate other cognitive functions, for example, the Hopfield network can infer good patterns from samples without any supervision, that is, without feedback on correctness of its performance while learning to classify patterns during training. The Hopfield Network can also remove noise from imperfect patterns, and is known as a technique for self-addressed memory.

## 29.3.4 Adaptive Resonance Theory

Adaptive Resonance Theory (*ART*) is a global theory of cognition using related models of brain and neuronal properties to assemble ANNs to simulate cognitive and other brain functions. Adaptive resonance is analogous to energy produced by a pattern match based on

processes of stored patterns (*top-down*) and of input management (*bottom-up*). When a match is achieved the system sends the information to the next module, by ANN routes, for further processing. ART has by these means addressed and simulated the theoretical processes that underlie numerous results from the literature of experimental psychology and neuroscience.

The fundamental unit of ART incorporates the dynamics of adaptive resonance and forms the common basis for many related models. Models have been formulated with different objectives but all with *ART* in the acronym, indicating that adaptive resonance is a fundamental feature of every model so derived. Adaptive resonance is the fundamental theoretical process of cognition.

Adaptive resonance entails a temporal process that unfolds during the creation of a meaningful perception from an input. The input may be a pattern to be identified or categorized, or it may be part of a temporal sequence such as speech to be comprehended. Having received input, ART initiates a comparison process is with the objective of maximizing a resonance function. In the comparison process, the bottom-up input signal interacts with top-down previously learned patterns, prototypes, and expectations. The interaction consists of repeated cycles of directing attention to combinations of bottom-up features deemed significant by a matching process and suppressing bottom-up features deemed irrelevant. In repeated cycles, the resonance function is optimized and the information can be passed on to the artificial neurons in the next module for further processing.

ART is currently silent when it comes to generating overt responses, although some indication has been given of a proposed approach to the problem. For ART, the perceptual system derives resonance from achieving a match. For the motor response, the system issues a goal and leaves it at that. The suggestion has been put forward that the motor response might be shaped by a *complementary* process, a sort of mirror image of resonance. In the proposed process, the complementary energy analog of resonance would be generated not by a match, but by a mismatch between actual and desired action, the mismatch indicating the desired goal has not yet been reached. Motor functions are addressed and characterized thus [29.13]:

“The START model proposes how adaptively timed inhibition of the hippocampal orienting system [...] and adaptively timed disinhibition of cerebellar nuclear cells [...] may be coordinated to enable motivated attention to be maintained on a goal while adaptively timed responses are released to obtain a valued goal. [...] Biological learning in-

cludes both perceptual/cognitive and spatial/motor processes. Accumulating experimental and theoretical evidence show that perceptual/cognitive and spatial/motor processes both need predictive mechanisms to control learning. Thus there is an intimate connection between learning and predictive dynamics in the brain. However, neural models of these processes have proposed, and many experiments have supported, the hypothesis that perceptual/cognitive and spatial/motor processes use different types of predictive mechanisms to regulate the learning that they carry out. [...] The need for different predictive mechanisms is clarified by accumulating theoretical and empirical evidence that brain specialization is governed by computationally complementary cortical processing streams that embody different predictive and learning mechanism.”

### 29.3.5 Summary

Both ACT-R and ART characterize dynamics of mental processes theoretically observable through brain imaging. Both models characterize cognition and performance as separate processes. Cognition may be

required for a performance, but cognition and performance are two different processes. Behavior is taken as a window on mental processes, that is, at the completion of the cognitive process, a goal may be issued to a motor system. Behavior, then, indicates what goal was set. Separating cognition and action is, however, not a necessary feature of these types of models, an integration of the two is an explicit goal for both ACT-R and ART.

With regard to complexity, both ACT-R and ART have interrelated communicating subsystems, modules which act in cooperation, rather than in concert, that is, usually sequentially, not simultaneously. As such, they do not invite the techniques of complexity science. The fact that ACT-R specifically addresses symbols and rules of their manipulation does not prohibit application of nonlinear dynamic systems analysis, as there has been developed a method of *symbolic dynamics* [29.14].

Not time, but timing is an essential feature of both models. That is, what is known from brain imaging about the active areas of the brain and about the times required for particular brain activities is incorporated into both models. These are reflected in temporal restrictions on sequencing and when passing information is permissible between modules.

## 29.4 Cognition and Action Intrinsically Linked

### 29.4.1 Methods

In discussions of theories for which cognition and action are intrinsically linked, it will be useful to reserve the word *model* to refer to properties of the agent. The word is commonly used in two senses, each an example of some kind of entity for prediction of events, evaluation of evidence, and revision of beliefs. The first type is the scientific model using various techniques to generate predictions, guide the formulation of experiments, and prescribe routines for evaluating results. These are the models to which the title of this chapter refers. For clarity and brevity in the presentation of models which intrinsically link cognition and action such scientific models will be referred as *theories*. The second usage of the word includes models which instantiate a set of beliefs held by the agent about the state of the external world based on patterns of sensations. They include beliefs in models of processes in the external world, such as the belief that a convivial friend will enjoy the party. They also include beliefs held by the agent about his actions and the consequences thereof in the external world, such as the belief that opening the cupboard will reveal a tasty snack. Beliefs held by the agent will be called models in the remainder of this chapter. Thus,

theories may contain hypotheses about the existence and properties of models. This is especially so for theories which assert cognition and action to be intrinsically linked. Such theories are usually associated with methods by which to characterize the processes by which the agent’s beliefs are created and altered. Two such methods will be described next, Bayesian multiprocess models and particle filters.

#### Bayesian Multiprocess Models

According to the theory of multiprocess models of cognition and behavior [29.15], the agent generates expectations for what will happen next from each of numerous mental models pertaining to the experience. These expectations take the form of a prediction for the next event and assignment of a probability from each model to each possible outcome of the event or, equivalently, to each possible error of prediction. The models themselves may be of any sort, that is, they may contain features of complexity, nonlinearity, and feedback, or they may be simple stochastic models. The word multiprocess indicates that each of several models may be characterized as a belief about the dynamics of some event. The relative amount of belief in each model is expressed as its probability. The models are required to

be mutually exclusive and jointly exhaustive as far as beliefs are concerned.

The important aspect of mental models is they make a specific probabilistic prediction for the very near future, that is, they attach a probability to every event which might possibly happen next. After an event occurs, each model is re-evaluated according to the support each receives from the evidence of the event. For example, consider an agent who has two models for a coin, that it is either fair or biased. The fair coin model,  $z_{50}$ , is expressed as  $P(H) = 0.5$  and  $P(T) = 0.5$ . The biased coin model,  $z_{80}$ ,  $P(H) = 0.8$  and  $P(T) = 0.2$ . Suppose before the coin is tossed he believes 60-40 that the coin is fair, that is, his *prior* amount of belief in each model is expressed in the probabilities  $P(z_{50}) = 0.6$  and  $P(z_{80}) = 0.4$ . The two models and his relative degree of belief in each form the context for his interpretation of the subsequent event, which will be the outcome of a toss of the coin. For each model the agent generates a prediction and a probability for any other outcome, for  $z_{50}$  he might predict heads  $H$  and note a 0.5 probability of error, namely  $T$ . For  $z_{80}$  he will predict  $H$ , but with a 0.2 probability of error. The coin is tossed and comes up  $H$ . The question is how does this outcome affect his degree of belief in each model to yield revised or *posterior* probabilities? The answer is given by Bayes rule, in the odds form, applied to each model separately in (29.4)

$$\frac{P(z_{50} | x_H)}{P(z_{80} | x_H)} = \frac{P(x_H | z_{50}) P(z_{50})}{P(x_H | z_{80}) P(z_{80})}, \quad (29.4)$$

where  $x_H$  is the event of having  $H$  occur after predicting  $H$ , that is, having predicted  $H$  accurately. Although prediction from each model is accurate, that is, prediction error is zero for each, the probability of a zero error is different for each model. Evaluating (29.4) along with the condition that the models are jointly exhaustive, yields the effect of the event on the belief in each of the two models, posterior beliefs of  $P(z_{50} | x_H) = 0.48$  and  $P(z_{80} | x_H) = 0.52$ . Given the same prediction  $H$ , if the outcome of the coin toss had been  $T$ , the result would have been different with  $P(x_T | z_{50}) = 0.5$  and  $P(x_T | z_{80}) = 0.2$ . Then the result would have been the posterior beliefs of  $P(z_{50} | x_T) = 0.79$  and  $P(z_{80} | x_T) = 0.21$ .

In the theory of multiprocess models of cognition, the models invoked by the agent arise from both internal sources and experience. The set of models together with their degrees of belief form the context by which the agent understands events. In any situation, the prediction error is used to revise the degree of belief in each model. The effect of repeated application of Bayes rule is to alter beliefs to reduce errors of prediction.

In the dynamics of multiprocess models, the prediction error serves the same purpose  $V$  does for complex systems, that is, the system of beliefs forming the context of the experience, evolves in such a way always to reduce errors of prediction by systematically bringing the successive priors closer to their respective posteriors. In this way, ongoing experience produces and refines the context of the experience.

### Particle Filters

Particle filters provide a method for applying Bayes rule in an environment of constant flux where the agent has both beliefs about his actions as they affect his environment and beliefs derived from evidence about the state of the environment. By incorporating beliefs about the effects of action, new models may be introduced to the set, providing a flux of models to accommodate the flux of the environment.

Particle filters give a best-guess approximate solution to the problem of finding prior beliefs about otherwise unknown states of an agent moving in a changing world. The method uses such prior beliefs, a *motion model*, input to a *map model*, and current stimulation to generate updated beliefs about current state [29.16]. Its application can be illustrated with a simple example of an agent moving in the dark around the furniture in a familiar room.

The *particles* in question are simple hypotheses, such as a statement about location. One particle might claim *You are here at A*. another *You are here at B*. and so forth. Having started into the room from the threshold and taken three steps, he consults his motion model and believes he has arrived at one of three points,  $A, B, C$  with respective probabilities 0.2, 0.3, 0.5. To further delineate his location, he reaches out and finds that he touches a table, providing evidence  $x$ . He then consults his mental model of a map of the familiar room and determines the probability of touching the table from  $A, B, C$ , is respectively, 0.7, 0.5, 0.2. These yield posterior probabilities for  $A, B, C$ , given  $x$ , of 0.36, 0.38, 0.26. At this point, the filter reweights each particle according to the degree to which touching the table was a surprise for it. The weight for each particle is calculated as the ratio of its posterior according to the map to its prior according to the motion model. The particles are then re-sampled with replacement according to the weights to yield a new probability density function (*pdf*) for final belief of location. The posteriors for  $A, B, C$ , respectively are 0.50, 0.36, 0.14. He can use these posteriors as priors in the motion model, for his next steps, then once again reach out, then consult his map about the result. At this time it is quite likely a new particle  $D$  might come into the picture, justifying the re-weighting and

re-sampling of the posteriors for his next input to the motion model.

The particle filter is a method for continuously bootstrapping probabilities which cannot simply be dragged from one situation to another because the question and the environment are continually changing. The question is not simply *Where am I?*, but rather *Now that I have taken three steps from one of three places I was at with varying probabilities, where am I?* It gives weight to the previous beliefs from models, but sheds them when new circumstances and other models come into play.

Although it is not stated explicitly in terms of prediction errors, by the procedure just described, particles with smaller prediction error become more likely to be sampled to estimate the pdf, while particles with greater errors tend to drop out. This keeps neighboring particles more influential and distant particles less. The dynamical feature of this model is that cognition changes always in a way to reduce a potential function, in this case, the quantity minimized is surprise, the discrepancy between the prior and posterior beliefs.

### 29.4.2 Embodied Cognition

Theories of embodied cognition hold that phenomena of cognition are all, or in large part, emergent from coordination of components of a complex motor system. The psychology of infant development has been a source of examples of the theory, taking advantage of the fact that infants change over time in correlated cognitive and motor abilities. The theory overview is that over a period of growth, motor subsystems settle into new patterns of coordination in a manner analogous to coupled oscillators, a feature of increasing motor size, strength, and complexity. The patterns give the appearance of new cognitive abilities but the theory holds in certain cases the cognitive property exists only in new patterns of the motor coordination. Thus eye movements and limb movements may become coordinated in a pattern which gives the appearance of a new level of belief about properties of objects, but that emergent property is not independent of motor coordination. The embodiment theory of cognitive development relies on concepts from both complexity science and nonlinear dynamic systems theory [29.17], Chap. 30.

An illustration of the dynamical approach to cognitive development concerns a prototypical phenomenon known as the *A-not-B* error. To demonstrate the developmental difference in *A-not-B* the infant is shown a toy, which is then hidden at location *A* within easy reach. The infant reaches to uncover and retrieve the toy at *A*. This is repeated several times, then the toy is shown being hidden at location *B* also within easy reach. After a short delay, the infant is allowed to reach

for the toy. If the infant is 10 months old he will reach for *A* not *B*, apparently making an error of cognition in the sense that the infant appears to believe that the toy hidden at *B* nevertheless will still appear at *A*. At 12 months, the infant will correctly reach to *B*, appearing to have reached a new concept that toys put someplace will not move from there on their own. This consistently reproducible error had previously been interpreted as a sign that between 10 and 12 months, the infant develops an understanding of object permanence, that is, develops a belief that the object will not magically jump from *B* to *A*. The dynamical model takes issue with this interpretation proposing the same intellectual factors enter into the two types of responses and the same process but the process is complex, made up of two motor subprocesses with different timing at different ages.

The first process is a motor memory of reaching for *A*, made strong by the initial repetitions. The second is memory for the looking where the toy was recently hid, *B*. For a younger infant, the memory of looking at *B* is hypothesized to decay faster and by the end of the delay the memory of reaching for *A* comes to dominate. For older, a different time course of decay for the two memories leaves the memory of looking dominant at the end of the delay. This dynamical interpretation has been successful in several tests using variations of conditions intended to differently affect the time-courses of decay of the two memories. In this way, the relation between the time-courses of decay for two memories, each of the result of its respective motor process, gives rise to an apparent cognitive advance, object permanence. The cognitive advance is thereby an emergent property of the system, created from more elementary subsystems. Instead of the motor function obeying the cognitive command, the cognition arises as an epiphenomenon of motor coordination.

Outside of developmental psychology, the theory of embodied cognition has been applied to mental imagery. The theory of embodied mental imagery holds that even when there is no overt behavior representing the cognition, it nevertheless is body based. Abstractions such as mental imagery, working memory, episodic memory, implicit memory, reasoning, and problem solving which operate in the absence of overt behavior may be called *off-line* cognition. The process from which off-line cognition derives, is linked to decoupling of mental processes from overt behavior, a process by which mental processes which formerly accompanied overt behavior have decoupled from the behavioral aspect and go forward on their own [29.18].

As a matter of principle, the off-line theory of embodied cognition holds that decoupled, abstract cognitive activities are remnants of bodily activities. By this

reasoning, mental processes which originally only accompanied veridical perception and action, have been adapted to operate off-line, without requiring input or output, but nevertheless retain features characteristic of perception and action [29.18]:

“Off-line aspects of embodied cognition, in contrast, include any cognitive activities in which sensory and motor resources are brought to bear on mental tasks whose referents are distant in time and space or are altogether imaginary. These include symbolic off-loading, where external resources are used to assist in the mental representation and manipulation of things that are not present, as well as purely internal uses of sensori-motor representations, in the form of mental simulations. In these cases, rather than the mind operating to serve the body, we find the body (or its control systems) serving the mind.”

Almost in contrast to the off-line view is a theory of embodiment which holds that the mind extends into the physical world. For example, this theory asserts that mental activity includes actions such as using paper and pencil to solve an arithmetic problem or write a sentence. The rules of manipulation of symbols, and the symbols themselves are extensions of the mind into the physical world. In this way, the theory asserts the mind increases its capacity for memory and rule application [29.18].

### 29.4.3 Motor Theory

Motor theories of perception link action to cognition. Understanding or perceiving an observed action by others is accomplished by the covert production of that action. The early example of such a theory is the motor theory of speech perception. The motor theory holds that speech is perceived through the listener’s covert production of the same speech [29.19]:

“As for speech perception, there is now evidence that perceiving speech involves neural activity of the motor system. Two recent studies involving the use of transcranial magnetic stimulation of the motor cortex have demonstrated activation of speech-related muscles during the perception of speech.”

Concepts in the motor theory of speech perception have been extended to a more general theory, applying to any observed action by others. The general motor theory of perception has received much support from studies of neuronal activation and brain imaging which shows perceiving actions involve the same neuronal, brain, and motor system as producing the action. Complexity in production, complexity in perception, and

complexity in coupling the two are central features of motor theories of perception.

### 29.4.4 Simulation Theory

Simulation theory [29.20] holds, in the large, that mental life, particularly imagination, consists of processes by which the brain synthesizes sensations and perceptions which do not arise from the external world and actions which do not affect the external world. To achieve this, the brain activates the same pathways used in veridical sensation, perception, and action, but interrupts their contact with the external world. In this way, a replica, or simulation of external events and processes can be experienced without requiring the presence of their veridical counterparts. Simulation can be either of a stable perception, or of a dynamic unfolding of a process of simulated perception, action, and anticipation of the consequences of action.

Simulation theory requires that the brain contain structures which can accommodate perception, action, and anticipation in the absence of external input, as contrasted with veridical perception and action. The resulting motor stimulation is stopped short of execution, resulting in simulated behavior [29.20]:

“Saying that behaviour can be simulated here means nothing more than that the signal flow from the prefrontal cortex via the premotor areas may occur even if it is interrupted before it activates the primary motor cortex and results in overt behaviour. A simulated action is thus essentially a suppressed or unfinished action.”

Simulation theory explains imagination and anticipation, both arising from sensations in the absence of external input. It is characterized as a variety of perception involving the same parts of the brain which occur with veridical perception. In addition to being stimulated by input from the external world and transmitting the stimulation to higher parts of the brain, the parts of the brain that produce sensation can also be stimulated by a retrograde flow from higher parts to sensation. Such sensations may be distinguished from veridical sensations by the fact that they occur in an episode during which overt action is being suppressed.

Anticipation is characterized as the imagined consequences of suppressed action. From experience, the agent learns to anticipate consequences of action and can fold this information into the simulated experience. Anticipation thus consists of models of the effects of actions. It returns the effects of the imagined actions as imagined sensations. In accordance with simulation theory, after some amount of veridical experience, perception, action, and consequence, all

may occur without concurrent contact with the external world.

### 29.4.5 Free Energy Theory

Free Energy Theory connects beliefs with actions as two sides of the same coin. The theory is presented with rigor, definitions, and distinctions in [29.21]. The theory addresses cognition and action with a notational system which accommodates interfaces between the external world and the sensations it produces for both cognition and action.

On the cognition side, it distinguishes between brain states and *causes*. Brain states are analogous to the models of Bayesian multiprocess models, while causes are part of the external world. *The recognition density is a probabilistic representation of what caused a particular sensation* [29.21, p. 128]. It is the aim of minimization of free energy to have the brain states match the causes, thereby reducing occasions of surprise. On the action side, the theory offers a particular kind of model, labeled *m*, which links an action to its consequences, changes in the external world.

It is the aim of action to alter sensations to more closely match beliefs associated with brain states, which it can accomplish most effectively by turning up evidence confirming the most likely model. Thus cognition and action are each part of comprehending the sensations which arise from experience, the former by identifying its causes, the latter by seeking confirmation of the most likely causes by manipulating the environment. Both cognition and action are governed by the same principle, the minimization of free energy.

The purpose of the following illustration is to explain how causes and models can be connected to free energy. Certain conditionals have been dropped in the interest of clarity and brevity. Thus, in (29.5)–(29.7) the symbol *z* should be understood as a *belief about the external causes of sensation given the brain state*. There can be many *z*s, each with some initial degree of belief, expressed as  $Q(z)$ . The quantity *x* is used here to represent external states or events given the sensations, the causes, and the model of action. These representations of *z* and *x* are similar but not identical to the models of Bayesian multiprocess theory and simulation theory. In particular, free energy theory explicitly expresses *x* as the result of a filtering process, not the unobservable external process itself ( $\varphi$ ), but an estimate of it, instantiated in neural activity, in a time series of vectors of sensations.

In the simplified example, assume the agent observes an event, *x*, for which he has prior probabilities,  $Q(z)$ , for each *z*, yielding an approximation  $Q$  to the optimum posterior probability  $P(z|x)$ . The goal is to

come to a conclusion in which the discrepancy between  $Q$  and  $P$  is minimal. This can be accomplished by minimizing a measure of the discrepancy, the Kullback–Liebler (*KL*) divergence  $D(Q||P)$ , expressed in (29.5)

$$D(Q||P) = \sum_z Q(z) \ln \frac{Q(z)}{P(z|x)}, \quad (29.5)$$

which expands to

$$D(Q||P) = \sum_z Q(z) \ln \frac{Q(z)}{P(z,x)} + \ln(p(x)). \quad (29.6)$$

On the right-hand side of (29.6) the second term is the negative of the information content of the event *x*. The first term is referred to as free energy. Rearranging the terms of (29.6) shows free energy  $F$  is equal to the KL divergence plus the information in *x* represented in (29.7) which suggests free energy may be minimized by changing the discrepancy between  $Q$  and  $P$  or by changing the event *x*

$$F = D(Q||P) - \ln(p(x)). \quad (29.7)$$

When the conditionals are included, Free Energy Theory expresses the  $F$  of (29.7) as  $F(s, \mu)$ , where *s* stands for sensory states and  $\mu$  stands for brain states or, equivalently, neural processes representing links between *s* and its causes  $\varphi$ . In addition, the set of models, *m*, link actions to changes in *s* by their effect of altering the external world. There are two ways to minimize  $F$ , both central to free energy theory, the first by changing brain states  $\mu$ , the second by changing sensations *s* through action on the environment. The role of changing brain states is one of coming to some degree of belief in new ideas of causal relationships between the external world and the accompanying sensations. In the case of action, free energy can be reduced most effectively by a particular sort of action, namely action which changes the environment to uncover evidence (event *y*) favoring the most likely cause of *s* for a given brain state. The models *m* determine which action *a* will likely uncover event *y* which has the minimizing effect,  $F(z, y) < F(z, x)$ . Free Energy Theory predicts the organism will act in a way to uncover evidence consistent with the most likely cause, because doing so most effectively minimizes  $F$ .

A model in *m* might be of any variety, for example, a simulation or a simple probability. The only requirement is it link actions to their predicted consequences. In this way, the action is conceived, not as carrying out orders to obtain certain goals, but rather as being a feature of the way the brain interacts with the physical

world to increase predictive accuracy and, equivalently, lessen surprise.

As an example of the role of action, suppose an actor cannot read a word written in poor handwriting. Assume the uncertainty is high because, considering only the word in isolation, there are several equally likely possibilities. The actor can take action to reduce the prediction error by altering the input, namely reading what he can of the words in the surrounding context. The context can alter the respective probabilities of the possibilities for the problem word. That is, action changes the sensory input. When reading the context, the action is quite directed, via the action model  $m$ . The actor is not flipping pages or scanning the room, he is acting in a way to confirm his most likely hypothesis, that this word is part of a meaningful sentence. His strongest hypothesis guides his action. Alternatively, he could instead, or in addition, have tried an approach not involving changing the environment. For example, he could have made guesses about handwriting quirks of the writer. This would introduce new mental models for the letters, thereby changing perception via changing brain state  $\mu$ . Either of these approaches can be called an effort to reduce free energy.

Free Energy Theory characterizes mental activity as a complex process, guided by optimization. In addition, free energy theory has been asserted to apply to mental activity both large and small scale. The examples apply it to mental dynamics on the scale of human activity and perception, such as finding one's way in the dark. In extension, the same concepts and formulas apply it to brain activity on a neuronal scale, as revealed by brain imaging and single-neuron techniques. The methods of nonlinear dynamic systems analysis provide a formalization of such scale invariance.

### 29.4.6 Evolution of Cognitive Search

The evolutionary theory of cognitive search proposes that processes of attention and memory include search strategies analogous to behavioral strategies used in the search of physical space for objects of value. On an evolutionary scale, cognitive search has arisen di-

rectly from physical search [29.22] from behavioral to cognitive, physical to mental. According to the theory, analogous processes occur in cognitive and physical search. For example, both have strategies of remaining in one area (*patch*) until its resources have been fully exploited or otherwise depleted, only then exploring for a new patch to be exploited. Both also are associated with the same areas of brain activities and transmitter substances. Thus, the evolutionary theory of cognitive search asserts important aspects of the relation between cognition and behavior have been developed over a long time scale. The relation between cognition and action is not one of the behavior creating the illusion of cognitive entities, but rather brain functions which govern behavioral search acting as a paradigm for brain activity governing cognitive search.

### 29.4.7 Summary

Where cognition and action are intrinsically linked, theories range from denying the existence a category of cognition separate from the complex coordination of behavioral subsystems, to a complex system of cognition and action combined, to a brain system created by analogy to a complex behavioral system. Complexity is a feature of theories that link cognition and action, almost by definition, since there are applications of complexity science to motor processes even when they are not linked to cognition. The time associated with coordination of subsystems and unfolding of processes, also enters requiring concepts of nonlinear dynamic systems theory.

For free energy theory, the goal does not direct the search, but the search policy inevitably uncovers things of value. For the theory of evolution of cognitive search, behavior and cognition are connected, but in a different way. Cognitive search, in particular, is seen as internalized replica of behavioral search. There is no single way in which all theories of linkage claim cognitive and behavioral functions are linked, but there is great agreement among them that the linkage is there. The dynamical features of these models follow directly from that link.

## 29.5 Conclusion

Unequivocally, theories which combine mental and motor into a unified process are dynamical theories of cognition. Elements of the integrated process are clearly quantified by measures of complexity, real-time coordination, and time series data, which invites application of methods of complexity science and nonlinear dynamic systems theory, the methodology of dynamical models.

From the sampling of cognitive models presented here, incorporating action appears to be a sufficient, but not a necessary condition for a cognitive model to be called dynamical.

Application of a dynamical model to a data set does not necessarily require a comprehensive theory. This is evident in the examples of data-based studies.

Breadth of theory is not a necessary starting point. What is required is instead a commitment to the ideas can be generated by a coherent application of dynamical methodology.

One of the central features of dynamical methodology is optimization of an expression of potential. The system proceeds in a way that minimizes some expression of potential, such as formulated by (29.1), (29.2), (29.3), or (29.7). Such optimization can reveal how it is that the system settles into an attractor and how it moves from one attractor to another. Minimizing potential gives direction and predictability to complex processes. Identification and formalization of a potential  $V$  of a dynamical system paves the way for understanding its stable states and transients.

Dynamical models may emphasize the role of optimization both as a method of determining important quantities in the theory and as a fundamental principle of cognitive processes. This is evident in Free Energy Theory, in which optimization is the organizing principle of thought and behavior. According to free energy theory, the optimizing process occurs in a scale-invariant way at every level from brain structures to cognition–action complex. At every level, optimization in the form of minimization of free energy brings the organism to a state of decreased surprise.

Optimization of a potential function does not have the same overarching role in theories for which cognition and action appear as separate systems. In ART, maximizing adaptive resonance is an optimizing principle at one stage of processing, designed to direct top-down and bottom-up procedures to identify the input pattern or create a new pattern in a way that is useful for further processing. Adaptive resonance and the changes that take place during training of an ART network are examples of dynamic aspects of the ART. These features are usually embedded in a network of modules to which the methodology associated with complexity is not explicitly applied.

Both theories, ART and ACT-R, address the interaction of the symbols, patterns, and rules of cognition and the relationships of these to brain function. Major objectives of ART and ACT-R are to explain how symbols and rules are manipulated and combined in the operations of pattern recognition, classification, and inference, both deductive and inductive. These operations are of central interest to both ART and ACT-R, especially along with their correlation with brain areas

and functions as revealed primarily through brain imaging. When ART or ACT-R is analyzed in contrast to dynamical theories, it is symbols and their rules of manipulation that underlie the contrast.

Symbols and rules of their manipulation are the durable, stable products of mental activity. According to dynamical models of cognition, an alphabet, for example, is the product of dynamical forces of cognition and behavior. One theory of embodiment claims that symbols are physical extensions of mind. They exist as long as general usage and culture keeps them far from equilibrium, the increased entropy of which would turn them to dust. Thus, symbols and rules have the features of attractors in a dynamical system. This is emphasized by the data-analytic method of symbolic dynamics. From this point of view, computational models address relationships among attractors, while dynamical models address the process that brings attractors into existence and govern the transients among them.

Philosophical questions arise from the dynamical point of view concerning the status of the contents and products of mind. What is the philosophical status of an internal model such as those of simulation theory or free energy theory? How are they the same as or different from scientific theories? If brains have brain-state models, and action models, do they not also have symbols? How is a model or a brain state different from a symbol? What is the status of the durable external products of mental activity; alphabets, numerals, rules of inductive and deductive logic, art and engineering, novels and history books? Are these extensions of mind?

The benefits of a dynamical point of view to modeling cognition, in addition to its intuitive appeal, are the wealth of finely developed methods, some of which have been described here. Complexity science introduces new methods which make it possible to address questions which have previously been inaccessible for formalizing and quantifying mental processes. Non-linear dynamic systems theory introduces systematic methods for characterizing the phenomena of nonlinear recursive processes using new concepts, such as formulation of trajectories and their features, including attractors and measures of predictability or dimension of the process. To preserve and further develop benefits such as these, the associated methodologies would be a valuable addition to the curriculum of psychology for the study of the mechanics and properties of mind.

## 30. Complex versus Complicated Models of Cognition

Ruud J.R. Den Hartigh, Ralf F.A. Cox, Paul L.C. Van Geert

As humans, we continuously adapt our behavior to changes in our environment, and our cognitive abilities continuously develop over time. A major question for scientists has been to discover the (cognitive) mechanism that underlies the control of human behavior in real time, as well as cognitive development in the long term. This chapter will discuss two kinds of general approaches, which we shall refer to as the reductionist approach and the complex dynamic systems (CDS) approach. Roughly speaking, the reductionist approach assumes that separate cognitive components, such as brain areas or processing mechanisms, are primarily responsible for behavior and development, by processing (and responding to) specific environmental cues. The CDS approach assumes that cognition and thereby the control of behavior and development are distributed over the brain, body, and environment, which continuously interact over time. The aim of this chapter is to compare the two approaches in terms of their assumptions, research strategies, and analyses. Furthermore, we will discuss the extent to which current research data in the cognitive domain can be explained by the two different approaches. Based on this review, we conclude that the CDS approach, which assumes a *complex* rather than a *complicated* model of cognition, provides the most plausible approach to cognition.

At present, two classes of approaches are used to explain cognition. The first class proceeds from the idea that human behavior is controlled by separate cognitive (processing) components, which we refer to in this chapter as the reductionist approach. The second class assumes that cognition can be considered as a complex, dynamic set of components, and that human behavior is an emergent consequence. We shall refer to the latter as the complex dynamic systems (CDS). The first part of this chapter starts with an overview of the two approaches and the explicit and implicit as-

sumptions they make (Sect. 30.1). In Sect. 30.2, we discuss the research strategies and analyses applied by researchers proceeding from a reductionist or CDS approach. Then, in Sect. 30.3 we demonstrate the extent to which complicated (related to the reductionist approach) and complex models (related to the CDS approach) fit with research data on real-time cognitive performance and long-term cognitive development. Finally, in the concluding section, we discuss which kind of model seems to explain human cognition best (Sect. 30.4).

## 30.1 Current Views on Cognition

On 30 September, 2014, President Obama announced that the White House would make new investments in the BRAIN initiative. President Obama explained that:

“As humans we can identify galaxies light years away, we can study particles smaller than an atom, but we still haven’t unlocked the mystery of the three pounds of matter that sits between our ears.”

Not only researchers, philosophers, but also world leaders and their scientific advisors are fascinated by the question why humans behave the way they do, and more specifically *what controls* human behavior. Human adults appear to have the most evolved prefrontal cortex, neocortex, and temporal lobes of all creatures. Explicitly mentioned or implicitly assumed, for many scholars the mind – or its physical instantiation, the brain – is a key to explain human’s superior cognitive and behavioral capacities. It is generally believed that our abilities for language, abstract reasoning, problem solving, learning and memory, interacting with other people, and using tools ultimately reside in our brain. The prevailing notion today, and throughout a large part of the modern history of psychology, is that fairly localized structures (or *modules*) in the brain play specialized and identifiable roles in how we perceive, how we act, what and how we (can) learn, and even in our emotions and personality [30.1]. Cognition, as amalgam of many such distinct *cognitive* functions and subfunctions, is a mechanistic apparatus consisting of specialized modules linked together in a linear causal chain. This premise has directed the research attention to localizing these *modules* or components and the functions they perform. We shall refer to this approach, in which cognition and the explanation of human behavior is reduced to localized functions, as the reductionist approach.

Obviously, the environment also contributes to how we behave and learn. In the reductionist view, the role of the environment is rather dissociated, that is, it provides input to cognitive processes. More specifically, environmental cues are cognitively processed, after which the *best* subsequent action can be computed, and the situational input can be cognitively stored in order to respond optimally the next time a comparable situation is encountered [30.2–4].

In the past decades, several researchers have criticized the above-mentioned point of view, in particular that human cognition can be compared with a very complicated computational machine [30.1, 5–7]. The computational requirements to perform the most optimal actions would be too high to be feasible in the

context of a natural, changing environment in which humans are acting [30.8]. Rather, behavior would emerge from interactions among various nonspecific interacting processes across the brain, body, and environment (see [30.9–14] for empirical demonstrations), which we shall refer to in this chapter as the CDS approach. According to this approach, cognition is thus *distributed* across (changing) processes of brain, body, and environment, which are intertwined [30.15] (see also related discussions in cognitive sciences on *component dominant* dynamics versus *interaction dominant* dynamics [30.16]; *computationalism/cognitivism* versus *embodiment* [30.2]; and *dissociation* view versus *dynamic* view [30.17]).

Throughout this chapter, we will discuss the reductionist and CDS approaches using illustrations of various domains that the scientific study of cognition pertains to, such as sports [30.17–20], language development [30.21–23], and scientific development [30.24, 25]. We will start with an overview of assumptions that the two classes of approaches proceed from.

### 30.1.1 Central Control versus Self-Organization

One key assumption that the reductionist approach proceeds from is that specific mechanisms are responsible for the way humans behave and learn. In this sense, some environmental stimulus is represented in the mind, and based on algorithms performed by the internal cognitive components the behavioral output is produced [30.3, 26–29]. For instance, in a sports context a football player perceives the positions of his teammates and the opponents, and cognitively computes the best next move [30.30]. Expert football players would better master this skill given their extensive knowledge base, or *software*, of previous encounters with different kinds of situations. This approach implicitly takes the computer as a metaphor in order to explain behavior, and typically conceives of the mind, or brain, as a central computing agent that encodes the environmental inputs and controls subsequent behavior (see the review of *Van Gelder* [30.7] for an extensive discussion of this view). This entails that the brain, comprising the different component processes, is considered as the *central controller* of human behavior.

The idea that the brain controls our behavior, and that the body and environment provide (only) input to the brain, was first challenged by Gibson’s ecological approach [30.31–33]. He proposed that action possibilities are not cognitively computed, but are directly guided by information from a structured environment

to which an organism attunes its actions. In other words, behavior is guided by the direct information and action exchange between the organism and its environment. Gibson's theory has laid the foundation for what has come to be known as *ecological psychology*, which shares its major assumptions with the CDS approach. In Gibson's words: "Control lies not in the brain, but in the animal-environment system" [30.33], which suggests that Gibson conceived cognition as a set of interacting components, distributed across the brain, body, and environment [30.1, 15, 34–39]. Accordingly, the CDS approach considers cognition as a dynamic process characterized by the self-organization of interacting component processes. For instance, the most appropriate next action of a football player would not be computed in terms of a sequence of computational steps, but rather take the form of an ongoing loop of flexible attunement of the action, which occurs more or less simultaneously with changes in the task constraints [30.40, 41]. Hence, the control of human behavior is not centralized, but rather an emergent process.

### 30.1.2 Static versus Dynamic Models

The reductionist assumption that a given behavior or psychological state is generated by one or a few components or determinants is usually associated with the construction and application of static models, in which the levels of some set of dependent variable(s) ( $y_i$ ) are directly and uniquely related to (or caused by) the levels of some other set of independent variable(s) ( $x_i$ )

$$y_i = f(x_i) . \quad (30.1)$$

In this functional description, any possible set of values of  $x_i$  generates a corresponding value for the dependent variables  $y_i$ . In other words, if we know the values of  $x_i$ , we can predict the values of  $y_i$ . An implicit assumption here is that the operating causal variables remain stable for the duration of the behavior or psychological state they would cause.

Take, as an illustration, the development of a child's lexicon. A typical *static* study would consist of assessing the maternal talk to children of different ages, for instance of 1, 2, and 3 years old. The size of the lexicon can then be predicted by explanatory variables such as age, maternal talk, or a combination of these two variables (Fig. 30.1). Note that, although age is in fact a continuously changing temporal parameter, it is used in a typically static way as a sequence of values (ages), similar to the way maternal talk is treated as a series of static values. In line with the reductionist view, the implicit assumption here is that the child's cognitive

**Fig. 30.1** A simple illustration of a reductionist explanation of a child's lexicon size

language-processing *device* is the underlying mechanism through which maternal talk affects the lexicon size [30.42, 43].

In Fig. 30.1, age and maternal talk are thus treated as the independent variables. However, in order to increase the explained variance in lexicon size, the model can be made more complicated by assuming – and statistically showing – that age is also affecting maternal talk (for all other conditions remaining equal, mothers of older children tend to produce richer maternal talk than mothers of younger children). It is even possible to also draw an arrow between age and the arrow connecting maternal talk and lexicon size, implying that age moderates the effect of maternal talk on the lexicon size (older children can profit more from the same maternal talk than younger children). Another way of increasing the complicatedness is by adding additional variables, such as socioeconomic status (SES), the mother's intelligence quotient (IQ), time spent at the day care center and so forth. Thus, generally speaking, the reductionist approach proceeds from the idea that the explanatory power should be increased by increasing the number of specific factors (i. e., components) involved and the links between them. As already mentioned, temporal change, represented by age in the example, is treated as a factor like any other factor in the model.

According to the CDS approach, however, the causal principle of behavioral or psychological change does not lie in the values of some variables or components at a certain moment in time. As noted earlier, cognition could be envisioned as a dynamic *process*, which entails that *time* is an essential aspect to take into account. More specifically, the change in the cognitive system is a function of its preceding state

$$y_{t+1} = f(y_t) , \quad (30.2)$$

where  $y_{t+1}$  corresponds to the state of the system at time  $t + 1$ , which is a function of state  $y$  at the previous time point  $t$ . Hence, the CDS approach proposes models of change that involve recursive relationships ( $y_t$  leads to  $y_{t+1}$ , which leads to  $y_{t+2}$ , and so forth) [30.44]. Returning to the explanation of a child's lexicon, a simple explanation would be that learning new words at time  $t$  depends (among possible other things) on the words the

child already knows and on the words that are spoken by the mother with whom the child communicates at time  $t$  (Fig. 30.2). This also entails that the child's lexical change is *embedded* in the environment, referring to the real-time events taking place, such as the maternal talk. Consequently, and in line with the concept of self-organization (Sect. 30.1.1), the properties of the system change over time as the underlying components interact with each other. That is, as the child's lexicon develops, the mother will change the way she speaks to the child, which feeds back to the development of the child's lexicon, and so forth (Fig. 30.2; see also the work of Van Dijk and colleagues [30.45]).

**Fig. 30.2** A simple illustration of a dynamic explanation, in which the child's lexicon at a particular moment provides the basis for the lexicon at the next time point(s), while this change is also shaped by the dynamic interactions (literally and metaphorically) with the mother

## 30.2 Explaining Cognition

In the previous sections, the terms *complicated* and *complex* have been mentioned a few times. In scientific models, these terms refer to different explanatory conceptions [30.46]. The reductionist approach generally provides a *complicated* model of cognition, whereas the CDS approach proceeds from a model of *complexity*. In the following subsections, we will explain and contrast these different kinds of modeling, and how they naturally fit with different kinds of research strategies and analyses to capture cognition.

### 30.2.1 Research Strategies and Complicated Models

In a complicated model of cognition, many components are involved, which can be studied in isolation, and the resulting psychological and performance states can be understood when knowing the contributions of the individual components (Fig. 30.1). In case researchers are interested in cognitive expertise of athletes in real time, for example, they would design a study in which cognitive measures can be obtained in a standardized environment. As an illustration, Williams and colleagues [30.30] showed skilled and less skilled football players sequences of attacking game plays in a research lab. After a brief delay, participants watched another set of sequences and indicated which sequences they already viewed before. Two variables were measured: response time and response accuracy. The authors found that skilled players responded quicker when they were shown game plays that they viewed earlier. Williams and colleagues proposed that these results indicate that expert soccer players have more refined (stored) knowledge structures of soccer game plays. Because the skilled players can access these modules quickly, they would be better able to respond rapidly [30.2].

It is assumed to be likely that this information processing mechanism facilitates decision making on the football field, which results in choosing the most appropriate (next) action (remember the computer metaphor in Sect. 30.1.1).

In order to further untangle the full richness of cognition, researchers keep increasing the complicatedness of their models by basically adding more underlying explanatory modules or variables and links between them (see also the explanation of static models in Sect. 30.1.2). For instance, referring back to the study of Williams and colleagues [30.30], they also found that skilled participants better recalled the relational information between players (how they moved relative to each other). To explain this finding, the authors added the concept of (cognitive) *motion integrators* as a possible explanation for this result, which would be integral to skilled pattern recognition [30.26].

### 30.2.2 Research Strategies and Complex Models

According to the CDS paradigm, real-time cognitive performance can be explained by a model of *complexity*. Importantly, complexity is not reflected in the number of components that are involved in cognitive performance (the number of separate cognitive modules that process information, the number of environmental variables that influence people's cognitive processing, etc.). On the contrary, a complex cognitive system is typically characterized by continuous *dynamic interactions* and multicausality between various intrapersonal and environmental components, from which the (changing) state of the cognitive system emerges (Fig. 30.2) [30.37, 47, 48]. Thus, in contrast to a complicated model of cognition, a complex model proceeds from the idea that it

is *not* possible nor feasible to reduce cognition to separate, fairly isolated components (recall the concept of self-organization again in Sect. 30.1.1).

Referring back to the example of football, according to the CDS approach the actions of a (attacking) player are emergent from the underlying self-organization dynamics (changing positions of players, the ball, etc.) [30.18, 40]. Of primary interest to researchers is therefore the unfolding of footballers' actions in real-time. A typical study would focus on the emergence of action patterns that are continuously shaped by the way the system components attune to each other, involving for instance the attackers' and defenders' relative distance to each other [30.49, 50] and to the goal [30.51], or more generally the size of the field [30.52]. As an illustration, *Headrick* and colleagues [30.51] revealed that the distance between the defender and the ball stabilized at higher values – indicating low risk-taking behavior of the defender – when the defender–attacker duel occurred close to the goal, than when it occurred relatively far from the goal.

### 30.2.3 Analyses to Untangle Cognition Based on Complicated Models

Given the different assumptions of the reductionist and CDS approaches, not only the research strategy (Sect. 30.2.2), but also the applied analyses are different [30.53]. In the reductionist approach, the analysis is focused on finding the linear associations at the level of isolated variables. Researchers therefore typically apply the so-called control of variables strategy, which in standard accounts of the scientific method is seen as the quintessential way of explaining the nature of reality, namely to disentangle the variables and control the variables separately to see what changes in those variables actually do. The way one variable controls another variable is assumed to be a property that can be isolated from other properties and other variables. The reasoning is that the most general way in which a variable can control another one is the way in which a variable co-varies with another one over the entire population. Hence, the study of the way a variable controls another one is based on samples that are big enough to be a good representative of that population. This also points to the importance of the generalizability issue, which is understood as the degree to which the statement based on a sample is true of the population that the sample is intended to represent (see also *Hasselmann* and colleagues [30.54] for a discussion of theorizing in cognitive science).

In the example of the relationship between maternal talk and a child's lexicon (Sect. 30.1.2), a researcher may analyze the effect of the quantity and sophisti-

cation of maternal lexical input on the child's lexicon [30.43, 44, 55]. The outcome is framed in terms of the variance in the child's lexicon that can be explained by (co-varies with) the variance in the maternal input variables. In other words, the researcher attempts to find a linear relationship between the lexical input of the mother and a child's lexicon (the output variable). The relationship between maternal input and a child's lexicon as it is found across a sample of mother–child dyads, is implicitly assumed to govern the process of language learning at the level of individual children [30.56].

### 30.2.4 Analyses to Capture the Complexity of Cognition

According to the CDS approach, the associations between variables as they are observed at the sample level, cannot be used as valid approximations of the dynamic relations that govern the process. More specifically, if we assume that components change over time, influence each other reciprocally, which gives rise to (changing) patterns of behavior, analyzing associations between variables in large samples cannot tell us how the process actually works (cf. the ergodicity problem as described by *Molenaar* and colleagues [30.57, 58]). According to CDS theorists, if a researcher is interested in *why* and *how* actual change occurs, the process of interest should be studied over time [30.44, 53, 56, 59, 60]. Therefore, researchers often apply time series analyses, and they focus on particular signatures of the time series, as well as on the underlying dynamic rules that may explain the dynamics of the time series.

*Van Geert* and colleagues have conducted several studies on language development from a CDS perspective [30.21, 22, 61–63]. The authors consistently found discontinuities in individual children's language development, which provided valuable information about lexical change. For example, *Bassano* and *Van Geert* [30.21] studied early language development among French children, and they showed that the discontinuities in the time series mark the transition from a one-word to a combinational mode, and from single combinations to more abstract syntactic modes of language. In CDS terms, the language modes can be considered as *attractors*, that is, states or patterns toward which the system tends to converge [30.36, 48, 64–66]. Thus, the increase in variation signals the transition to another attractor, and thereby to another milestone in children's language development (see also the work of *Van Dijk* and *Van Geert* [30.62]).

Interestingly, whereas variation patterns carry highly valuable information about the cognitive process

according to the CDS approach, variation is typically considered as *random* error according to the reductionist approach. In classical repeated measures designs, for instance, variation around the (linear) tendency over time is considered as error variance. On the contrary, periods of variation have been consistently found to be markers of a transition stage to another attractor in a variety of cognition-related (dynamical) research, not only in studies on language development (see the example above), but also on cognitive reasoning [30.67, 68], perception [30.69], and motor control [30.70].

Finally, returning to the study of *Bassano* and *Van Geert* [30.21], they proposed a mathematical model, defined as a dynamic growth model in which the growth of the language modes, and how they mutually influence each other, could be reliably modeled for the

individual children. This means that the authors were not concerned with providing a model of the average language development across the population of children, which is typical for the reductionist approach, and which would probably result in an unrealistic picture of what individual language development may look like (many children do not develop according to the statistically average child). Rather, *Bassano* and *Van Geert* proposed a dynamic model that could also be *generalized* to the individual. In other words, the authors provided insights into the lawful mechanisms, or CDS principles, underlying language development over time (for a comparable example of model building in mother–child linguistic interactions and the associated developmental process in the child, see the recent work of *Van Dijk* and colleagues [30.45]).

### 30.3 Is Cognition Best Explained by a Complicated or Complex Model?

Currently, the majority of researchers in behavioral and social sciences apply the reductionist approach, whereas a relatively small group of researchers applies the CDS approach. Ideally, researchers should proceed from the kind of approach that fits best with the research question and/or topic under study. For example, if a researcher was interested in the effect of maternal smoking during pregnancy on children’s later academic achievements, a reductionist approach may provide the best fit, because it is desirable that the variables of interest are studied in isolation to determine the effect. Indeed, when this question addresses the population level it can, for instance, be used in campaigns and medical advice. In a typical study, *Batstra* and colleagues [30.71] adjusted for confounders such as socioeconomic status and pre- and perinatal complications, and across 1186 children they found that maternal smoking during pregnancy was independently related to the children’s arithmetic and spelling skills between the ages of 5.5 and 11 years. Note that this study was not focused on explaining cognition, but rather on one potential risk factor, that is, the distribution of maternal smoking across the population and its statistical association with a population-defined effect (distribution of arithmetic and spelling skills).

However, as discussed earlier, the reductionist approach is also widely used to provide an understanding of the (complicated) mechanism that drives cognitive performance in real time, as well as cognitive development across the life span. The extent to which the reductionist approach on the one hand, or the CDS approach on the other hand, is most applicable to cognition that depends on whether it is a *complicated* or

*complex* model that is best able to explain cognition. In the next section we will discuss some studies, the outcomes of which render one of the two approaches more or less convincing. We will first discuss studies focused on cognitive performance in real time, after which we will discuss cognitive development across the life span.

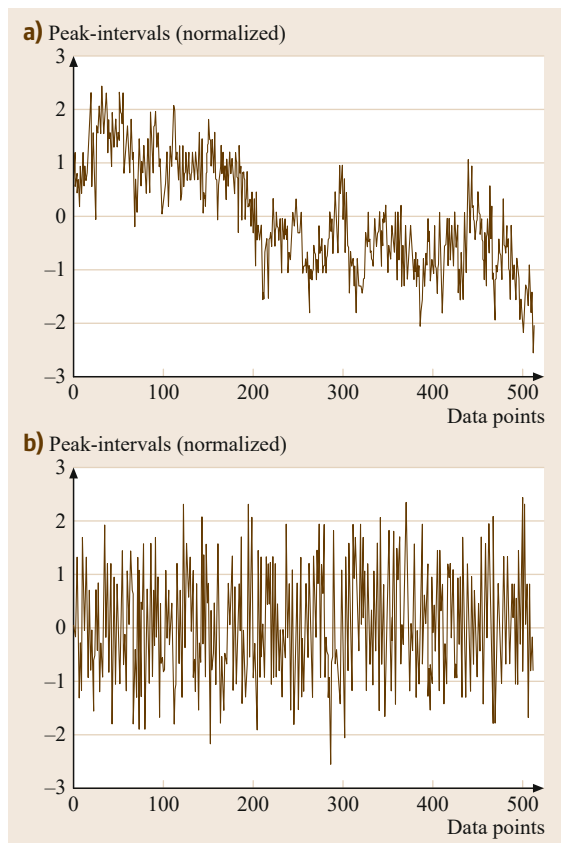

#### 30.3.1 Explaining Real-Time Cognitive Performance

In a recent study, *Den Hartigh* and colleagues [30.72] were interested in the mechanism underlying the (cognitive) control of a motor (rowing) task. The authors let rowers perform a practice session on rowing ergometers, consisting of 550 strokes at the rowers’ preferred rhythm. A force sensor was attached to the handle of the ergometer, which measured the exerted force of the rowers at 100 Hz. Subsequently, the authors analyzed the time series of the durations from force-peak-to-force peak (the force peak intervals). With the reductionist approach in mind, one would expect that each new stroke is controlled by specific modules or component processes (e.g., central pattern generators [30.73]). This entails that each new stroke would be independently controlled from the previous stroke, and that the results should reveal interval series characterized by some average interval value with random variation around it (recall that variation is typically treated as random noise in the reductionist approach).

On the other hand, a CDS is characterized by an iterative process involving interactions between various component processes at different levels (e.g., in this case cell activity, muscle contractions, limb move-

ments) and across multiple time scales (e.g., from a few seconds to several minutes of performance [30.74]). Such ongoing component interactions would cooperatively generate the rower's performance, and are assumed to generate time series characterized by a structured pattern of variation, called pink (or  $1/f$ ) noise. More specifically, the coordination among interacting component processes across multiple time scales within the system, and between the system and its (task) environment, would result in small fluctuations on a short time scale (a few rowing strokes) that are nested in larger fluctuations across longer time scales (tens or hundreds of strokes). The temporal structure of variation can be quantified in terms of the fractal dimension (FD): A FD close to 1.5 corresponds to random (white) noise, and a FD close to 1.2 corresponds to pink noise [30.38].

Figure 30.3a provides a representative example of a time series of one of the rowers. Based on only visual inspection, one can observe that minor fluctuations are embedded in waves of larger fluctuations. In line with this (seemingly) structured pat-

**Fig. 30.3a,b** A rower's actual peak-interval series (a) and shuffled interval series (b)

tern of variation, we found a FD of 1.22, which is close to pink noise, and a comparable pattern was found for the other rowers in the sample. These results strongly suggest that the performance of the rowers emerged from complexity, that is the *interaction* between many components on various scales, as opposed to (just) the *contribution* of many components. Figure 30.3b displays the performance data of the same rower as the one in Figure 30.3a, but in this case the force-peak interval data are randomized. Hence, the average interval and the *size* of the variation (standard deviation) are exactly the same in the two graphs, only the temporal order is different. In line with the fact that this randomization made each next rowing stroke independent of the previous one(s), we found a FD close to 1.5, which reflects random noise.

In line with the study of *Den Hartigh* and colleagues [30.72], the occurrence of pink noise in cognitive performance seems a universal phenomenon [30.39, 75]. Virtually any cognitive or motor performance in which time series of healthy individuals are analyzed reveal pink noise patterns, ranging from reaction times in psychological experiments and reading fluency, to stride intervals of human gait and rhythmical aiming tasks [30.14, 16, 34, 38, 74, 76–80]. These studies provide robust and converging evidence to the claims of the CDS approach, which makes it likely that real-time cognitive performance emerges from complexity, and cannot be reduced to separate, rather independently operating components that perform specific functions to control human behavior [30.72].

### 30.3.2 Explaining Long-Term Cognitive Development

In order to discover the model underlying cognitive development on the long term (e.g., the life span), computer simulations provide a useful tool [30.23, 81, 82]. Computer simulations can be used to (a) generate predictions in terms of which developmental patterns are generated by which kinds of model principles, and (b) compare the simulation results with actual data collected in longitudinal studies on cognitive development. As an illustration, take the development of cognitive abilities in terms of scientific talent development. According to the literature, in order to develop one's scientific abilities various factors play a role, including genetic endowment, the individual's interest and commitment, as well as environmental variables such as the support of the teacher, family support, and so forth [30.83, 84]. As noted earlier, the reductionist approach attempts to fit a complicated model to explain how a state of cognitive development can be

**Fig. 30.4** Graphical representation of a CDS model of scientific ability development. Note that this is a snapshot, and that the network constantly develops through changes in the levels of the nodes, among others as a consequence of the interactions with other nodes

predicted by particular determining factors, often including the age of the child, in a linear fashion (see also Sect. 30.1.2).

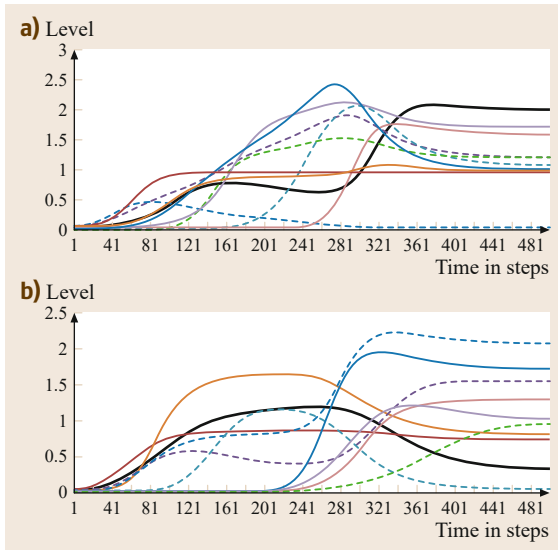

Interestingly, the literature on human development, and more specifically cognitive development, hardly reveals linear patterns [30.81]. In the specific case of scientific talent development, some defining properties have been summarized by *Simonton* in one of his articles on talent [30.85]. An example of these properties is that a similar form of (scientific) talent may emerge at different ages. Another is that the level of talent is not necessarily monotonically raising or stable. It can change or even disappear during a person's life span.

We will briefly show how to apply computer modeling to test whether a particular model would be able to generate valid predictions of scientific talent development, such as the properties mentioned above. In line with the CDS approach, we will demonstrate a model in which development is shaped by the ongoing interactions with other components, which also undergo change. The key mathematical principles of such a (relatively simple) dynamic systems model consist of the scientific ability ( $L$ ) that changes over time ( $t$ ) as a function of two kinds of resources. One remains relatively stable across time ( $K$ ), for instance, the individual's genetic endowment. The second type of resource ( $V$ ) may change on the same time scale as the change of the scientific ability, and comprises components such as commitment and teacher support. These components may dynamically interact with the scientific ability component and with each other. The interaction between the components is governed by a number of parameters, including the degree in which

an ability profits from the constant resources ( $r$ ), the weight of the connection ( $s$ ) with other components ( $i, j$ , etc.) and a general limiting factor ( $C$ ) that keeps the growth within realistic maximum values

$$\left. \begin{aligned} \frac{\Delta L_A}{\Delta t} &= \left( r_{L_A} L_A \left( 1 - \frac{L_A}{K_{L_A}} \right) + \sum_{v=1}^{v=i} s_v L_A V_v \right) \left( 1 - \frac{L_A}{C_A} \right) \\ \frac{\Delta L_B}{\Delta t} &= \left( r_{L_B} L_B \left( 1 - \frac{L_B}{K_{L_B}} \right) + \sum_{v=1}^{v=j} s_v L_B V_v \right) \left( 1 - \frac{L_B}{C_B} \right) \\ &\dots \\ &\dots \\ &\dots \end{aligned} \right\} \quad (30.3)$$

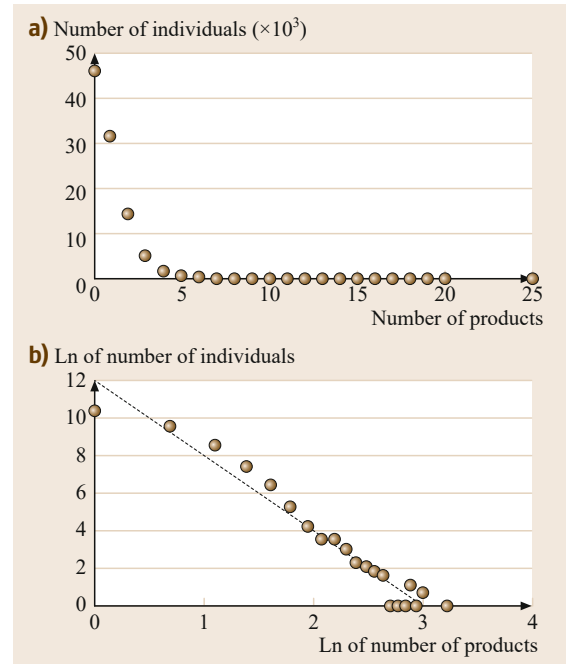

For simplicity, we simulated a system consisting of 10 components. Each simulation represents a particular individual trajectory, which is based on initial parameter values that were randomly drawn from symmetric distributions. Furthermore, the average degree of connectivity between the nodes is 25%, and the connections are randomly distributed over the nodes [30.86]. Figure 30.4 provides a graphical representation of a typical network of relationships specified by this kind of model. The nodes correspond to different variables that interact with the ability growth and with each other (think of the individual's commitment and family support). The sizes of the nodes reflect the magnitudes of the variables. Furthermore, each directed arrow between two nodes represents a supportive (green) or competitive effect (brown) of one variable on another. The strength of the relationships between the variables is reflected in the thickness of the edges.

**Fig. 30.5a,b** Simulations of the scientific ability development of two individuals (**a,b**). The *black solid lines* in the graphs represent the abilities, the *other lines* reflect the dynamic variables that have supportive, competitive, or neutral relationships with the ability and with each other

When simulating various individuals based on the dynamic systems principles explained earlier, a first observation is that the model reveals very different patterns of scientific ability development. Figure 30.5 provides two representative simulation examples. The black lines in the graphs correspond to the scientific ability, whereas the other lines correspond to the other variables. The figure shows that the ability development of one individual develops in a step-wise fashion, and reaches a plateau during the second half of the life cycle (Fig. 30.5a). On the other hand, the ability of the second individual (Fig. 30.5b) starts with a relatively rapid increase, which levels off, and in the second half of this individual's life span the ability development declines. Together, Fig. 30.5a and b correspond to the typical properties of scientific talent development, namely that it can take different forms, that it is not a linear (monotonic) process, and that talent may diminish or disappear over time [30.85] (for more extensive demonstrations of dynamic systems modeling of cognitive development, see the work of *Van Geert* [30.23, 81, 82]).

A final observation in the literature is that exceptional abilities are rare [30.86–89]. Specific abilities, such as the scientific ability required to write papers for high-ranked journals, are in most cases only measurable by referring to the typical performances or products (i. e., the number of published articles in high-

**Fig. 30.6a,b** Simulated productivity distribution according to the complexity model. The raw (simulated) data are displayed in graph (**a**), and the natural log–log representation, which approaches a straight line, is displayed in graph (**b**)

ranked journals). The actual productivity of scientists is extremely right skewed with very few researchers having many high-impact publications and relatively many with one high-impact publication. In fact, the distribution is so right skewed that the log–log representation corresponds with a straight line [30.87, 90–92]. In combination with various product models discussed in the literature [30.87, 93], simulations of the CDS model reveal an extremely skewed distribution that is in accordance with the distribution of scientific productivity of scientists in various scientific domains (Fig. 30.6). The typical reductionist model would try to explain the product distributions on the basis of linear combinations of underlying predictor variables. However, such a model is unable to predict the typical and ubiquitous heavy-skewed distribution of the products, in this case the publications [30.86].

Taken together, based on data on real-time cognitive performance and computer modeling of long-term cognitive development, researchers can choose the model that most likely underlies the empirically observed patterns. We have presented some examples of data that can be better explained by model predictions stemming from the CDS approach (a complex model) than from a reductionist approach (a complicated model).

## 30.4 Conclusion

Every human behaves and develops in a different way, and is embedded in a rich, constantly changing environment. This has made it challenging for scientists to explain cognitive development and the control of human behavior. In the past decades, human cognition has, on the one hand, been approached as localized in the brain and controlled by separate components, and, on the other hand, as a dynamic process consisting of nonlocalized interacting component processes. The first approach – the reductionist approach – assumes that research practice should be focused on finding the explanation of cognition in the specific functions of the components, whereas the second approach – the complex dynamic systems approach – assumes that we should focus on the underlying (complex) dynamic principles to understand cognition. In our belief, researchers often apply the approach that they and their close colleagues are most familiar and comfortable with. Often, this is the reductionist approach, which has been widely applied in social and behavioral sciences since the cognitive revolution in the 1950s, whereas the CDS approach has relatively slowly gained ground since the 1990s [30.7, 34, 46, 65, 81].

In this chapter, we started with an overview of some key differences between the approaches without taking a position in which of the two is the *better* one (Sects. 30.1 and 30.2). Subsequently, we discussed findings on real-time processes and long-term cognitive development (Sect. 30.3). First, we showed that cognitive performance measured in real-time reveals a structured pattern of variation (pink noise), which is difficult to reconcile with the reductionist view according to which a pattern of random variation would be expected. On the other side, it fits with the CDS

approach that cognitive performance emerges from ongoing component interactions, resulting in a time series in which short-term adaptations are embedded in slower but larger changes (Sect. 30.3.1).

Second, we demonstrated predictions that were focused on long-term cognitive development (i. e., scientific ability development). The reductionist approach assumes that cognitive development is shaped by the addition of relevant explanatory components or variables (e.g., genetic endowment, commitment, and teacher support), whereas the CDS approach proceeds from the idea that cognitive development is shaped by the ongoing *dynamic interaction* between the relevant variables. We showed that some typical properties of cognitive development, scientific talent development in particular, are generated by a model that is based on CDS principles (Sect. 30.3.2).

The plausible predictions that followed from the CDS approach suggest that cognition can best be explained by a *complex* model. Therefore, in light of future model building, we hope that researchers who apply the reductionist approach will keep an open mind regarding the potential of the CDS approach to capture the full richness of cognition and behavior. At the same time, CDS theorists should continue exploring whether a reductionist explanation may also fit with obtained results on (time-serial) cognitive processes. By doing so, researchers will be in a better position to provide a model to unlock the *mystery of the three pounds of matter between our ears*, and, importantly, how this is situated in our bodies and the environment we interact with. Given the current state of knowledge, we should keep in mind that the answer to this mystery, and the model we need, may not be *complicated*, but *complex*.

# 31. From Neural Circuitry to Mechanistic Model-Based Reasoning

Jonathan Waskan

Model-based reasoning in science is often carried out in an attempt to understand the kinds of mechanical interactions that might give rise to particular occurrences. One hypothesis regarding in-the-head reasoning about mechanisms is that scientists rely upon mental models that are like scale models in crucial respects. Behavioral evidence points to the existence of these mental models, but questions remain about the neural plausibility of this hypothesis.

This chapter will provide an overview of the psychological literature on mental models of mechanisms with a specific focus on the question of how representations that share the distinctive features of scale models might be realized by neural machinations. It is shown how lessons gleaned from the computational simulation of mechanisms and from neurological research on mental maps in rats can be applied to make sense of how neurophysiological processes might realize mental models.

The goal of this chapter is to provide readers with a general introduction to the central challenge facing those who would maintain that in-the-head model-based reasoning about mechanisms in science is achieved through the use of scale-model-like mental representations.

A central form of model-based reasoning in science, particularly in the special sciences, is model-based reasoning about mechanisms. This form of reasoning can be affected with the aid of external representational aids (e.g., formalisms, diagrams, and computer simulations) and through the in-the-head manipulation of representations. Philosophers of science have devoted most of their attention to the former, but the latter is arguably at the heart of most of what passes for explanatory understanding in science (Sect. 31.1). Psychologists have long theorized that humans and other creatures (e.g., rats) reason about spatial, kinematic, and dynamic relationships through the use of mental representations, often termed *mental models*, that are structurally sim-

ilar to scale models, though clearly the brain does not instantiate the very properties of a modeled system in the way that scale models do (Sect. 31.2). A key challenge facing this view is thus to show that brains are capable of realizing representations that are like scale models in crucial respects. There have been several failed attempts to show precisely this, but a look at how computers are utilized to model mechanical interactions offers a useful way of understanding how brains might realize mental representations of the relevant sort (Sect. 31.3). This approach meshes well with current research on mental maps in rats. In addition, it has useful ramifications for research in artificial intelligence (AI) and logic (Sect. 31.4), and it offers a promising account

of the generative knowledge that scientists bring to bear when testing mechanistic theories while also shedding

light on the role that external representations of mechanisms play in scientific reasoning (Sect. 31.5).

## 31.1 Mechanistic Reasoning in Science

A common reason that scientists engage in model-based reasoning is to derive information that will enable them to explain or predict the behavior of some target system. Model-based explanations provide scientists with a way of understanding how or why one or more *explanandum* occurrences came about. A good model-based explanation will typically provide the means for determining what else one ought to expect if that explanation is accurate – that is, it will enable one to formulate predictions so that the explanation may (within widely known limits) be tested. (One must bear in mind, however, that models are often accurate only in certain respects and to certain degrees [31.1].)

Model-based reasoning can, corresponding to the diversity of representational structures that count as models – including external scale models, biological models, mathematical formalisms and computer simulations – take many forms in science. As for what models represent, it is now widely accepted that mechanisms are one of the principal targets of model-based reasoning. This is most obviously true in the nonbasic sciences (e.g., biology, medicine, cognitive science, economics, and geology).

In philosophy of science, much of the focus on mechanisms has thus far been on the role they play in scientific explanation. The idea that *all* genuine scientific explanation is mechanistic began to gain traction in contemporary philosophy of science with the work of *Peter Railton*, who claimed that [31.2]

“if the world is a machine – a vast arrangement of nomic connections – then our theory ought to give us some insight into the structure and workings of the mechanism, above and beyond the capability of predicting and controlling its outcomes [...].”

Inspired by Railton, *Wesley Salmon* abandoned his statistical-relevance model of explanation in favor of the view that “the underlying causal mechanisms hold the key to our understanding of the world” [31.3]. In this view, an “explanation of an event involves exhibiting that event as it is embedded in its causal network and/or displaying its internal causal structure” [31.4]. Salmon was working in the shadow of Carl Hempel’s covering law model of explanation, according to which explanations involve inferences from statements describing laws and, in some cases, particular conditions. Salmon tended, in contrast, to favor an ontic account,

according to which explanations are out in the world. He thought that progress in understanding those explanations requires *exhibiting* the relevant mechanisms. However, even though he rejected representational and inferential accounts of explanation, he naturally recognized that reasoning about mechanisms, which requires representations (models), plays a big part in the process of exhibiting those mechanisms.

A more recent formulation of the mechanistic account of explanation is supplied by *Machamer et al.*, who claim that “Mechanisms are entities and activities organized such that they are productive of regular changes from start or set-up to finish or termination conditions” [31.5]. A central goal of science, in their view, is to formulate models, which take the form of descriptions of mechanisms that render target occurrences intelligible [31.5]:

“Mechanism descriptions show *how possibly*, *how plausibly*, or *how actually* things work. Intelligibility arises [...] from an elucidative relation between the *explanans* (the set-up conditions and intermediate entities and activities) and the *explanandum* (the termination condition or the phenomenon to be explained) [...].”

As with *exhibiting* for Salmon, the process of *elucidating* how set-up conditions lead to termination conditions requires a significant contribution from model-based reasoning.

*Bechtel* offers a related account of mechanisms. He claims [31.6]:

“A mechanism is a structure performing a function in virtue of its component parts. The orchestrated functioning of the mechanism is responsible for one or more phenomena.”

As compared with other mechanists, Bechtel is much more explicit about the role that model-based reasoning plays in science and about the diverse forms of representation that may be involved (e.g., descriptions, diagrams, scale models and animal models). He is, moreover, among the few to acknowledge the importance of *in-the-head* model-based reasoning. He suggests that its central form may involve a kind of mental animation. As *Bechtel* and *Wright* put it, “One strategy is to use imagination to put one’s representation of the mechanism into motion so as to visualize how

that phenomenon is generated” [31.7]. Bechtel claims that the representations underlying this mental animation process may have a structure similar to that of the diagrams scientist use in their thinking and to the animated renderings of computer simulations scientists construct to represent proposed mechanisms in action. As for prediction, he notes [31.6]:

“what the scientist advances is a representation of a mechanism [...] She or he then evaluates the representation by using it to reason about how such a mechanism would be expected to behave under a variety of circumstances and testing these expectations against the behavior of the actual mechanism.”

In other words, once the scientist possesses a model of the mechanisms that may be responsible for an occurrence, which may take the form of a *mental* model,

## 31.2 The Psychology of Model-Based Reasoning

Given the potentially crucial role that mental models play in the process of mechanistic explanation and prediction, it may be that we cannot hope to attain a truly adequate, deep understanding of science without first understanding how the mental modeling process works. An obvious way of going about making sense of the role mental models play in science is to inquire into the nature of those models themselves. A good question to ask here is: What form must our mental models take if they are to play the role that they do in science? One increasingly popular answer has its origins in *Craik’s* landmark monograph, *The Nature of Explanation*. Regarding everyday reasoning, *Craik* suggests [31.9]:

“If the organism carries a *small-scale model* of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise [...] and in every way to react in a much fuller, safer, and more competent manner to the emergencies which face it.”

In *Craik’s* view, scientific explanation is just an extension of this everyday reasoning process – that is, it involves the construction of internal world models that are akin to scale models. (*Bechtel* is explicit in crediting *Craik*, when he maintains that the use of mental models in scientific reasoning about mechanisms is to be understood by analogy with the use of external images and scale models [31.6]. Fellow mechanists *Nancy Ners-*

he or she may then use it to formulate predictions in order to test that model.

While external representational artifacts may sometimes be required in order to achieve explanatory understanding of how a mechanism could produce a given phenomenon, plausibly those artifacts are not themselves sufficient for explanatory understanding. (For evidence that there is a crucial psychological component to explanatory understanding, see [31.8].) Instead, representational artifacts may have the important function of facilitating understanding by enhancing the scientist’s ability to mentally simulate the process by which the proposed mechanism would produce the target phenomenon. (As shown in Sect. 31.4.2, external representational aids may also enable forms of reasoning that would otherwise (e.g., due to the complexity of the mechanism) be impossible.) Through manipulation of those mental simulations, scientists may also discover novel predictions of a given model.

*essian* [31.10] and *Paul Thagard* [31.11] also credit *Craik*.)

What may be considered the first attempt to put this view to experimental scrutiny came in the prelude to the cognitive revolution with *Edward Tolman’s* seminal studies of spatial navigation in rats [31.12]. In his most famous experiment, *Tolman’s* team placed rats in a simple alley maze, similar to the one depicted in Fig. 31.1a, and rewarded the animals with food when they reached the end. After learning to perform the task without hesitation, the maze was replaced with a radial maze similar to the one in Fig. 31.1b, where the alley that the rats had previously learned to traverse was blocked. Upon discovering this, the vast preponderance of rats then chose the alley that led most directly to where the food source had been in previous trials. On the basis of such experiments, *Tolman* concluded that rats navigate with the

Fig. 31.1a,b Alley maze (a) and radial maze (b) (after [31.12])

aid of cognitive maps of the relative spatial locations of objects in their environment.

Later, *Shepard* and *Metzler* would show that the time it takes for people to determine if two three-dimensional (3-D) structures have the same shape is proportional to the relative degree of rotational displacement of those structures [31.13]. One neat explanation for this finding is that people engage in the mental rotation of 3-D models of the two structures until they are aligned in such a fashion as to enable easier comparison. In another landmark study of mental imagery, *Kosslyn* showed that reaction times for scanning across mental images of a map was proportional to distance, but not to the number of intervening objects, suggesting that spatial reasoning is better explained by a process akin to scanning across a real map than to a process of sentence-based reasoning (e.g., working through a list structure) [31.14].

All of this research points to the existence of mental models of two-dimensional (2-D) and 3-D spatial relationships, but to support the full range of inferences implicated in mechanistic model-based scientific reasoning, mental models would need to capture kinematic and dynamic relations as well. There is some support for the existence of these models as well. For instance, *Schwartz* and *Black* observed similar, proportional reaction times when subjects were asked to determine whether or not a knob on one gear would, when that gear is rotated, fit into a groove on a connecting gear (Fig. 31.2a) [31.15]. *Schwartz* and *Black* found, moreover, that subjects were able to “induce patterns of behavior from the results depicted in their imaginations” [31.16]. Subjects might, for instance, infer and remember that the second in a series of gears will, along with every other even-numbered gear, turn in the opposite direction of the drive gear (Fig. 31.2b). Having inferred this through simulation, the information becomes stored as explicit knowledge, thereby eliminating the need to generate the knowledge anew for each new application.

In addition, [31.17, 18] have shown that mental modeling of dynamic relationships is often affected in piecemeal fashion, a process that is much better suited for tracing a sequence of interactions through a system than for simulating collections of dynamic effects all at

once. All of this research fits well with *Norman*'s early assessment of mental models. He notes [31.19]:

- “1. Mental models are incomplete.
2. People’s abilities to *run* their models are severely limited.
3. Mental models are unstable: People forget the details of the system they are using [ . . . ]
4. Mental models do not have firm boundaries: similar devices and operations get confused with one another.”

These limitations on the human ability to construct and manipulate mental models surely have a great deal to do with more general limitations on the capacity of human working memory and with the high cognitive load associated with creating, maintaining, and manipulating mental models.

In everyday reasoning with mental models, the behaviors of the component structures in our models will not typically be tied in any direct way to fundamental physical laws (e.g., Newtonian, quantum mechanical, or relativistic). Rather, many of the kinematic and dynamic principles governing object behavior in our mental simulations will be rooted in early experiences of collisions, impenetrability, balance and support, projectiles, blocking, and so forth [31.20–22]. In addition, in everyday reasoning, and even more so in scientific reasoning about mechanisms, many of the behaviors of the components of our models will not be the result of early learning. Some of these will be one-off *brute* events – such as a meteor striking the earth, a gene mutating, or a latch coming undone – for which one does not have or require (in order to formulate a satisfactory answer to the question of why the *explanandum* occurred) any deeper explanation. Such occurrences might be imposed upon a mental model in much the same way that one would impose them – that is, through direct intervention – on a scale model. In the same way, one could also impose newly learned or hypothesized regularities on a model. Some of these might be discovered through simple induction (one might notice that one’s car engine becomes louder in cold weather) or through prior model-based reasoning (as in *Schwartz*’ study with gears). However, when formulating mechanical explanations, particularly in science, one sometimes simply hypothesizes, as a way of making sense of the available data, that a particular regularity obtains. A good example of this is the way that the hypothesis of periodic geomagnetic pole flipping was used to make sense of the patterns of magnetization in rocks found lateral to mid-ocean rifts [31.1]. Such ideas accord well with recent work regarding mechanistic explanation in the philosophy of science, where it is generally recognized that our models of mechanisms

**Fig. 31.2a,b** Knob and groove on connecting gears (a), (after [31.15]). Gears in series (b), (after [31.16])

typically bottom out at brute *activities* [31.5] or *functions* [31.6].

The above empirical research sheds light on the properties of the models we use to reason about mechanisms in everyday life and in science. There is, in addition, a great deal of research that simply hypothesizes that we do utilize such models to understand other cognitive processes such as language comprehension, concepts [31.23], or learning [31.24–30].

The hypothesis of mental models has also been invoked by *Johnson-Laird* to explain deductive reasoning, though here the term *mental model* is used somewhat differently than it is in the research cited above [31.31]. (Below, I explain in greater depth, the contrast between deductive reasoning more generally and the mental models approach to mechanistic reasoning espoused here.) Like many proponents of mental models, *Johnson-Laird* and *Byrne* do claim to be directly inspired by Craik, an inspiration that shows up in their suggestion that mental models have “a structure that is remote from verbal assertions, but close to the structure of the world as humans conceive it” [31.32]. However, if we look more closely at the way in which *Johnson-Laird* employs the mental models hypothesis in accounting for reasoning processes (deductive, inductive, and abductive), it begins to look as though he has something very different in mind. For instance, with regard to deductive reasoning – that is, reasoning

that mainly involves the semantic properties of top-neutral logical operators such as *if...then...*, *and*, *all*, and *some* – *Johnson-Laird* proposes that we reason internally through a process not unlike the formal method of truth table analysis. For instance, on *Johnson-Laird*’s view, the conditional, *If the door is pushed, then the bucket will fall*, would be mentally represented as something like the following spatial array, which lists those scenarios (models) that would be consistent with the truth of the statement ( $\neg$  here signals negation)

door pushed	bucket falls
$\neg$ door pushed	bucket falls
$\neg$ door pushed	$\neg$ bucket falls

If presented with the additional premise, *The bucket did not fall*, one could then eliminate all but the last of these models, enabling a valid deduction to *The door was not pushed*. The formal, topic-neutral nature of this strategy means that it works in exactly the same way regardless of what items (e.g., balloons, satellites, or mice) we are reasoning about. To say nothing of the viability of the approach, *Johnson-Laird*’s proposals regarding deductive (as well as inductive and abductive) reasoning thus seem, except insofar as they appeal to such structures as *spatial* arrays, at odds with his avowed view that mental models have a structure closer to the world than to our descriptions of it.

### 31.3 Mental Models in the Brain: Attempts at Psycho-Neural Reduction

While there has been considerable research on mental models in recent years, what has been very slow to materialize is a demonstration that brains do or, what is even more worrisome, *that they could* harbor mental models that are like scale models in crucial respects. One can see how this might raise concerns about the mental models hypothesis. After all, if brains cannot realize such models then the above explanatory appeals to mental models come out looking misguided from the outset. At the same time, there is a competing hypothesis which faces no such difficulties. In its most audacious form, it is the proposal that all of cognition is affected through formal computational operations – that is, operations that involve the application of syntax-sensitive inference rules to syntactically structured (sentential) representations.

Proponents of the computational theory of cognition know that they have nothing to fear, at least with regards to the matter of whether or not brains are capable of realizing the relevant kinds of syntax-crunching operations. *McCulloch* and *Pitts* showed,

decades ago, that collections of neuron-like processing units can implement logic gates and, in principle, a universal Turing machine [31.33]. Indeed, it was in no small part because von Neumann recognized the functional similarities between *McCulloch–Pitts* neurons and electronic switches (e.g., transistors) that he was inspired to create the first fully programmable computers, ENIAC and EDVAC. More recently, it has been shown that recurrent neural networks are, memory limitations notwithstanding, capable of implementing computers that are Turing complete [31.34]. There is, then, no longer any doubt that it is possible to bridge the divide between neural machinations and syntax-crunching operations.

In contrast, a satisfactory demonstration that neural machinations might realize mental models – that is, nonsentential mental representations that are like scale models in crucial respects – has proven far more elusive. Indeed, difficulties arise the moment one tries to specify what the *crucial respects* might be, as is evidenced by the fact that each past attempt at doing this

has been argued, not without justification, to run afoul of one or the other of the following two desiderata:

1. An adequate account of mental models must be compatible with basic facts about the brain.
2. An adequate account of mental models must be specific enough to distinguish mental models from other kinds of representation (sentential representations).

Again, this is no small matter, for given that brains are known to be capable of formal computational operations, if it cannot be shown that they are also capable of realizing mental models, this will cast doubt on all those psychological theories mentioned above that advert to mental models. This is a concern made all the more pressing by the fact that proponents of the computational theory of cognition have no shortage of alternative explanations for the behavioral data cited in support of mental models. For instance, to the extent that people report having model-like phenomenology, this might be dismissed as a mere *epiphenomenon* of the actual, underlying computational operations. Similarly, to the extent that behavioral data, such as reaction times, suggests reliance upon model-like mental representations that undergo continuous transformations, this might be chalked up to demand characteristics (subjects may feel compelled to pretend that they are scanning a map). Some of these specific objections could be vulnerable in that they give rise to their own testable predictions [31.35], but, as explained below, proponents of the computational theory have an ace up their sleeve, for computational accounts are flexible enough to handle virtually any behavioral data. All of this is quite general, so let us turn to some of the specific attempts to spell out the distinctive features of mental models.

### 31.3.1 From Structural to Functional Isomorphism

As we have seen, from the outset, the claim made on behalf of putative mental models is that they are *like* scale models in one or more crucial respects. Of course, scale models are themselves *like* the actual systems they represent in a very obvious respect: They instantiate the very same properties as what they represent. It is thus no surprise that the dominant theme in attempts to specify what makes mental models *models* is the invocation of one form or another of isomorphism between mental models, scale models and the modeled world.

#### Mere Isomorphism

The most straightforward form of isomorphism invoked in this literature is what might be termed *bare* isomorphism, or isomorphism *simpliciter*, which is

a purported relationship between mental models and what they represent. Despite initial appearances, this is the form of isomorphism that *Craik* seems to have had in mind. He claims, for instance: “By a model we thus mean any physical or chemical system which has a similar relation-structure to that of the process it imitates” [31.9]. Latter-day proponents of this proposal include *Cummins* [31.36] and *Hegarty*, who, in an attempt to summarize the dominant view of mental models in psychology, notes [31.18]:

“a mental model (or situation model) is a representation that is isomorphic to the physical situation that it represents and the inference processes simulate the physical processes being reasoned about.”

One serious concern about this approach is that it is too liberal, which is to say that it leads one to classify too wide a range of representations as *models*. Consider, for instance, that one of *Craik*’s favored examples of a representation with a *similar relation structure* to what it represents is Kelvin’s Tide Predictor, a device that consists of an ingenious system of gears and pulleys arranged so as to support truth-preserving inferences regarding the tides (Fig. 31.3). Says *Craik* [31.9],

“My hypothesis then is that thought models, or parallels, reality—that its essential feature is [...] symbolism, and that this symbolism is largely of the

**Fig. 31.3** Kelvin’s first tide predicting device (photo by William M. Connoley)

same kind as that which is familiar to us in mechanical devices which aid thought and calculation.”

This, of course, is no different from what proponents of the computational theory of cognition currently maintain. After all, any syntax-crunching system capable of supporting truth-preserving inferences with respect to a given physical system will have to be isomorphic with it – that is, there will have to be correspondences between the parts and relations in the system and the components of the representation – in ways that get preserved over the course of computation. To that extent, one might even say that the inference process *simulates*, or even *pictures* [31.37], the process being reasoned about. In short, then, the proposal that mental models are merely isomorphic with what they represent is thus far too vague to satisfy desideratum (2.) above. Indeed, it is for this very reason that researchers have tried to find a more restrictive notion of isomorphism, one that can distinguish models from sentential representations.

#### Physical Isomorphism

Perhaps the most restrictive such notion is that of *structural* [31.38] or *physical* [31.39] isomorphism, which involves instantiating the very same properties, and arrangements thereof, as the represented system. This appears to be the kind of isomorphism that *Thagard* has in mind when he claims [31.11] (also see [31.40]):

“Demonstrating that neural representation can constitute mental models requires showing how they can have the same relational structure as what they represent, both statically and dynamically.”

Thagard cites Kosslyn’s research as indicative of how this demand might be met, and in Kosslyn too, we do find frequent appeals to structural isomorphisms. For instance, noting the retinotopic organization of areas of visual cortex that are implicated in mental imagery, *Kosslyn* claims, “these areas represent depictively in the most literal sense [...]” [31.41].

Unfortunately, the postulation of physically isomorphic mental representations is highly suspect for several reasons. To start with, the kind of retinotopy that one finds in areas such as V1 is highly distorted relative to the world due to the disproportionate amount of cortex devoted to the central portion of the retina (the fovea). A square in the visual field is thus not represented in the cortex by sets of neurons that lie in straight, let alone in parallel, lines. Moreover, visual representation seems not to be carried out through the activity of any single retinotopically organized neural ensemble. Rather, vision involves the combined activity of a variety of systems that are, to a considerable extent, anatomically

and functionally distinct [31.42–44]. Lastly, the kind of retinotopy pointed out by Kosslyn is restricted to two spatial dimensions, and a 2-D representational medium cannot realize representations that are physically isomorphic with what they represent in three dimensions. Nor, a fortiori, can such a medium realize representations that are physically isomorphic in both 3-D and causal respects. Crudely put, there are no literal buckets, balls, or doors in the brain. (Perhaps it is worth noting, as well, how inessential structural isomorphism is to information processing in neural networks, even in the case of 2-D retinotopic maps. The relative physical locations of neural cell bodies seems irrelevant when compared to the patterns of connectivity between neurons, the strengths and valences of connections, and the schemes of temporal coding the neurons employ. One would expect then that, so long as all of this is preserved, cell bodies might be tangled up in arbitrary ways without affecting processing.)

#### Functional Isomorphism

The main problem with the appeal to physical isomorphism, one that has long been appreciated, is that it fails to satisfy desideratum (1.). As *Shepard* and *Chipman* note, “With about as much logic, one might as well argue that the neurons that signal that the square is green should themselves be green!” [31.38]. Recognizing this, and recognizing the weakness of appeals to mere isomorphism, *Shepard* and *Chipman* push for the following moderate notion of isomorphism [31.38, italics added for emphasis]:

“isomorphism should be sought-not in the first-order relation between (a) an individual object, and (b) its corresponding internal representation-but in the second-order relation between (a) the relations among alternative external objects, and (b) the relations among their corresponding internal representations. Thus, although the internal representation for a square need not itself be square, it should [...] at least have a *closer functional relation* to the internal representation for a rectangle than to that, say, for a green flash or the taste of persimmon.”

The appeal to second-order isomorphism would, they hoped, provide an alternative to physical isomorphism that is both consistent with basic brain facts (desideratum (1.)) and distinct from sentential accounts (desideratum (2.)).

Another moderate account of isomorphism was put forward at the same time by *Huttenlocher* et al. [31.45]. They had a particular interest in how subjects make ordering inferences (viz., those involving the ordering of three items along such dimensions as size, weight and

height) like this one

Linus is taller than Prior.  
 Prior is taller than Mabel.  
 ∴ Linus is taller than Mabel.

*Huttenlocher* et al. suggested that subjects might use representations that “are isomorphic with the physically realized representations they use in solving analogous problems (graphs, maps, etc.) [...]” [31.45]. The essence of their proposal was that the mental representations that subjects form in order to solve such problems might function like spatial arrays rather than like sentences. For instance, what seems distinctive about *external* sentential representations of three-term ordering syllogisms like the one above is that, because each premise is represented in terms of a distinct expression, terms that denote particular individuals must be repeated. On the other hand, when such inferences are made with the aid of external spatial arrays, the terms need not be repeated. For instance, one can make inferences about the taller-than relation on the basis of the left-of relation with the help of marks on a paper like these

L P M

In fact, the introspective reports obtained by *Huttenlocher* et al. did support the idea that subjects were constructing the functional equivalents of spatial arrays – for instance, subjects reported that symbols representing individuals were not repeated – and on this basis they claimed that subjects might be carrying out three-term ordering inferences using mental representations that *function* like actual spatial arrays and unlike lists of sentences (see also [31.40]). This kind of isomorphism is thus sometimes termed *functional* isomorphism [31.39].

*Shepard* and *Chipman* [31.38] and *Huttenlocher* et al. [31.45] were clearly after a notion of isomorphism that satisfies desideratum (1.). Unfortunately, the solutions they offer appears, at least at first glance, to run afoul of desideratum (2.) – that is, appeals to functional isomorphism, of either the first or second-order variety, seem not to distinguish between computational representations and model-like representations. *Huttenlocher* et al. were among the first to suspect this. They note [31.45]:

“It is not obvious at present whether any theory which postulates imagery as a mechanism for solving problems can or cannot, in general, be reformulated in an abstract logical fashion that, nevertheless makes the same behavioral predictions.”

*Anderson* is generally credited with confirming this suspicion by pointing out the possible tradeoffs that can be made between assumptions about representational structure and those concerning the processes that operate over the representations [31.46]. He showed that the possible structure-process tradeoffs render computational accounts flexible enough to handle virtually any behavioral finding. Most have since endorsed his thesis that it is, at least after the fact, always possible to “generate a propositional (i. e., sentential) model to mimic an imaginal model” [31.46]. Alternatively, as *Palmer* puts it, if you create the right sentential model it will be functionally isomorphic to what it represents in just the sense that a nonsentential model is supposed to be [31.39].

### Imagery and Perception

One last way in which one might try to satisfy the above desiderata, at least with regard to spatial models, is to point out that visual mental imagery involves the utilization of visual processing resources. *Brooks* [31.47] and *Segal* and *Fusella* [31.48], for instance, discovered that performance on visual imagery tasks is diminished when subjects must perform a concurrent visual processing task but not when they perform an auditory task – that is, they found that there is interference between mental imagery and auditory perception but not between mental imagery and visual perception (see also [31.36]). However, if these findings are meant to provide a model-based alternative to computational theories, the attempt would appear to have the same fundamental flaw as the appeal to functional isomorphism. As *Block* notes, because perceptual processing can, in principle, also be explained in terms of computational processes [31.49] (see also [31.46, 50]):

“the claim that the representations of imagery and perception are of the same kind is irrelevant to the controversy over pictorialist versus descriptionalist interpretation of experiments like the image scanning and rotation experiments [...]”

That is, the claim that imagery utilizes visual processing resources fails to satisfy desideratum (2.).

### 31.3.2 Distinctive Features of Scale Models

The overall realization problem facing putative mental models, then, is just that it has proven exceedingly difficult to specify what sorts of representational structures mental models are in a way that is consistent with basic brain facts but that also distinguishes models from sentential representations. In order to finally see our way past these concerns, it will be helpful if we first take stock of a handful of features that are widely taken, even

by proponents of the computational theory of mind, to distinguish *external* images and scale models from sentential representations. Three such features concern the sorts of entities, properties, and processes that each form of representation is naturally suited for representing:

1. Images and scale models are not naturally suited for representing abstract entities, properties, and processes (e.g., war criminal, ownership, or economic inflation). They are much better suited for representing concrete entities, properties, and processes (e.g., a bucket, one object being over another, or compression).
2. Images and scale models are not naturally suited for representing general categories (e.g., triangles or automobiles). They are better suited for representing specific instances of categories (Note: Genera differ from abstracta in that the former can be concrete (e.g., rocks) and the latter can be specific (e.g., the enlightenment)).
3. Images and scale models are not naturally suited for singling out specific properties of specific objects [31.37, 50]. For instance, it would be difficult, using a scale model, to represent just the fact that Fred's car is green, for any such model will simultaneously represent many other properties, such as the number of doors and wheels, the body type, and so on.

In contrast, sentential representations (those constructed using natural and artificial languages) have little trouble representing abstracta (e.g., *war criminal*), genera (*triangle*), and specific properties of specific objects (e.g., *Fred's car is green*).

While images and scale models are relatively disadvantaged in the above respects, they are much better suited for supporting inferences regarding the consequences of alterations to specific, concrete systems. The fact that syntax-crunching systems are quite limited in this regard first came to light as a consequence of early work in formal-logic-inspired, sentence-and-rule-based AI. The general problem confronting syntax-crunching approaches came to be known as the *frame problem* [31.51].

In its original formulation, the frame problem had much to do with the challenge of endowing a sentence-and-rule-based representational system with the ability to anticipate what will *not* change following an alteration to the world (e.g., tipping over a bottle changes its orientation but *not* its color). Today, however, the frame problem is regarded as something more general – namely, the problem of endowing computational systems (and other artifacts) with the kind of com-

monsense knowledge that the average human possesses about what will change and what will stay the same following alterations to the objects in the world. As Hayes puts it [31.52]:

“The frame problem arises in attempts to formalise problem-solving processes involving interactions with a complex world. It concerns the difficulty of keeping track of the consequences of the performance of an action in, or more generally of the making of some alteration to, a representation of the world.”

The frame problem can actually be broken down into at least two component problems, the prediction problem [31.53] and the qualification problem [31.54].

As it confronts computational devices, the prediction problem can be summed up as follows: In order to support inferences about the consequences of alterations to even simple physical systems, a sentence-and-rule system would have to contain innumerable rules that explicitly specify how objects will behave relative to one another following each of innumerable possible alterations. For a simple illustration, consider what we all know about the consequences of different ways of altering the items in Fig. 31.4. We know, for example, what would happen were we to use the bucket to throw the ball through the open doorway, were we to place the bucket over the ball and slide the bucket through the doorway, were we to set the bucket containing the ball atop the slightly ajar door and then shove the door open, and so on indefinitely. To endow a sentence-and-rule system with the ability to predict the consequences of these various alterations, one would have to build in, corresponding to each one, a separate data structure

**Fig. 31.4** A toy world: A doorway, a bucket, and a ball (after [31.55])

specifying the starting conditions, the alteration, and the consequences of that alteration. If these take the form of conditional statements, the system could then make inferences utilizing domain-general (e.g., topic-neutral, deductive) machinery. Alternatively, the information could be encoded directly as domain-specific inference rules (e.g., production-system operators). Either way, from an engineering standpoint, the problem that quickly arises is that no matter how many of these statements or rules one builds into the knowledge base of the system, there will generally be countless other bits of commonsense knowledge that one has overlooked. Notice, moreover, that scaling the scenario up even slightly (e.g., such that it now includes a board) has an *exponential* effect on the number of potential alterations and, as such, on the number of new data structures that one would have to incorporate into one's model [31.53]. As Hayes says [31.52]:

“One does not want to be obliged to give a law of motion for every aspect of the new situation [...] especially as the number of frame axioms increases rapidly with the complexity of the problem.”

Moreover, as explained in the manual for a past incarnation of the production system Soar [31.56]:

“when working on large (realistic) problems, the number of operators (i.e., domain-specific rules) that may be used in problem solving and the number of possible state descriptions will be very large and probably infinite.”

As if the prediction problem were not problem enough, it is actually compounded by the other facet of the frame problem, the qualification problem [31.54]. This is because in order to capture what the average human knows about the consequences of alterations to a physical system, not only would innumerable distinct conditionals or inference rules be required, but each would have to be qualified in an indefinite number of ways. Notice, for instance, that placing the bucket over the ball and sliding it through the doorway will result in the ball being transferred to the other side of the wall, but *only if it is not the case that* there is a hole in the floor into which the ball might fall, there is a hole in the bucket through which it might escape, the ball is fastened securely to the floor, and so on indefinitely. To once again quote Hayes, “Almost any general belief about the result of his own actions may be contradicted by the robot's observations [...] there are no end to the different things that can go wrong, and he cannot be expected to hedge his conclusions round with thousands of qualifications” [31.52]. Thus, to capture what the average human knows, if only implicitly, about the consequences of this one alteration, all of the relevant

qualifications would have to be added to the relevant sentence or rule. Once again, in realistic situations, the challenge of specifying all of the qualifications is magnified exponentially.

The general failing of sentence-and-rule-based representations that the frame problem brings to light is that they only support predictions concerning the consequences of alterations and the defeaters of those consequences if those alterations, consequences, and defeaters have been spelled out, antecedently and explicitly, as distinct data structures. Representations of this sort – that is, representations that require distinct structures to support predictions regarding the consequences of each type of alteration to the represented system – are sometimes termed *extrinsic* representations. (The intrinsic-extrinsic distinction discussed here was introduced by Palmer [31.39] but modified by Waskan [31.57, 58].)

It is worth a quick digression to note that, while the terminology has changed, these general concerns about the limitations of extrinsic representations antedate work in contemporary AI by over three hundred years. They show up, for instance, in Descartes' *best-explanation* arguments for dualism in his *Discourse on the Method*. Descartes there despairs of there ever being a mechanical explanation for, or an artifact that can duplicate, the average human's boundless knowledge of the consequences of interventions on the world [31.59]:

“If there were machines which bore a resemblance to our bodies and imitated our actions [...] we should still have two very certain means of recognizing that they were not real men [...] (Firstly, humans have the ability to converse.) Secondly, even though some machines might do some things as well as we do them [...] they would inevitably fail in others, which would reveal that they are acting not from understanding, but only from the disposition of their organs. For whereas reason is a universal instrument, which can be used in all kinds of situations, these organs need some particular action; hence it is for all practical purposes impossible for a machine to have enough different organs to make it act in all the contingencies of life in the way in which our reason makes us act.”

Descartes thought that to match wits with even a *dull-witted* human, any natural or artificial device would need, *per impossibile*, to rely upon an infinite number of specific sensory-motor routines – which bear a striking resemblance to production-system operators – for each new situation the device might confront. What Descartes could not imagine, because he thought that all such knowledge had to be represented explic-

itly, was the possibility of (to use Chomsky's term) a *generative* inference mechanism – that is, one that embodies boundless knowledge of implications through finite means.

What Descartes failed to notice was that there were already artifacts (i. e., scale models) that exhibited the requisite generativity. Indeed, in contemporary AI, the benefits of an appeal to scale-model-like representations are now well known. Starting with the prediction problem, one can use a reasonably faithful scale model of the setup depicted in Fig. 31.4 in order to predict what would happen were one to use the bucket to throw the ball through the open doorway, were one to place the bucket over the ball and slide the bucket through the doorway, were one to set the bucket containing the ball atop the slightly ajar door and then shove the door open, and so on indefinitely. To use *Haugeland's* terms, the side effects of alterations to such representations mirror the side effects of alterations to the represented system *automatically* [31.60] – which is to say, without requiring their explicit specification. (This only holds, of course, to the extent that the model is a faithful reproduction. Unless the model is a perfect replica, which includes being *to* scale, there will be some limits on inferential fidelity, though this does not undermine the claim that scale models are generative.) Notice also that incremental additions to the represented system will only have an incremental effect on what needs to be built into the representation. The addition of a board to the system above, for instance, can be handled by the simple addition of a scale model of the board to the representation.

Nor do scale models suffer from the qualification problem. To see why, notice that much of what is true of a modeled domain will be true of a scale model of that domain. For instance, with regards to a scale model of the setup in Fig. 31.4, it is true that the scale model of the ball will fall out of the scale model of the bucket when it is tipped over, but only if the ball is not wedged into the bucket, there is no glue in the bucket, and so on indefinitely. Just like our own predictions, the predictions generated using scale models are implicitly qualified in an open-ended number of ways. With scale models, all of the relevant information is *implicit* in the models and so there is no need to represent it all explicitly using innumerable distinct data structures. Representations of this sort are termed *intrinsic* representations. Summing up, scale models are immune to the frame problem, for one can use them to determine, on an as-needed basis, both the consequences of countless alterations to the modeled system and the countless possible defeaters of those consequences – that is, one simply manipulates the model in the relevant ways and reads off the consequences.

### 31.3.3 Does Computational Realization Entail Sentential Representation?

The above distinguishing features can help us to know better whether we are dealing with model-like or sentence-like representations and, ultimately, to appreciate how one might bridge the gap from neurophysiology to mental models. As noted above, a similar bridge was constructed from neurophysiology to computational processes by showing that artifacts (e.g., collections of McCulloch–Pitts neurons or wires and transistors) characterized by a complex circuitry not unlike that of real brains can be configured so as to implement, at a higher level of abstraction, processes that exhibit the hallmarks of traditional syntax-crunching. Because neurons have similar information-processing capabilities as these artifacts, implementing a set of formal operations on an electronic computer is already very nearly an existence proof that brain-like systems can realize the same set of operations.

Might this strategy offer a template for constructing a similar bridge to high-level models? There is surely no shortage of computer simulations of mechanical systems, and at least as they are depicted on a computer's display, these simulations look for all the world like images and scale models. Many would argue, however, that this approach to bridging the neuron-model divide is a nonstarter. The worry, in short, is that it fails to satisfy desideratum (2.) above. To see why, it will be helpful to look at the kinds of computational models of mental imagery offered up by researchers such as *Kosslyn* [31.14] and *Glasgow* and *Papadias* [31.61].

*Kosslyn's* model of mental imagery has several components [31.14]. One is a long-term store that contains sentential representations of the shape and orientation of objects. These descriptive representations are utilized for the construction of representations in another component, the visual buffer, which encodes the same information in terms of the filled and empty cells of a computation matrix. The cells of the matrix are indexed by  $x$ ,  $y$  coordinates, and the descriptions in long-term memory take the form of polar coordinate specifications (i. e., specifications of the angle and distance from a point of origin) of the locations of filled cells. Control processes operate over the coordinate specifications in order to perform such functions as panning in and out, scanning across, and mental rotation.

One distinctive feature of actual (e.g., paper-and-ink) spatial matrix representations is that they embody some of the very same properties and relationships (spatial ones) as – which is just to say that they are physically isomorphic with – the things they represent. But *Kosslyn's* computational matrix representa-

tions (CMRs) are clearly not physically isomorphic with what they represent. After all, Kosslyn's visual buffer representations are not *real* matrix representations that utilize cells arranged in Euclidean space; they are *computational* matrix representations. To be sure, modelers may sometimes see literal pictures on the output displays of their computers, but the representations of interest are located in the central processing unit (CPU) (viz., in random-access memory (RAM)) of the computer running the model. Accordingly, the control operations responsible for executing representational transformations like rotation do not make use of inherent spatial constraints, but rather they operate over the coordinate specifications that are stored in the computer's memory. Details aside, at a certain level of description, there can be no doubt that the computer is implementing a set of syntax-sensitive rules for manipulating syntactically structured representations; this is what computers *do*. As Block puts it, "Once we see what the computer does, we realize that the representation of the line is *descriptive*" [31.49]. The received view, then, a view that has gone nearly unchallenged, is that if a representation of spatial, kinematic, or dynamic properties is implemented using a high-level computer program, then the resulting representations must be *sentential* in character [31.49, 62, 63]. (That Fodor shares this sentiment is suggested by his claim that "if [...] you propose to co-opt Turing's account of the nature of computation for use in a cognitive psychology of thought, you will have to assume that *thoughts themselves have syntactic structure*" [31.64]).

It would thus seem that the strongest claim that can possibly be supported with regard to CMRs is that they *function* like images. Yet, as Anderson notes, it is always possible, through clever structure-process tradeoffs, to create a *sentential* system that mimics an *imagistic* one [31.46]. Indeed, rather than supporting the mental models framework, one might well take computer simulations of mental modeling as concrete evidence for Anderson's claim. Likewise, there is a case to be made that CMRs and their brethren are, unlike scale models, *extrinsic* representations [31.62]. After all, the computers that run them implement syntax-sensitive rules that provide explicit specifications of the consequences of alterations. This is no small matter. From the standpoint of cognitive science, one of the most important virtues of the hypothesis that we utilize mental representations akin to scale models was that scale models constitute *intrinsic* representations of interacting worldly constraints and are thus immune to the frame problem. One could, then, be forgiven for thinking that any attempt to build a bridge from neurons to models by following the template set by computational theories – that is, by noting that certain computational

artifacts instantiate the relevant kind of processing – will be doomed to fail from the outset.

### 31.3.4 What About POPI?

Consider, however, that upon gazing directly at a vast collection of electrical or electrochemical circuits, one will see no evidence of the harboring or manipulation of *sentential* representations. In *Monadology*, Leibniz turned an analogous observation about perceptual experience into an objection to materialism [31.65]:

"It must be confessed, moreover, that perception, and that which depends on it, are inexplicable by mechanical causes, that is, by figures and motions. And, supposing that there were a mechanism so constructed as to think, feel and have perception, we might enter it as into a mill. And this granted, we should only find on visiting it, pieces which push one against another, but never anything by which to explain a perception."

A similar objection might be leveled regarding computational processes. Again, one sees no evidence of this kind of processing when one looks at electronic or electrochemical circuitry. Clearly something has gone wrong.

What Leibniz overlooked – and this may be because he lacked the conceptual tools made available by the information age – was a grasp of the principle of *property independence* (POPI). The basic idea of POPI is that properties characterizing a system when it is studied at a relatively low level of abstraction are often absent when it is studied at a higher level, and vice versa. It is POPI that allows computer scientists to say that a system which is characterized by electronic switches and relays at level  $n$  may nevertheless be best described in terms of the storing of bits of information in numerically addressable memory registers at level  $n + 1$  and in terms of the application of syntax-sensitive rules to syntactically structured representations at level  $n + 2$ . It is also the very thing that enables proponents of computational theories of cognition to say that brains and computational artifacts are, despite superficial appearances, capable of implementing the application of syntax-sensitive rules to syntactically structured representations.

However, when proponents of computational theories of cognition insist that computational implementation (e.g., of CMRs) entails *sentential* representation, they are turning their backs on the very principle that enabled them to bridge divide between low-level circuitry and high-level computational operations; they are turning their back on POPI. Indeed, nothing about POPI entails that all syntax-crunching systems must be char-

acterized in terms of sentences and inference rules at the *highest* level of abstraction. POPI thus opens up at least logical space for systems that engage in syntax-crunching operations at one level but that harbor and manipulate nonsentential models at a higher level.

In point of fact, in this logical space reside actual systems, including finite element models (FEMs). These were first developed in the physical (e.g., civil and mechanical) engineering disciplines for testing designs, but they have since become a staple tool in the sciences for exploring the ramifications of theories, generating novel predictions, and facilitating understanding. For our current purposes, what matters most about FEMs is that they provide an existence proof that computational processes can realize nonsentential representations that are like scale models and unlike sentential representations in all of the crucial respects listed above.

To see why, notice first that there are (among others) two important levels of abstraction at which a given FEM may be understood. As with scale models, one may understand FEMs at the relatively low level of the principles that govern their implementing medium. What one finds at this level are sentential specifications of coordinates (e.g., for polygon vertices) along with rules, akin to the fundamental laws of nature, which constrain how those coordinates may change (e.g., due to collisions and loads) (Fig. 31.5). (For a close analogy, think the basic rules of Conway's Game of Life.) When a given model is *run*, at this low level one finds a massive number of iterative number crunching operations. Not unlike Leibniz, enemies of the idea of computationally realized nonsentential models have seized upon this low level with their suggestion that computational systems harbor only sentential representations. At this level, however, it is not even obvious that we are dealing with representations (worldly objects and properties) at all, any more than we are, for instance, when we fixate upon the constraints governing the behaviors of individual Lego blocks.

**Fig. 31.5** Polymesh representation of a blunt impact to a semirigid sheet of material (after [31.57])

One only finds representations of objects when one turns to the higher level of the models that are realized, *and multiply realizable*, by the aforementioned modeling media. And when we take a close look at the properties of these high-level FEMs, we find that they share several characteristics that have long been taken, including by those who suggest that computational implementation entails sentential representation, to distinguish sentential representations from scale models.

To start with, like scale models and unlike sentential representations, FEMs are not (by themselves) naturally suited to representing abstract entities, properties, and processes (e.g., war criminal, ownership, economic inflation). They are much better suited for representing concrete entities, properties, and processes (e.g., a bucket, one object being over another, and compression). Nor are FEMs naturally suited to representing general categories (e.g., triangles or automobiles). They are far better suited for representing specific instances of those categories. Lastly, FEMs are not naturally suited to singling out specific properties of specific objects. For instance, using an FEM, it would be difficult to represent just the fact that Fred's car is green, for any such model will simultaneously represent many other properties, such as the number of doors and wheels, the body type, and so on. In short, just like scale models, FEMs are always representations of specific, concrete systems. By these reasonable standards, FEMs ought to be considered computationally-*realized* nonsentential models that are the close kin of scale models.

The case for this claim looks even stronger once we consider whether or not FEMs constitute intrinsic representations. As we have seen, the received view is that FEMs and their brethren (e.g., CMRs) are extrinsic representations, for the constraints governing how the coordinates of primitive modeling elements may change must be encoded antecedently and explicitly. Indeed, at the level of coordinates and transformation rules, one gets nothing *for free*. However, once a modeling medium has been used to construct a suitable FEM of a collection of objects, the model can then be altered in any of countless ways in order to determine the possible consequences of the corresponding alterations to the represented objects. One can, for instance, use a high-fidelity FEM of the door, bucket, ball system to infer, among other things, what would happen were we to place the bucket over the ball and slide the bucket through the doorway, what would happen were the bucket used to throw the ball at the open doorway, what would happen were the air pressure dramatically decreased, and so on indefinitely [31.57]. The consequences of *these* alterations need not be anticipated or explicitly incorporated into the system. Indeed, as with scale models, much of the point of constructing FEMs

is to *find out* how a system will behave in light of whichever alterations an engineer or scientist can dream up.

It bears repeating that it is not at the level of the primitive operations of an implementation base that we find intrinsic representations, but at the level of the representations *realized by* a given, primitively constrained implementation base. Part of what justifies this claim is the fact that certain constraints will be inviolable *at the level of the model*, and thus a great deal of information will be implicit in the model, because it has been implemented using a particular kind of medium. As *Pylyshyn* notes [31.63]:

“the greater number of formal properties built into a notation in advance, the weaker the notational system’s expressive power (though the system may be more efficient for cases to which it is applicable). This follows from the possibility that the system may no longer be capable of expressing certain states of affairs that violate assumptions built into the notation. For example, if Euclidean assumptions are built into a notation, the notation cannot be used to describe non-Euclidean properties [ . . . ]”

This, in fact, is very close to an apt characterization of what is going on in the case of FEMs. *Given* that a particular model has been realized through the use of a primitively constrained medium, certain constraints will be inviolable at the representational level and a great deal of information will be implicit [31.57]. As Mark Bickhard (in correspondence) summarizes the point:

“Properties and regularities are only going to be *intrinsic* at one level of description if they are built-in in the realizing level – or else they are ontologically *built-in* as in the case of strictly spatial relationships in physical scale models.”

While scale models are intrinsic for the latter reason, FEMs are intrinsic for the former. This shows up in the fact that FEMs exhibit a comparable degree of generativity to scale models and a correlative immunity to the frame problem. Like scale models, FEMs provide a finite embodiment of boundless tacit knowledge, which can be made explicit at any time, of the consequences of innumerable alterations to the systems they represent.

So how does all of this square with *Ander-son’s* [31.46] contention that it is always possible to construct a sentential system to mimic an imagistic or model-based system or *Palmer’s* [31.39] claim that if you create the right sentential model it will be functionally isomorphic to what it represents in just the sense that a nonsentential model is supposed to be? Ander-

son and Palmer are surely right that, post hoc, one can always constrain a sentential representational system so that it mimics the output of a model-based system, but the post hoc character of the strategy is precisely what gets sentential approaches into trouble vis-à-vis the frame problem. Consider, for instance, that the traditional AI approach is to take any physical implication of which humans express knowledge and, after the fact, to build it into the knowledge base of one’s system as a sentence or inference rule. (Despite its shortcomings, this strategy is alive and well, as is evidenced by Lenat’s massive ongoing Cyc project.) But to solve, or rather to avoid, the frame problem, one must rely upon representations that embody all of this boundless information as tacit knowledge – that is, the information cannot be explicitly encoded at the outset, but it can later be generated, and thereby become explicit knowledge, on an as-needed basis. Put simply, to exhibit anything approaching *true* functional isomorphism with scale models, what is needed are high-level, intrinsic, nonsentential models.

To sum up, those who would contend that FEMs (or even CMRs of 2-D spatial properties) are, *qua* computational, necessarily extrinsic and sentential have overlooked the fact that there are multiple levels of abstraction at which a given computational model can be understood. At the relatively low level of the modeling medium, there are unquestionably extrinsic representations of the principles governing the permissible transformation of primitive modeling elements. At a higher level, one finds models that share many distinguishing features, including immunity to the frame problem, with the scale models they were in large part invented to replace. Thus, we find once again that FEMs are like scale models and unlike paradigmatic sentential representations.

### 31.3.5 Bridging the Divide

All of this bears directly on the longstanding concern that there is no way to bridge the divide between neural machinations and the nonsentential models hypothesized by proponents of mental models. What the foregoing makes clear is that computational processes can realize nonsentential models that share with scale models the main characteristics that distinguish nonsentential models from sentential representations. Given that the brain is capable, at least in principle, of realizing any such computational processes, then one must also agree that brains can realize nonsentential models. Thus, by appealing to the above distinguishing features of scale models, we see that there is an account of mental models that (i) distinguishes them (on multiple grounds) from sentential representations and (ii) is

compatible with basic facts about how brains operate. All of this provides a much-needed foundation for all of that psychological work cited above that adverts to mental models.

One advantage of showing that low-level *computations* can realize higher-level mental models is that it renders the mental models hypothesis robust enough to withstand the discovery that the brain is a computational system at some level of description. Even if the brain is not a computational system (i. e., in the syntax-crunching sense), the manner in which computational systems realize intrinsic, nonsentential models will nevertheless remain quite instructive. It suggests a general recipe for the creation of intrinsic models that can be followed even without the computational intermediary: Start by creating a representational medium such that a large number of primitive elements are constrained to obey a handful of simple behavioral principles. Next construct models from this highly productive medium. (*Productive* is here used in *Fodor's* sense – that is, to denote a medium capable of representing an open-ended number of distinct states of affairs [31.66].) What emerges are generative structures capable of supporting an open-ended number of mechanical inferences. At the level of the medium, *running* such a model involves the recursive application of the basic constraints on the modeling-element behaviors. This will typically be a massive, parallel, constraint-satisfaction process. Given that this form of processing is the forte of neural networks, there should be little doubt that neural machinations are up to the task. (At the same time, one should not overestimate inherent immunity to the frame problem of neural networks [31.58]. It is only by implementing a primitively constrained modeling medium that neural networks can be expected to realize intrinsic representations of complex, interacting worldly constraints.)

### 31.3.6 Bottom-Up Approaches

Thus far, we have largely approached the question of the neural realizability of mental models in the abstract, and from the top down. This is partly because there has been a relative dearth of work that moves in the opposite direction, from the bottom up. One exception is *Thagard's* [31.11] recent work on the topic, which appeals to such biologically plausible simulations of neural networks as those of *Eliasmith* and *Anderson* [31.67]. Unfortunately, Thagard has yet to offer evidence that the neural encoding strategies he discusses exhibit any of the central features, discussed here, that distinguish modeling from syntax-crunching. Most notably, the neural representations he cites have not yet been shown to exhibit a significant degree of

spatial, kinematic, or causal generativity. The proof of the pudding here is in the eating.

To the extent that there have been significant advances in the bottom-up endeavor, they mostly issue from research – such as that of Nobel laureates John O'Keefe, May-Britt Moser, and Edward Moser – on the biological neural networks that underwrite spatial reasoning abilities in rats. As you will recall, Tolman's pioneering work on maze navigation suggested that rats have an onboard medium for the construction of generative spatial maps of their location relative to barriers and important items such as food and drink. *O'Keefe* and *Nadel* are famous for showing that the rat's hippocampus contains *place* cells which fire preferentially when an animal reaches a particular location in its environment, cells that fire in sequence as a rat moves from one location to another [31.68]. *Moser* and *Moser* subsequently showed that the rat's uncanny spatial navigation abilities also depend upon *grid* cells in the nearby entorhinal cortex [31.69]. Individual grid cells fire when an animal is in any of several, roughly evenly spaced locations. When lines are drawn to connect these points, they collectively form what (purely by coincidence) looks a great deal like the kind of 2-D polymesh shown in Fig. 31.5. While each grid cell is tuned to a collection of locations, different grid cells have sparser or denser coverage of the same region of space. Collectively they provide effective coverage of the entire region of space in which the animal finds itself.

Importantly, *O'Keefe* et al. note regarding place cells that [31.70]

“there does not appear to be any obvious topographical relation between the field locations (i. e., the places to which cells become temporarily tuned) and the anatomical locations of the cells relative to each other within the hippocampus.”

Nor do grid cells in the entorhinal cortex exploit any obvious structural isomorphisms between their respective anatomical locations and the spatial layout of the environment. However, acting in concert, the two types of cells enable effective navigation, as if the organism had an internal map that preserves relative locations (place cells) and distances (grid cells). In other words, the two systems encode maps that are *functionally* isomorphic with real maps of the environment. Moreover, they provide a productive modeling medium, one which, not unlike a collection of Lego blocks, can be used and reused, through a process called *remapping*, to encode information about an open-ended number of new environments [31.71]. The maps constructed in this medium are generative with regards to 2-D spatial properties in the aforementioned sense, as is shown by their role in enabling rats to find efficient new

ways to a destination when familiar routes are blocked. More recent research suggests that the rat's place cells are also somewhat sensitive to vertical displacement from a reference plane, perhaps enabling 3-D mapping capabilities [31.72]. Nor are the lessons learned here applicable only to rats, for a large body of research suggests that the same anatomical systems may be implicated in human spatial navigation [31.73].

Our deepest understanding of how real neural networks create spatial mental models thus suggests that brains implement a reusable modeling medium and, by exploiting the kinds functional, rather than physical, isomorphisms that make neural realizability feasible, nothing is lost in the way of generativity. It also bears mentioning that this modeling medium is well suited for producing models of the organism's location rela-

tive to its specific, concrete environment. As such, it may (taken in isolation) be ill suited for representing abstracta or genera. As for the singling out of specific properties of specific objects, it may be that models that are realized by neurophysiological processes have a natural advantage over scale models in that populations representing specific properties may *cry out* for attention (by oscillating at the appropriate frequency). There is, moreover, no reason why these lessons could not scale up, so to speak, to account for the human ability to run off-line models of spatial, kinematic, and dynamic relationships. Of course, in humans, the neocortex is likely to play a much more prominent role. As of yet, however, there is little understanding of the precise manner in which the neocortex does, or might, realize mental models.

## 31.4 Realization Story Applied

Though we clearly have a long way to go, the above hypothesis about what mental models are such that neural systems might realize them looks to have important ramifications for work in several fields, ranging from AI to the philosophy of science.

### 31.4.1 AI and Psychology: Towards an Intuitive Physics Engine

One obvious ramification of the above is what it suggests about how one might go about endowing computational artifacts with the kind of boundless commonsense knowledge of the consequences of alterations to the world that humans seem to possess. FEMs prove that there is a determinate computational solution to the prediction and qualification problems. FEMs are generative in that they can be manipulated in any of countless ways in order to make inferences about how alterations to the environment might play out and, by the same token, about the ways in which those consequences might be defeated. It would thus behoove AI researchers to incorporate media for the construction of intrinsic models within the core inference machinery of their devices. Indeed, there has been some movement in this direction in recent years. For instance, though past manuals for the Soar production-system architecture evidence a certain degree of exasperation when it comes to the frame problem, more recent manuals indicate that Soar's designers have begun to offload mechanical reasoning to nonsentential models. *Laird* notes, for instance [31.74]:

“With the addition of visual imagery, we have demonstrated that it is possible to solve spatial rea-

soning problems orders of magnitude faster than without it, and using significantly less procedural knowledge. Visual imagery also enables processing that is not possible with only symbolic reasoning, such as determining which letters in the alphabet are symmetric along the vertical axis (A, H, I, M, O, T, U, V, W, X, Y).”

While Soar's imagery module still only supports simple spatial reasoning, it is clearly a step in the direction of richer, intrinsic models of 3-D kinematics and dynamics.

There has also been some movement in the direction of using computationally realized intrinsic models as a way of making sense of behavioral findings regarding how humans engage in commonsense reasoning about the world. For instance, after paying homage to Craik, MIT researchers *Battaglia* et al. describe their innovative approach to commonsense reasoning as follows [31.75]:

“We posit that human judgments are driven by an *intuitive physics engine* (IPE), akin to the computer physics engines used for quantitative but approximate simulation of rigid body dynamics and collisions, soft body and fluid dynamics in computer graphics, and interactive video games.”

They simulate the IPE with FEMs of full-blown 3-D kinematic and dynamic relationships. They note that a similar IPE in humans might allow us to read off from our simulations the answers to questions of *What will happen?* regarding innumerable novel scenarios. Their pioneering work also breaks new ground in that it be-

gins to account for probabilistic reasoning by building a bit of uncertainty into models and treating multiple runs of a model as a statistical sample.

All of this work is very much in the spirit of Schwartz' claim that "inferences can emerge through imagined actions *even though people may not know the answer explicitly*" [31.76, italics mine]. It also fits with the following suggestion of Moulton and Kosslyn [31.35, italics mine]:

"the primary function of mental imagery is to allow us to generate specific predictions based upon past experience. Imagery allows us to answer *what if* questions by making explicit and accessible the likely consequences of being in a specific situation or performing a specific action."

### 31.4.2 Exduction

Another important lesson to be learned from computationally realized intrinsic models is that they support a form of mechanistic reasoning that has found its way into few, if any, standard reasoning taxonomies. As Glasgow and Papadias claim [31.61]:

"The spatial structure of images has properties not possessed by deductive sentential representations [...] spatial image representations [...] support nondeductive inference using built-in constraints on the processes that construct and access them."

Of course, there is more to be said about the process of model-based mechanistic reasoning than that it is *not* deductive. In fact, the process shares with (valid) deductive reasoning the property of being monotonic. What makes deduction a monotonic (indefeasible) reasoning process is that the conclusion of a valid argument cannot be overturned simply by adding premises; it can only be overturned by rejecting one or more of the premises from which the conclusion was deduced. Other forms of reasoning (inductive generalization, analogical reasoning, abduction) are defeasible in that one *can* overturn their conclusions simply by adding relevant premises. For instance, if I hear a meowing noise emanating from my daughter's closet door, I may

infer that the cat is trapped inside. But if I then see the cat walking through the kitchen and am told that my daughter was given a new electronic cat toy, my conclusion would be undermined while at the same time leaving the original premise (that there is meowing coming from the closet) intact.

One diagnosis for why deduction is monotonic is that, in a certain sense, the premises of a valid deduction already *contain* the information stated in the conclusion, so adding information takes nothing away from the support that those premises lend to the conclusion. That means that insofar as the original premises are true, the conclusion must be as well, and insofar as the conclusion is false, there must be something wrong with the premises used to derive it. But deduction is formal, in that topic-neutral logical particles are what bear the entirety of the inferential load – that is, the specific contents (consistently) connected and quantified over drop out as irrelevant.

The use of scale models and FEMs makes evident that there is another form of monotonic reasoning in addition to deduction. As explained above, information derived regarding the consequences of interventions on a modeled system are to a significant extent already *contained* (i. e., they are implicit) in the models themselves. The only way to overturn a model-based inference is to call into question some aspect or other of the model from which it was derived. By the same token, if the conclusion is incorrect, there must be something wrong with the model. But unlike deduction, model-based reasoning is not affected by abstracting away from specific contents and allowing logical particles to bear the inferential load. Instead, it is the specific, concrete contents of the models that do all of the work. As yet, this form of monotonic reasoning lacks a name. Let us thus call it *exduction* (*ex*-out and *duce*-lead). Like deduction, exduction may be implemented externally through the use of representational artifacts, but the hypothesis being explored here is just that we also sometimes engage in internal exductive reasoning through the use of mental models. If this hypothesis is correct, then exduction must be added to our standard taxonomy of internal reasoning processes and placed alongside deduction under the broader heading of monotonic reasoning.

## 31.5 Mechanistic Explanation Revisited

It was noted in the beginning that mental models may well play a crucial role in the process of mechanistic explanation and prediction. If that is so, then we can only hope to attain a deep understanding of science if

we first account for how the mental modeling process works. Now that we have a clearer conception of the distinctive features of mental models and of the way in which they might be realized by neurophysiological

processes, we can begin to see what the payoff might be in terms of our understanding of model-based reasoning about mechanisms in science.

### 31.5.1 The Prediction and *Ceteris Paribus* Problems

To give some of the flavor of where this might lead, consider that one benefit of the foregoing realization story regarding mental models for the philosophy of science is that it offers a solution to two longstanding problems: the surplus-meaning problem and the *ceteris paribus* problem (a.k.a., the problem of *provisos*). Both problems arose as a consequence of attempts to apply the methods of formal, mostly deductive methods in an attempt to provide a logical reconstruction of scientific reasoning.

The surplus-meaning problem has to do with the fact that explanatory hypotheses have, and are *known* to have, countless implications beyond the happenings they explain. To keep things simple, consider the non-scientific case of what a mechanic knows about the operation of an automobile engine. Imagine, in particular, that someone has brought an automobile into the mechanic's shop complaining that the engine has suffered a drop-off in power. Listening to the engine, the mechanic might decide that the engine has blown a ring. Setting aside the question of creativity, one might provide the following formal, deductive reconstruction of his explanatory model

If one of the cylinders has lost a ring,  
 then the engine will have lost power.  
 One of the cylinders has lost a ring.  
 ∴ The engine has lost power.

Consider, however, that the mechanic knows not only that the faulty ring will result in a loss of power (the *explanandum* occurrence); he also knows many other implications of this explanatory hypothesis, such as that oil will leak into the combustion chamber, the exhaust will look smoky, the end of the tailpipe will become oily, and the sparkplugs will turn dark. He also knows what interventions will and will not alleviate the problem – for instance, he knows that replacing the rings will restore power but replacing the air filter will not, and so on indefinitely. Any suitable deductive reconstruction of the mechanic's mental model of the source of the problem must thus account not just for the fact that it implies the *explanandum*; it must account for its countless further implications. The general problem with deductive reconstructions of explanations – a problem that will surely beset any attempt

to reconstruct mechanistic explanations using extrinsic representations – is that they fail to capture the full complexity of what anyone who possesses that explanation must know, if only implicitly. The problem is that there is too much *surplus-meaning* to express it all explicitly [31.77], and these added implications are essential to how we assess the adequacy of explanations, whether in everyday life or in science. As Greenwood explains [31.78]:

“Where this *surplus meaning* comes from [...] is a matter of some dispute, but that genuine theories poses [sic.] such surplus meaning is not—for this is precisely what accounts for their explanatory power and creative predictive potential.”

Notice also that the mechanic's model of why the car lost power not only contains information about the various other things he should expect to find if that model is correct; it also contains information about the countless ways in which each of these expectations might, consistent with the truth of the explanation, be defeated. The mechanic knows, for instance, that replacing the rings will restore power, but *only if it is not the case that one of the spark plug wires was damaged in the process, the air filter has become clogged with dust from a nearby construction project, and so on indefinitely.*

Whether we are dealing with commonsense or scientific reasoning about mechanisms, the problem with attempts at formalizing our knowledge of the ways in which a given implication is qualified is that what we know far outstrips what can be expressed explicitly in the form of, say, a conditional generalization. In philosophy of science, the qualifications that would have to be added are termed *ceteris paribus* clauses and *provisos*. As Fodor claims, the general problem is that “as soon as you try to make these generalizations explicit, you see that they have to be hedged about with *ceteris paribus* clauses” [31.79]. And as Giere claims, “the number of *provisos implicit* in any law is *indefinitely large*” [31.80, italics mine]. Deductive models, and others that rely upon extrinsic representations, are thus unable to capture the full breadth of what we know when we possess a mechanistic explanation for an occurrence. And all of this *dark information* plays a crucial role in the testing and retention of mechanistic hypotheses [31.81]. Accounting for it must thus be viewed as a central goal for the philosophy of science.

If we abandon deductive (or other extrinsic) schemes for making sense of scientific reasoning about mechanisms and instead adopt an exductive (and intrinsic) model-based account of reasoning, the surplus-meaning and *ceteris paribus* problems dissolve, and the

source of the dark information comes into focus. After all, these two problems are just variants on the prediction and qualifications problems of AI. This is not surprising given that both sets of problems were discovered through early attempts to deductively reconstruct everyday and scientific reasoning about mechanisms. Naturally, the same solution applies in both cases: Eschew the appeal to extrinsic representations and formal inferences in favor of an appeal to intrinsic models and exductive inferences. The promising idea that emerges is that scientists may be utilizing intrinsic mental models to understand the mechanisms that are (or might be) responsible for particular phenomena. Such models would endow the scientist with boundless tacit knowledge of the further implications of a given mechanistic hypothesis and of the countless ways in which those implications are qualified.

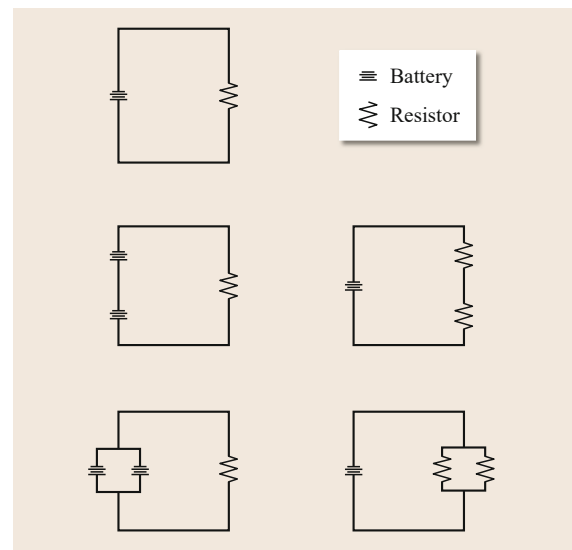

### 31.5.2 Beyond Mental Models

We must not forget, however, that our mental models are limited by working memory capacity and by the heavy cognitive load associated with mental modeling. Even so, scientists are somehow able to formulate and comprehend some remarkably complex mechanical explanations. Seen in this light, it is no surprise that, in their reasoning about mechanisms, humans rely heavily upon external representational artifacts such as diagrams. These can act as aids to memory, both short- and long-term, enabling us to off-load some of the cognitive burden to the world and thereby compensating for our otherwise limited ability to keep track of the simultaneous influences of many mechanical components (see [31.82]). Indeed, when aided by external diagrams, *Hegarty* et al. found that high- and low-imagery subjects performed about *equally well* on a task that required model-based reasoning about mechanisms [31.18]. The compensatory influence of external representations is strong indeed (see also *Bechtel*, Chap. 27).

Of course we do not just utilize static pictures to make sense of natural phenomena; we also sometimes use scale models [31.83]. On the present view, the reason so many have come to view these models as an apt metaphor for in-the-head reasoning may be that scale models recapitulate, albeit in a way that overcomes many of our cognitive frailties, the structure of our internal models of mechanisms. However, with the advent of sophisticated computer models, we now have an even better tool for investigating the implications of mechanical hypotheses. As we have seen, certain computer models (e.g., FEMs) are like scale models in that they constitute intrinsic nonsentential representations of actual or hypothetical mechanisms. However,

these models have the added virtue that one can easily freeze the action, zoom in or out, slow things down, and even watch things play out in reverse. These models thus constitute what *Churchland* and *Sejnowski* term a “fortunate preparation” [31.84]. Such models provide an even more apt analogy for understanding our own native mental models, for both sorts of models are realized at a low level by complicated circuitry, and both tend to bottom-out well above the level of nature’s fundamental laws. (One way of describing the interplay between external models (in their various forms) and internal mental models would be to say that the latter are part and parcel of scientific cognition, whereas the former are representational artifacts created to aid cognition. An alternative, somewhat speculative, proposal is that our external models are no less part of the fabric of scientific cognition than are our internal mental models [31.85]).

As noted in Sect. 31.2, over and above the quantitative limits imposed by working memory capacity, scale models and FEMs are, and our own mental models may well be, limited in certain qualitative respects, such as their ability to represent abstracta. But surely thoughts about abstracta play a big role in scientific reasoning. One way of accounting for this is to say that our deficiencies with regards to modeling abstracta are the precise problem that analogy and metaphor were created to solve. This would make sense of why the language we use to represent abstracta (e.g., *economic inflation*) is so shot through with analogies and metaphors rooted in concrete domains [31.86–88].

**Fig. 31.6** Various configurations of circuitry, batteries, and resistors

Gentner and Gentner's study of human reasoning about electricity lends some credence to this view [31.89]. Gentner and Gentner found that in conversation, nonexpert subjects commonly likened the flow of electricity to water moving through pipes or crowds moving through corridors. Each analogy happens to yield its own unique set of inaccurate predictions about how electrical current moves through particular configurations of electrical components (Fig. 31.6).

## 31.6 Conclusion

It was noted in the beginning that mental models might play a crucial role in the process of mechanistic explanation and prediction in science. As such, we can only attain a deep understanding of science itself if we first understand that nature of this mental, model-based, reasoning process. We then saw that experimental psychologists have long maintained that mental models are distinct from sentential representations in much the way that scale models are. Insofar as this hypothesis is viable, we can expect that experimental psychology will provide crucial insight into both the nature and limits of our onboard mental models. At the same time, it is important to recognize that the many appeals to distinctively model-like mental representations in psychology will be considered suspect so long as we lack a reasonable way of spelling out what sorts of representational structures mental models are supposed to be in a way that (i) shows these models to be distinct from sentential representations while (ii) allowing for their realization by neurophysiological processes. We can see the way forward, however, if we first pay attention to some

Gentner and Gentner found that subjects' errors in reasoning about these components tracked the analogies they invoked when discussing electricity. This suggests that these analogies run deeper than the surface features of language and penetrate right into subjects' mental models of the flow of electricity. Analogies and metaphors are perhaps not the whole story of how we think about abstracta, but they may well be an important part of it.

of the distinctive features of scale models that distinguish them from sentential representations. If we then turn to the computational realm, we see that these very features (including immunity to the notorious frame problem) are exhibited by certain computational models of mechanisms such as FEMs. An appeal to the principle that sustains the computational theory of cognition (POPI) enables us to understand how this could be so and how high-level, nonsentential, intrinsic models of mechanisms could in principle be realized by neurophysiological processes. The broader viability of this realization story for mental models is suggested by recent work in both AI and experimental psychology and by the elegant solution it offers to the surplus-meaning and *ceteris paribus* problems in the philosophy of science. Going forward, the idea that our scientific reasoning about mechanisms might, to a large extent, involve the manipulation of representations that are like scale models in crucial respects can be regarded as at least one, sturdy pillar of a promising hypothesis regarding the nature of model-based reasoning in science.

### 37 Biorobotics

Edoardo Datteri, Milano, Italy

Since the 1950s computational progress has been contributing to increasing the relevance of the discourse about models, making it not only relevant to scientists and philosophers, but also to computer scientists, programmers, and logicians. Emphasis has been put both on the application of computational tools to a range of disciplines and on the computational issues themselves. Computing is playing an increasing role in several scientific endeavors, in modeling and simulating different entities, and in practically enhancing the performance of various scientific activities. At the same time, computational tools are becoming more and more complex and present several open issues that require consideration from technical, methodological, and epistemological points of view.

This part of the *Handbook of Model-Based Science* discusses the modeling and computational issues arising in this context, with the aim of giving back an articulated, although necessarily incomplete, picture of the field. It is composed of six different chapters that alternate with general perspectives and specific fields of application.

This part opens with **Chap. 32** on *Computational Aspects of Model-Based Reasoning* by *Gordana Dodig-Crnkovic* and *Antonio Cicchetti* offering an introductory overview on the use of computational models and tools for the study of cognition and model-based reasoning. From simple agents, like bacteria, to the complex human cognitive systems, computation is meant as physical, natural, embodied, and distributed, and it is discussed in relation to the view of symbol manipulation of classical computationalism.

**Chapter 33** by *Peter Sozou*, *Peter Lane*, *Mark Addis*, and *Fernand Gobet* discusses *computational scientific discovery* as a particularly interesting and successful field of application of computer-supported model-based science. The chapter reviews the application of computational methods in the formulation of scientific ideas and acknowledges the importance of this field not only for historical reasons, with the first systems having played a disruptive role in the philosophical debate on scientific discovery, but also for testifying its increasing importance in many areas of science.

**Chapter 34**, *Computer Simulations and Computational Models in Science* by *Cyrill Imbert* presents a very rich examination of computational science and computer simulations by giving reason to the constant attempts of extending human computational capacities. The chapter covers a wide variety of topics and themes

with the awareness that epistemological analyses of simulations are, to a large degree, contextual and that these analyses require developing insights about the evolving relation between human capacities and computational science.

Simulation is also the topic of **Chap. 35**, *Simulation of Complex Systems* by *Paul Davidsson*, *Franziska Klügl*, and *Harko Verhagen*, which opens with a discussion on what characterizes complex systems, such as huge ecosystems and traffic systems. Different approaches to model complex systems are presented, but particular attention is devoted to agent-based simulations, to their intuitiveness and flexibility, to some solutions proposed in the last years, and to the still open problems that are discussed in a critical perspective.

**Chapter 36**, by *Francesco Amigoni* and *Viola Schiaffonati*, *Models and Experiments in Robotics*, surveys the practices being employed in experimentally assessing the special class of computational models embedded in robots. This assessment is particularly challenging due to the difficulty of satisfactorily estimating the interactions between robots and their environments. Moreover, by considering also related topics such as simulations, benchmarks, standards, and competitions, this chapter shows how the recent debate on the implementation of the experimental method in this field is still very open.

**Chapter 37**, *Biorobotics* by *Edoardo Datteri*, provides an overview of the biorobotic strategy for testing mechanistic explanations of animal behavior starting from a reflection on the various roles played by robotic simulations in scientific research. Besides the history and state of the art of biorobotics, the chapter also addresses some key epistemological and methodological issues mainly concerning the relationships between biorobots and the theoretical models under investigation.

It is not by chance that this part of the volume ends with this chapter on biorobotics: if one of the main common traits of the other chapters has been the foundational role of the philosophical tools in discussing computational models in model-based science, this last chapter also shows how computational models and tools can offer new insights to traditional philosophical problems, and thus represents an ideal and critical conclusion offering further reflections on the articulation between computation and philosophy.

## 32. Computational Aspects of Model-Based Reasoning

Gordana Dodig-Crnkovic, Antonio Cichetti

Computational models and tools provide increasingly solid foundations for the study of cognition and model-based reasoning, with knowledge generation in different types of cognizing agents, from the simplest ones like bacteria to the complex human distributed cognition. After the introduction of the computational turn, we proceed to models of computation and the relationship between information and computation. A distinction is made between mathematical and computational (executable) models, which are central for biology and cognition. Computation as it appears in cognitive systems is physical, natural, embodied, and distributed computation, and we explain how it relates to the symbol manipulation view of classical computationalism. As present day models of distributed, asynchronous, heterogeneous, and concurrent networks are becoming increasingly well suited for modeling of cognitive systems with their dynamic properties, they can be used to study mechanisms of abduction and scientific discovery. We conclude the chapter with the presentation of software modeling with computationally automated reasoning and the discussion of model transformations and separation between semantics and ontology.

### 32.1 Computational Turn Seen from Different Perspectives

Computation is central for our entire contemporary civilization – research and sciences, communications, government, manufacturing, control, transports, financial sector, education, entertainment, arts, humanities, technology in general, and especially engineering. It also affects in profound ways our outlook of the world and determines what can be conceptualized and how. In the following, we will describe current understanding of the processes and structures of the computational turn from different perspectives.

From the point of view of conceptual, cognitive aspects, *Brian Cantwell Smith* recognizes the computational turn as present constantly increasing importance of computation (cited in [32.1, p. 3]):

“Everyone knows that computational and information technology has spread like wildfire throughout academic and intellectual life. But the spread of computational ideas has been just as impressive.

Biologists not only model life forms on computers; they treat the gene, and even whole organisms, as information systems. Philosophy, artificial intelligence, and cognitive science don't just construct computational models of mind; they take cognition to be computation, at the deepest levels.

Physicists don't just talk about the information carried by a subatomic particle; they propose to unify the foundations of quantum mechanics with notions of information. Similarly for linguists, artists, anthropologists, critics, etc."

With the emphasis on philosophical facets of the computational turn, *Charles Ess* and *Ruth Hagengruber* depict the same process of steady increase in the role of computation as follows [32.2]:

"In the West, philosophical attention to computation and computational devices is at least as old as Leibniz. But since the early 1940s, electronic computers have evolved from a few machines filling several rooms to widely diffused – indeed, ubiquitous – devices, ranging from networked desktops, laptops, smartphones and *the internet of things*. Along the way, initial philosophical attention – in particular, to the ethical and social implications of these devices (Norbert Wiener, 1950) – became sufficiently broad and influential as to justify the phrase *the computational turn* by the 1980s.

In part, the computational turn referred to the multiple ways in which the increasing availability and usability of computers allowed philosophers to explore a range of traditional philosophical interests – e.g., in logic, artificial intelligence, philosophical mathematics, ethics, political philosophy, epistemology, ontology, to name a few – in new ways, often shedding significant new light on traditional issues and arguments. Simultaneously, computer scientists, mathematicians, and others whose work focused on computation and computational devices often found their work to evoke (if not force) reflection and debate precisely on the philosophical assumptions and potential implications of their research."

Looking from the perspective of arts, humanities, and social sciences *David M. Berry* [32.3] observes:

"The importance of understanding computational approaches is increasingly reflected across a number of disciplines, including the arts, humanities and social sciences, which use technologies to shift the critical ground of their concepts and theories – something that can be termed a computational turn.

This is shown in the increasing interest in the digital humanities (Schreibman et al., 2008) and

computational social science (Lazer et al., 2009), as evidenced, for example, by the growth in journals, conferences, books and research funding. In the digital humanities 'critical inquiry involves the application of algorithmically facilitated search, retrieval, and critical process that [...] originat[es] in humanities-based work'; therefore 'exemplary tasks traditionally associated with humanities computing hold the digital representation of archival materials on a par with analysis or critical inquiry, as well as theories of analysis or critical inquiry originating in the study of those materials' (Schreibman et al., 2008: xxv). In social sciences, *Lazer et al.* argue that 'computational social science is emerging that leverages the capacity to collect and analyze data with an unprecedented breadth and depth and scale' (2009).

*Latour* speculates that there is a trend in these informational cascades, which is certainly reflected in the ongoing digitalisation of arts, humanities and social science projects that tends towards 'the direction of the greater merging of figures, numbers and letters, merging greatly facilitated by their homogeneous treatment as binary units in and by computers (Latour, 1986: 16)."

Finally, from the perspective of computing itself as a field, *Peter J. Denning* ascertains [32.4, p. 1-1; p. 1-4]:

"Computing is integral to science – not just as a tool for analyzing data but also as an agent of thought and discovery. It has not always been this way. Computing is a relatively young discipline. It started as an academic field of study in the 1930s with a cluster of remarkable papers by Kurt Gödel, Alonzo Church, Emil Post, and Alan Turing. The papers laid the mathematical foundations that would answer the question, *what is computation?* and discussed schemes for its implementation. These men saw the importance of automatic computation and sought its precise mathematical foundation."

"All this suggests that computing has developed a paradigm all its own (Denning and Freeman, 2009). Computing is no longer just about algorithms, data structures, numerical methods, programming languages, operating systems, networks, databases, graphics, artificial intelligence, and software engineering, as it was prior to 1990. It now also includes exciting new subjects including Internet, web science, mobile computing, cyberspace protection, user-interface design, and information visualization. The resulting commercial applications have spawned new research challenges in social networking, endlessly evolving computation, music, video, digital photography, vision, massive

multiplayer online games, user-generated content, and much more. [...] The central focus of the computing paradigm can be summarized as information processes—natural or constructed processes that transform information. They can be discrete or continuous.”

Denning reminds that in the beginning of the field “Computation was taken to be the mechanical steps followed to evaluate mathematical functions. Computers were people who did computations.” while, today computing plays a much more diverse role: “Computing is not only a tool for science but also a new method of thought and discovery in science.” [32.4, p. 1-3]

Computing is the fourth great domain of science, together with traditional domains of physical-, life-, and social sciences [32.5].

In more detail, here is how Computer Science is relevant for other sciences in view of *Samson Abramsky* and *Bob Coecke* [32.6]:

“Computer Science has something more to offer to the other sciences than the computer. In particular, in the mathematical and logical understanding of fundamental transdisciplinary scientific concepts such as interaction, concurrency and causality, synchrony and asynchrony, compositional modeling and reasoning, open versus closed systems, qual-

itative versus quantitative reasoning, operational methodologies, continuous versus discrete, hybrid systems and more. Computer Science is far ahead of many other sciences, due in part to the challenges arising from the amazing rapidity of the technology change and development it is constantly being confronted with. One could claim that computer scientists (maybe without realizing it) constitute an avant-garde for the sciences in terms of providing fresh paradigms and methods.”

All the above observations made by researchers with different perspectives on computing provide evidence supporting the commonly observed emergence of computational turn in its different manifestations – from technological to cultural, artistic, cognitive, conceptual, and modeling aspects. As Edsger Dijkstra famously said, “Computing is no more about computers than astronomy is about telescopes” (as quoted in [32.7]) – that is to say that computers (as we know them and develop them) are only the tools for computing. Understanding of computing requires understanding of computational processes and their mechanisms.

Generative computational methods, according to *Stephen Wolfram*, enable the development of a *new kind of science* [32.8], and a new way of thinking that *Jeanette M. Wing* termed *computational thinking* [32.9].

## 32.2 Models of Computation

Interestingly, in spite of the broadly shared perception of the current computational turn [32.10], it is still an open question what exactly is computing.

English word *computing* [32.4] in German, French, and Italian languages translates into the respective terms *informatik*, *informatique*, and *informatica* (that would correspond to *informatics* in English). However, there is a slight difference in the emphasis. While the English term *computing* has an *empirical* character, the analogous German, French, and Italian term *informatics* has an *abstract* nature [32.11]. The question of nomenclature, *informatics* versus *computing*, can also be seen in the light of the dichotomy *information* versus *computation* or *structure* versus *process* [32.1].

Information as the central idea of informatics/computing is both scientifically and sociologically indicative. Scientifically, it suggests a view of informatics as a generalization of information theory that is concerned not only with the transmission/communication of information but also with its transformation and interpretation. Sociologically, similar to the industrial revolution, which was concerned with the utilizing of matter/energy, we have the information revolution,

which is concerned with the utilizing of information/computation [32.11].

Information is a field of intense theory building, with diverse perspectives and levels of description, with various goals addressed. In the work of *Mark Burgin*, the focus of theory of information is on its fundamentality, diversity, and unification with specific chapters dedicated to general, statistical, semantic, algorithmic, dynamics, and pragmatic information theory [32.12]. *The Handbook of Philosophy of Information* [32.13] addresses major technical approaches, transformation and use of information in the sciences and humanities. Information logic and dynamics is a separate topic addressed in the work of *Johan van Benthem* and *Patrick Allo* [32.14–17]. No wonder that no single definition can embrace the complexity of the knowledge about information.

Equivalent situation can be found in the studies of computation and the subject of computing [32.4, 5, 18, 19]. Among variety of definitions of computing, the following example is indicative of instrumental approach as one describes *the processes* performed by computing machinery: Computing is [32.20]

“[t]he process of utilizing computer technology to complete a task. Computing may involve computer hardware and/or software, but must involve some form of a computer system.”

It is general enough, as a description of *computation* process but leaves open the question of what actually is *computer*. It implicitly seems to assume computer to be a technological device. However in recent years a new field of computing is being developed labeled as *Natural Computing* [32.21] or *Computing Nature* [32.22, 23], where processes in nature are understood as being some kind of (intrinsic, physical) computation.

### 32.2.1 Turing Model of Computation and Its Scope

The first classical model of computation that also served as a definition of computation is the Turing machine model, which takes computation to be *computation of mathematical function*. Logical Computing Machine (Turing’s own expression for Turing machines) was an attempt to give a mathematically precise definition of an algorithm that is a mechanical procedure (followed by a human using pencil and paper, and given unlimited resources). The Church–Turing thesis says that *a function on the natural numbers is computable* [32.24, 25] if and only if it is describable by a Turing machine model.

Besides the Turing machine model, several other models of computation were defined such as lambda calculus, cellular automata, register machines, and substitution systems, which have been shown to be equivalent to using general recursive functions. The Church–Turing thesis has long served as a *definition for computation*. There has never been a proof, but the evidence for its validity comes from the evident practical equivalence of mentioned computational models.

*Georg Kampis* claims that the Church–Turing thesis applies only to *simple systems* [32.26]. According to Kampis, complex systems such as found in biology must be modeled as self-referential, self-organizing structures called *component systems* whose behavior goes far beyond the simple Turing machine model as a more general model of computation [32.26, p. 223]:

“a component system is a computer which, when executing its operations (software) builds a new hardware [...] [W]e have a computer that re-wires itself in a hardware-software interplay: the hardware defines the software and the software defines new hardware. Then the circle starts again.”

I would add an obvious remark. The Turing machine is supposed to be given from the outset – its logic, its (unlimited) physical resources, and the meanings ascribed to its actions. *The Turing Machine essentially*

*presupposes a human as a part of a system* – the human is the one who poses the questions, provides resources, sets up the rules and interprets the answers.

However, today the dramatically increased interactivity and connectivity of computational devices have changed our understanding of the nature of computing [32.27]. Computing models have been successively extended from the initial abstract symbol manipulating models of stand-alone, discrete sequential machines, to the models of physical computing in the natural world, which are in general concurrent, asynchronous processes. For the first time it is possible to model living systems, their informational structures, and dynamics on both symbolic and subsymbolic information processing levels [32.28]. Currently the computation models are being developed to describe embedded, interactive, and networked computing systems [32.29] with an ambition to encompass present-day distributed computational architectures with their concurrent time behavior.

Ever since the time of Turing, the definition of computation is the subject of a debate. The special issue of the journal *Minds and Machines* (1994, 4, 4) was devoted to the question *What is Computation?* The most general is the view of computation as information processing, found in number of mathematical accounts of computing; see [32.30] for exposition. Understanding of computation as information processing is also widespread in biology, neuroscience, cognitive science, and number of other fields. An illuminating case is presented by *David Baltimore* in *How biology became an information science* [32.31]. *Barry Cooper* and *Jan van Leeuwen* Turing centenary volume [32.32] illustrates the current state of the art regarding Turing model and its scope.

In general, for a process to qualify as computation, a mechanism that ensures definability of its behavior must exist, such as algorithm, network topology, physical process, or similar [32.11].

The characterization of computing can be made in several dimensions with orthogonal types: digital/analog, symbolic/subsymbolic, interactive/batch, and sequential/parallel. Nowadays digital computers are used to simulate all sorts of natural processes, including those that in physics are understood as continuous. However, it is important to distinguish between the *mechanism* and *model* of computation [32.33].

### 32.2.2 Computation as Information Processing

*Luciano Floridi* [32.34] presents the list of the five most interesting areas of research for the field of information (and computation) philosophy, containing 18 fundamental questions. Information dynamics is of special interest, as information processing (computation).

Information and computation are two complementary ideas in a similar way to continuum and a discrete set. In its turn continuum – discrete set dichotomy may be seen in a variety of disguises such as time – space; wave – particle; geometry – arithmetic; interaction – algorithm; computation – information. Two elements in each pair presuppose each other, and are inseparably related to each other so that *Dodig-Crnkovic* introduces the concept of info-computation which emphasizes this dual character of information and computation as its dynamics [32.1, 35, 36]. The field of Philosophy of Information is so closely interconnected with the Philosophy of Computation that it would be appropriate to call it Philosophy of Information and Computation, having in mind the dual character of information-computation. *Burgin* puts it in the following way [32.30]:

“It is necessary to remark that there is an ongoing synthesis of computation and communication into a unified process of information processing. Practical and theoretical advances are aimed at this synthesis and also use it as a tool for further development. Thus, we use the word computation in the sense of information processing as a whole. Better theoretical understanding of computers, networks, and other information processing systems will allow us to develop such systems to a higher level.”

The traditional mathematical theory of computation is the theory of algorithms. Ideal, theoretical computers are mathematical objects and they are equivalent to algorithms, or abstract automata (Turing machines), or effective procedures, or recursive functions, or formal languages. New envisaged future computers are information-processing devices. That is what makes the difference. Syntactic mechanical symbol manipulation is replaced by information (both syntactic and semantic) processing. Compared to new computing paradigms, Turing machines form the proper subset of the set of information-processing devices, in much the same way as Newton’s theory of gravitation is a special case of Einstein’s theory, or the Euclidean geometry is a limit case of non-Euclidean geometries.

According to [32.30] there are three distinct components of information-processing systems: hardware (physical devices), software (programs that regulate its functioning), and infoware that represents information processed by the system. Infoware is a shell built around the software–hardware core, which was the traditional domain of automata and algorithm theory. Communication of information and knowledge takes place on the level of infoware.

*Peter J. Denning* comments on the relationship between computation and information with respect to the

classical Turing idea that computation is equivalent to *algorithm execution* [32.4]:

“First, some information processes are natural. Second, we do not know whether all natural information processes are produced by algorithms. The second statement challenges the traditional view that algorithms (and programming) are at the heart of computing. Information processes may be more fundamental than algorithms.”

*Floridi’s* philosophy of information, developed as [32.37]

“a new philosophical discipline, concerned with a) the critical investigation of the conceptual nature and basic principles of information, including its dynamics (especially computation and flow), utilization and sciences and b) the elaboration and application of information-theoretic and computational methodologies to philosophical problems.”

can be seen as parallel to the philosophy of computation as developed by *Cantwell Smith* in his *Origins of Objects* [32.18].

To better represent information processing in biological systems, computational modeling is applied with computation taken to be *distributed, massively concurrent, heterogeneous, and asynchronous*. *Dodig-Crnkovic* proposes to adopt *Hewitt et al.’s* actor model of computation [32.38, 39]. In this model, computation is the process of message passing between actors (agents) in an interacting network. *Hewitt* provides the following description [32.40, p. 161]:

“In the Actor Model, computation is conceived as distributed in space, where computational devices communicate asynchronously and the entire computation is not in any well-defined state. (An Actor can have information about other Actors that it has received in a message about what it was like when the message was sent.) Turing’s Model is a special case of the Actor Model.”

*Hewitt’s* computational systems consist of computational agents – informational structures capable of acting on their own behalf. Unlike logical model of Turing machine, *Hewitt’s* model of computation is inspired by physics [32.23].

When defining computation as information processing in a network of agents, those networks can consist of molecules or cells like bacteria or neurons, thus constituting networks of networks on the hierarchy of scales of informational structures with computational dynamics.

As we base the model of computation on the concept of information, it is in place to analyze the relationships between the two in more detail.

### 32.3 Computation Versus Information

In this section, we detail the concept of computation as information processing to later on make explicit its connections to cognition in the following sections.

Sometimes the current lack of the consensus about the definition of information is termed *scandal of information*. At the same time, we can talk even about the corresponding *scandal of computation*, that is, the current lack of consensus about the concept of computation. *Denning* describes historical development of the concept of computation [32.4] as it appears in different contexts and various communities of practice.

However, this situation is not as unique as it may seem. There is no simple commonly accepted definition of life, and yet biologists study it and make constant

progress in understanding its different aspects, forms, and processes. Actually no such unique definition of many among central concepts of sciences exists, and yet this situation is not experienced as a scandal. A fresh example is *dark energy*, which together with *dark matter* constitutes 95.1% of the content of the universe. We do not know what they actually are.

Instead of understanding a concept as equivalent to a (linear) string of symbols that constitute its definition, we can rather represent it as a network of relationships such as *is kind of*, *is a member of*, *is a part of*, *is a substance of*, *is similar to*, *pertains to*, *causes*, etc., which connect the concept with other concepts that are connected with still further concepts.

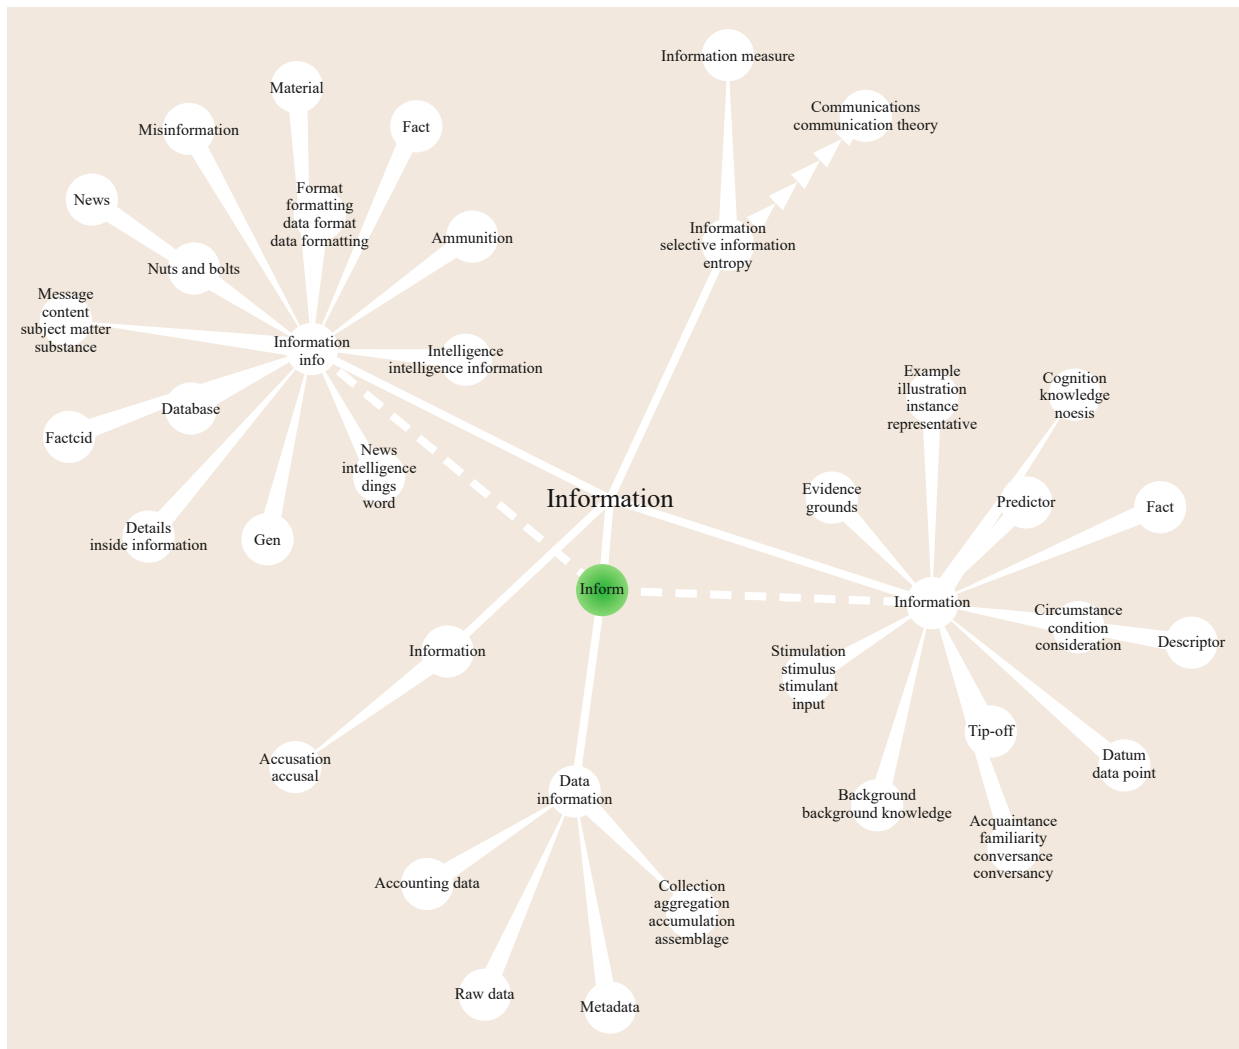

Fig. 32.1 Information concept (after [32.41])

This constitutes *family resemblance* (Familienähnlichkeit) of Ludwig Wittgenstein [32.42, §66] where

“There is no reason to look, as we have done traditionally – and dogmatically – for one, essential core in which the meaning of a word is located and which is, therefore, common to all uses of that word. We should, instead, travel with the word’s uses through ‘a complicated network of similarities overlapping and criss-crossing (PI §66)’”

Wittgenstein explains in [32.42, §67]:

“Why do we call something a *number*? Well, perhaps because it has a direct relationship with several things that have hitherto been called number; and this can be said to give it an indirect relationship to other things we call the same name. And we extend our concept of number as in spinning a thread we twist fibre on fibre. And the strength of the thread does not reside in the fact that someone fibre runs through its whole length, but in the overlapping of many fibres.”

As a result, boundaries dissolve [32.42, §68]:

“What still counts as a game and what no longer does? Can you give the boundary? No.”

Figures 32.1 and 32.2 illustrate how visualizations of the concepts *information* and *computation* may look like and where Wittgenstein’s idea of *family resemblance* becomes apparent.

Given that information/computation are common ideas spanning fields from physics, chemistry, biology, and theories of mind, to ecologies and social systems, the bridging over such a large range is achieved by a network of inter-related concepts (*family of concepts*) that enable us to traverse from field to field, the main point being keeping a common thread. That means that the concept is not a reductionist one, but networked rhizomatic idea in the sense of [32.43].

World today is seen as governed and controlled by natural laws that in-materio execute *programs* unlike the mechanistic world governed by fixed and unchangeable laws expressed by equations of Newtonian physics. Wolfram is arguing that “information processes underlie every natural process in the universe” [32.8].

The important difference is that while equations operate on *data*, programming languages can operate even on higher level *data structures* and even on *physical objects* such as in case of cyber-physical systems.

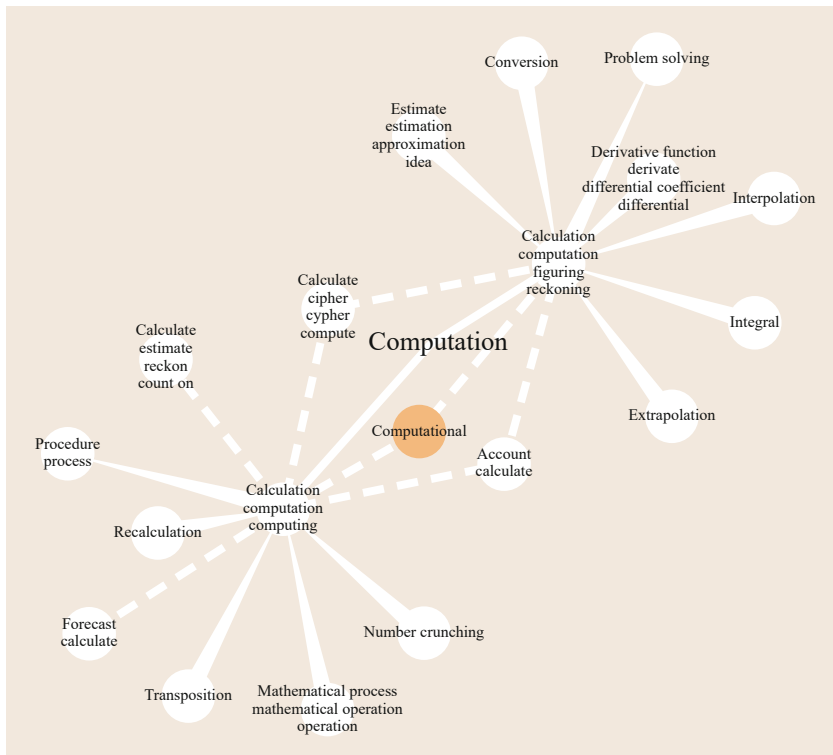

Fig. 32.2 Computation concept network (after [32.41])

## 32.4 The Difference Between Mathematical and Computational (Executable) Models

The belief in mathematical/geometrical essence of the world can be traced back to Plato and the Pythagoreans, which later on reappears with Galileo, in his 1632 *Dialogue Concerning the Two Chief World Systems*, where he argues that the book of nature is written in language of mathematics. Plato's ideal of eternal, unchangeable forms can be found in mathematics to this day. Even though mathematical formulas can be used to compute time-dependent processes, equations themselves are symbolic structures, persistent and immovable. Time dependency comes from human performing computation, actively using static structures of mathematical algorithms to trace time behaviors of real-world systems. Platonic ideal forms, however remote from the physical realizations and questions of finite material resources, were long considered to represent the true nature of the world, while changes were supposed to be something ephemeral, uninteresting, and too earthly for a mathematician or a scientist to bother about. Up to quite recently this detachment from the *real-time* aspects of the world was commonly taken for granted and justified. The change happened with computing machinery getting integrated with dynamically changing physical objects, such as in embedded systems technologies or process control, where real-time computation processes must match real-time behaviors of the physical environment. This situation radicalized even more with the mobile distributed information and communication technologies for which the *system dynamics* is the most prominent characteristics. Rapidly, eternal forms are becoming something remote and less noted. Everything is in the process of change, communication, timely response, and resource optimization, as this new world of embodied and embedded computation is physical in nature and thus substrate-dependent. The whole field of cyber-physical systems is emerging, at different levels of scale, from nano to macroscopic. In this decisive step from idealized abstract forms toward concrete material processes, computation has come close to the messy and complex world of concurrent and context-dependent processes in living beings [32.27]. One important shift is also in the role of an *observer* [32.4]:

“Computational expressions are not constrained to be outside the systems they represent. The possibility of self-reference makes for very powerful computational schemes based on recursive designs and executions and also for very powerful limitations on computing, such as the noncomputability

of halting problems. Self-reference is common in natural information processes; the cell, for example, contains its own blueprint.”

One important aspect of modeling is the direction of their generation – bottom up or top down. Mathematical models are typically top-down while computational models are frequently bottom-up or generative, described by *Wolfram* as a *new kind of science* [32.8]. Fields modeling living organisms like synthetic biology present challenge of bridging the gap between the two, enabling the circular motion from bottom up to top down and back.

*Barry S. Cooper* addresses this difference between mathematical and computational approaches [32.44] in his article detecting *the mathematician's bias* and the current return to embodied (physical, natural) computation.

Unlike pure mathematics, computing can provide modeling tools for biomolecular systems such the abstraction of molecule as computational agent in which a system of interacting molecules is modeled as a system of interacting computational agents [32.45]. *Petri nets, State charts, and the Pi-calculus*, developed for systems of interacting computations, can be successfully used for modeling of biomolecular systems, such as signaling, regulatory, and metabolic pathways and even multicellular processes. Processes, the basic interacting computational entities of these languages, have an internal state and interaction capabilities. *Process behavior is governed by reaction rules specifying the response to an input message based on its content and the state of the process*. The response can include state change, a change in interaction capabilities, and/or sending messages. Complex entities are described hierarchically [32.45].

Computer science distinguishes between two levels of description of a system: *specification* (what the system does) and *implementation* (how the system is built). Biological function of a biomolecular system emerges thus from the semantic equivalence between the low-level and high-level computational descriptions [32.45].

The difference between mathematical and computational models can be summarized as distinction between denotational and operational semantics models given by *Fisher and Henzinger* in the following [32.46]:

*Denotational (mathematical) models* present set of equations showing relationships between different quantities and their time changes. They are approximated numerically.

*Operational semantics models* are based on algorithms, which execution (computation) simulates the behavior of the system in time.

The two semantics have different roles – while ex-

ecutable algorithms connect directly to the physical process and can be used in interactions with them, denotational semantics is descriptive and can be used to reason about systems.

## 32.5 Computation in the Wild

### 32.5.1 Physical Computation – Computing Nature as Info-Computation

Some processes in nature that show high regularity and symmetry have fascinated people for millennia – intricate forms of crystals, shells, flowers, patterns on water or sand, etc. Those have been studied extensively in the literature [32.8, 47–50] as they by their regularities invite algorithmic models. Wolfram, for example, emphasizes the importance of simple generative computational models that in number of iterative steps produce intricate forms that resemble ones found in nature, such as in shells or plants. Forms and processes found in nature in recent years inspired the development of a field of *natural computing*. In the Handbook of Natural Computing [32.21], the following types of natural computation are presented: amorphous computing; molecular computation; RNA-guided DNA assembly; synthetic biology; evolutionary computation; DNA nanomachines; artificial immune systems; evolutionary computation; computational swarm intelligence; quantum computing; genetic programming; membrane computing; and neural networks.

According to [32.51]:

“Natural computing is the field of research that investigates models and computational techniques inspired by nature and, dually, attempts to understand the world around us in terms of information processing. [...] There is information processing in nature, and the natural sciences are already adapting by incorporating tools and concepts from computer science at a rapid pace. Conversely, a closer look at nature from the point of view of information processing can and will change what we mean by computation.”

James Crutchfield et al. [32.52] make a distinction between *designed computation* (that is what computer machinery performs) from *intrinsic computation* (that is all processes in nature that are inherently computational and that are used in computing machinery to compute on the basic hardware level). In that way, they are able to *argue that information processing in dynamical systems as well is computational in nature* –

a claim that earlier was strongly denied. Nature thus presents an implementation substrate for computation. Similar claim is presented in [32.53] that argues that all dynamics of information present some computation, on different levels of description. *Nir Fresco* [32.54] provides an argument that the explanatory frameworks of computationalism, connectionism, and dynamicism, contrary to frequent claims, are not mutually exclusive but rather mutually complementary approaches, suggesting the way for their integration under the assumption of physical computation.

One way to characterize physical computation is via morphology – defining computational processes as the dynamic of morphological structure. *Turing* made pioneering contributions in the field of morphogenesis [32.55] even though he did not think of a process itself as computation. Later on models of robotics systems are made using morphology of a robot body to perform *computation in materio* in that way providing solutions to passive walking robots or artificial muscles [32.56].

*Helmut Hauser, Rudolf M. Füchslin and Rolf Pfeifer* in their *Opinions and Outlooks on Morphological Computation* point out [32.57]:

“Morphological Computation is based on the observation that biological systems seem to carry out relevant computations with their morphology (physical body) in order to successfully interact with their environments. This can be observed in a whole range of systems and at many different scales. It has been studied in animals – e.g., while running, the functionality of coping with impact and slight unevenness in the ground is *delivered* by the shape of the legs and the damped elasticity of the muscle-tendon system – and plants, but it has also been observed at the cellular and even at the molecular level – as seen, for example, in spontaneous self-assembly.”

As can be observed in nature, living systems from the simplest unicellular to the most complex multicellular organisms are heterogeneous, distributed, massively concurrent, and largely asynchronous (in spite of certain common regularities like circadian rhythm

with oscillation of about 24 hours, which is found in animals, plants, fungi, and bacteria). *This kind of systems are hardest to cope with in conventional computing* [32.58]. The approach to modeling such systems suggested by *Luca Cardelli* is as “collectives of interacting stochastic automata, with each automaton representing a molecule that undergoes state transitions” [32.59]. *Aviv Regev* and *Ehud Shapiro* suggest that we should use lessons learned from modeling sequence and structure in biomolecular systems, which already have good computational models [32.45]:

“Sequence and structure research use computers and computerized databases to share, compare, criticize and correct scientific knowledge, to reach a consensus quickly and effectively. Why can’t the study of biomolecular systems make a similar computational leap? Both sequence and structure research have adopted good abstractions: *DNA-as-string* (a mathematical string is a finite sequence of symbols) and *protein-as-three-dimensional-labeled-graph*, respectively. Biomolecular systems research has yet to find a similarly successful one.”

### 32.5.2 New Computationalism. Nonsymbolic versus Symbolic Computation

*Greg Chaitin* argued in [32.60], in the tradition from Leibniz to  $\Omega$  number, epistemology can be seen as information theory. Reality for an agent is defined by information and its processes [32.61] where information processes for a cognizing agent proceed from deepest levels of cell-cognition, self-organized and with emergent properties from subsymbolic signal processing up to symbolic level of human (natural and formal) languages.

As presented in [32.23, pp. 1–22], it is often argued that computationalism is the opposite of connectionism and *that connectionist networks and dynamic systems are not computational*. This would imply that human mind, as network of processes resulting from the activity of human brain, cannot be adequately modeled computationally. However, if we define computation in a sense of natural computation, instead of symbol manipulation as in the Turing machine, it is obvious that processes in the physical substrate of the human brain are natural computation and consequently models of *connectionist networks and dynamical systems do correspond to computational processes*.

One of the central and long-standing controversies when it comes to understanding of computation in biological (cognitive) systems is the relationship between symbolic and subsymbolic computation, where symbol

manipulation is the way of classical Turing computation, while subsymbolic processes such as going on in dynamic systems are frequently not even considered as computing. *Andy Clark* argues convincingly for the necessity of both kinds of processes, subsymbolic and symbolic for human-level cognition [32.62]. Information is relative to a cognizing agent and what is information, symbolic, subsymbolic, continuous, or discrete is a question of level of description or agency. From the everyday experience of a human agent, water and air are continua. However, on the molecular level (thus from the perspective of molecular agency) water and air consist of discrete objects – molecules. Atomic nucleus is seen as a continuum in Bohr’s liquid drop model, while on the level of constituent nucleons, it is a discrete system. On the level of nucleons, we can see continuum but on the deeper level of their constituent quarks as agents, there is a discrete behavior. In general, what an agent registers as continuous or discrete depends on both the system one examines and the type of agent – its structures and ways of interaction. In the dynamic systems models, [32.63]:

“[T]he general idea is that cognition should be characterized as a continual coupling among brain, body, and environment that unfolds in real time, as opposed to the discrete time steps of digital computation. The emphasis of the dynamical approach is on how the brain/body/environment system as a whole changes in real time, and dynamics is proposed as the best framework for capturing that change. This is said to contrast with computation’s focus on *internal structure* i. e., its concern with the static organization of information processing and representational structure in a cognitive system.”

Computational modeling of cognitive processes requires computing tools that contain not only Turing Machine model but also physical computation on the level of biological substrate. That is also the claim made by *Matthias Scheutz* in the Epilogue of the book *Computationalism: New Directions* [32.64, p. 176] where he notices that:

“Today it seems clear, for example, that classical notions of computation alone cannot serve as foundations for a viable theory of the mind, especially in light of the real-world, real-time, embedded, embodied, situated, and interactive nature of minds, although they may well be adequate for a limited subset of mental processes (e.g., processes that participate in solving mathematical problems). Reservations about the classical conception of computation, however, do not automatically transfer and

apply to real-world computing systems. This fact is often ignored by opponents of computationalism, who construe the underlying notion of computation as that of Turing-machine computation.”

Classical computationalism was the view that the classical theory of computation (Turing-machine model, universal, and disembodied) might be enough to explain cognitive phenomena. New computationalism (natural computationalism) emphasizes that embodiment is essential and thus physical computation, hence natural computationalism. The view of Scheutz is supported by *Gerard O'Brien* [32.65] who is arguing that

“cognitive processes, are not governed by exceptionless, representation-level rules; they are instead the work of defeasible cognitive tendencies subserved by the non-linear dynamics of the brains neural networks.”

Dynamical characterization of the brain is consistent with the analog interpretation of connectionism. But dynamical systems theory is typically not considered to be a computational framework. *O'Brien* and *Opie* [32.66] thus search for an answer to the question how connectionist networks compute, and come with the following characterization:

“Connectionism was first considered as the opposed to the classical computational theory of mind. Yet, it is still considered by many that a satisfactory account of how connectionist networks compute is lacking. In recent years networks were much in focus and agent models as well so the number of those who cannot imagine computational networks has rapidly decreased.”

As in classical computationalism only symbolic computation was taken into account, it is important to understand the connection between symbolic and sub-symbolic information processing [32.67, p. 119]:

“Symbolic simulation is thus a two-stage affair: first the mapping of inference structure of the theory onto hardware states which defines symbolic computation; second, the mapping of inference structure of the theory onto hardware states which (under appropriate conditions) qualifies the processing as

a symbolic simulation. Analog simulation, in contrast, is defined by a single mapping from causal relations among elements of the simulation to causal relations among elements of the simulated phenomenon.”

Both symbolic and subsymbolic (analog) simulations depend on causal/analog/physical and symbolic type of computation on some level but *in the case of symbolic computation it is the symbolic level where information processing is observed*. Similarly, even though in the analog model symbolic representation exists at some high level of abstraction, it is the *physical agency of the substrate and its causal structure that define computation* (simulation).

*Gianfranco Basti* [32.68] suggests how to

“integrate in one only formalism the physical (*natural*) realm, with the *logical-mathematical* (*computation*), studying their relationships. That is, the passage from the realm of the *causal necessity* (*natural*) of the physical processes, to the realm of the *logical necessity* (*computational*), and eventually representing them either in a sub-symbolic, or in a symbolic form. This foundational task can be performed, by the discipline of *theoretical formal ontology*.”

*Walter Jackson Freeman* offers an accurate characterization of the relationship between physical/subsymbolic and logical/symbolic level in the following passage [32.69]:

“The symbols are outside the brain. Inside the brains, the construction is effected by spatiotemporal patterns of neural activity that are operators, not symbols. The operations include formation of sequences of neural activity patterns that we observe by their electrical signs. [...] Neural operators implement non-symbolic communication of internal states by all mammals, including humans, through intentional actions. [...] I propose that symbol-making operators evolved from neural mechanisms of intentional action by modification of non-symbolic operators.”

Subsequently, brain uses internal subsymbolic computing to manipulate relevant external objects/symbols.

## 32.6 Cognition: Knowledge Generation by Computation of New Information

In the framework of *Humberto Maturana* and *Francisco Varela*, cognition is capacity of all living beings, no matter how small or simple [32.70]. It is characteristics of organisms that increase in complexity from the simplest ones such as bacteria, to the most complex forms of cognition found in humans. Maturana and Varela's view is gaining substantial support through the study of cognitive capacities of bacteria [32.71–79] and others. Social cognition has been studied in bacterial colonies, swarms, and films. *Lorenzo Magnani* and *Emanuele Bardone* summarize current findings in the following [32.80]:

“[A]ll organisms, including bacteria, are able to perform elementary cognitive functions because they *sense* the environment and process internal information for ‘thriving on latent information embedded in the complexity of their environment’ (Ben Jacob, Shapira, and Tauber, 2006) p. 496.”

In light of the contemporary research results, the earlier completely dominating, and to this day still widespread view of cognition as an exclusively human capacity occurs as a gross simplification. The more we learn about the ways living organisms cope with their environments, the more we understand that even the simplest organisms exhibit cognitive behaviors, that is, adaptive information processing increasing their probability of survival. According to *James Alan Shapiro* [32.78]:

“bacteria utilize sophisticated mechanisms for intercellular communication and even have the ability to commandeer the basic cell biology of *higher* plants and animals to meet their own needs.”

As an example of the level at which the subtleties of bacterial cognitive behavior is known, we refer to *Stephan Schauder* and *Bonni L. Bassler* who reveal the specifics of bacterial communication and quorum sensing both within and between species of bacteria [32.75]:

“Bacteria communicate with one another using chemical signaling molecules as words. Specifically, they release, detect, and respond to the accumulation of these molecules, which are called autoinducers. Detection of autoinducers allows bacteria to distinguish between low and high cell population density, and to control gene expression in response to changes in cell number. This process, termed quorum sensing, allows a population of bacteria to coordinately control the gene expression of the entire community.”

Insights into the cognitive processes of bacteria have very far-reaching consequences for our understanding of life and cognition [32.78]:

“[T]he recognition of sophisticated information processing capacities in prokaryotic cells represents another step away from the anthropocentric view of the universe that dominated pre-scientific thinking. Not only are we no longer at the physical center of the universe; our status as the only sentient beings on the planet is dissolving as we learn more about how smart even the smallest living cells can be.”

Regarding information processing (computation) in bacteria, [32.73] emphasizes that bacterial information processing differs from the Turing machine model of computation. Unlike the Turing machine, in a bacterial colony, in response to an input (signals or molecules from the environment), *hardware* (physical system, bacteria) changes through information processing resulting in a new configuration/form plus possibly some output in signals/molecules. Bacteria typically exchange molecules as information, and it might also be exchange of genetic material. This type of computation is example of *Kampis' component systems* [32.26] and presents *physical computation* [32.54, 81–83]. Yet another take on physical processes behind living agency and its evolution is elaborated by *Terrence Deacon* [32.84]. Even though Deacon himself is not a computationalist, models he develops can be understood as mechanistic and interpreted as computation. For [32.85], bacterial cognition is a case of interactive biological (hyper)computation, that is, computation beyond Turing machine model.

According to [32.86] dynamical systems [32.87], analog neural networks [32.88] and oracle Turing machines [32.89] have in common that they introduce elements that are not Turing computable, that is, they introduce *hyper-computation*. *Bournez* and *Cosnard* compare capabilities of discrete versus dynamical systems and conclude that “many dynamical systems have intrinsically super-Turing capabilities.” Models of hypercomputation or super-Turing computation models of biological systems are studied in [32.90].

Advancing computational models of cognition and bridging the gap between bacterial and human cognition calls for studies of cognition in other living organisms. Even though human cognition is usually superior to animal and plant cognition, it is not always the case. For example, many animals have superior senses like vision, hearing, far better motoric skills, and some

of them like chimpanzees can beat humans in certain memory tasks [32.91]

“Young chimpanzees have an extraordinary working memory capability for numerical recollection – better even than that of human adults tested in the same apparatus following the same procedure.”

Understanding cognition in other organisms has extraordinary value in understanding mechanisms of cognition and their evolution. For example study of cognition in fish can help us find ecological factors that affect the evolution of particular cognitive abilities. One can study the relationship between size of specific brain areas and cognitive abilities and the stages in the development of decision abilities [32.92]. Animal studies can be used for tracing evolution of cognitive capacities, and quantitatively testing possible correlations between certain cognitive abilities and life history, morphology, or socioecological variables, measure if phylogenetic similarity corresponds to the cognitive skills throughout species, etc. [32.93]. However, traditional and even to this day predominant view is that only humans possess cognition. As a consequence, cognitive science developed vast majority of its models and theories exclusively about human cognition.

### 32.6.1 Distributed Cognition and Model-Based Reasoning

Even though animals (including birds) use tools for different purposes, human intelligence is defined as “faculty to create artificial objects, in particular tools to make tools” [32.94]. In the embodied interaction with the environment humans are “engaged in a process of *cognitive niche construction*” as they delegate certain cognitive functions to the environment [32.80]:

“In this sense, we argue that a cognitive niche emerges from a network of continuous interplays between individuals and the environment, in which people alter and modify the environment by mimetically externalizing fleeting thoughts, private ideas, etc., into external supports. [...] Artifactual cognitive objects and devices extend, modify, or substitute *natural* affordances actively providing humans and many animals with new opportunities for action.”

Underlying computational cognitive mechanisms enable the process of model construction. If we take *knowledge* to include not only the propositional knowledge (knowledge that) but also nonpropositional knowledge (knowledge how), we can say that bacteria *know how* to find food and avoid dangers in the environment.

According to [32.95]:

“Knowledge generation can be naturalized by adopting computational model of cognition and evolutionary approach. In this framework knowledge is seen as a result of the structuring of input data (data → information → knowledge) by an interactive computational process going on in the agent during the adaptive interplay with the environment, which clearly presents developmental advantage by increasing agent’s ability to cope with the situation dynamics.”

Scientific knowledge is obviously human knowledge and it includes both propositional (typically theoretical) and nonpropositional (typically practical) knowledge. *Ronald N. Giere* suggests that models in science are best understood “as being components of distributed cognitive systems,” where the process of scientific cognition “is distributed between a person and an external representation” [32.96].

The idea of distributed cognition can be traced back to *David Rumelhart* and *James McClelland* [32.97], and it has been developed during the years in a number of prominent works such as [32.98, 99, 99–102].

The related idea termed *extended mind* has been proposed by *Andy Clark* and *David Chalmers* in [32.103] meaning that humans use tools and other suitable objects in the environment to perform cognitive tasks. *Enactivism* is a connected movement in the philosophy of mind whose proponents argue that we should understand mental abilities as essentially related to the extended body and to action [32.104].

In the study of the capabilities of networks of simple processors, *Rumelhart* and *McClelland* [32.97] found that they are good at recognizing patterns in the input. The generalization to human brain is that it recognizes patterns through the activation of changes in the states of neurons induced by sensory inputs. *Rumelhart* and *McClelland* suggest that “humans do the kind of cognitive processing required for these linear activities by creating and manipulating external representations.”

In a distributed cognitive system information processing happens through parallel distributed processing (PDP). In this view “the regular or law-like behavior of a complex system is the consequence of interactions among constituent elements” [32.105]. The main ideas of PDP models – such as that cognitive functions arise from neural mechanisms, representations are distributed, cognitive development is driven by learning, cognitive structure is quasi-regular, behavior is sensitive to multiple ordered constraints, processing is ordered and continuous – are now standard assumptions in many research domains.

As a consequence of distributed cognition language is seen as a means of socially distributed cognition that supports human communication [32.106]:

“There is no *language of thought*. Rather, thinking in language is a manifestation of a pattern matching brain trained on external linguistic structures (see also [32.107]).”

This distributed view of language implies that “cognition is not only embodied, but also embedded in a society and in a historically developed culture” [32.101].

Even here, as in the case of *language games* we see social aspect of cognitive artifacts. In the same way as a concept is a node in a network of related concepts, connected with several types of relationships, distributed cognition in general is a network that in principle can extend indefinitely. What we consider to be relevant depends on the agent and the context.

The computational model of cognition is closely related to the idea of agency. An agent in this context is defined as an entity capable of acting on its own behalf. Agent models are especially suitable for modeling of distributed cognitive systems and they are used for study of adaptive behavior and learning. Among new trends in modeling there are generative agent-based models, where complexity of a system results from the time development of the interactive behavior of simple constitutive parts (such as swarm). Especially successful are new network models of complex systems [32.108] where the focus is on the properties of various network structures in an emerging network science. Commenting on the current development of computing, [32.109] declare:

“Multiplicities, flux, materialities, heterogeneities, and co-construction are features that are becoming increasingly evident within new configurations of computing.”

Those features are particularly suitable in modeling of living (cognitive) systems.

### 32.6.2 Computational Aspects of Model-Based Reasoning in Science

Nancy Nersessian [32.110] searches for “the cognitive basis of model-based reasoning in science,” especially for model-based creative reasoning that results in “representational change across the sciences,” thus investigating the central issue of creativity in science asking “how are genuinely novel scientific representations created, given that their construction must begin with existing representations?”

Nersessian addresses methodological issues in scientific cognition, and the nature of model-based reasoning in science in order to give an account of their cognitive basis and the role they play in representational change. She introduced the term *model-based reasoning* to denote the construction and manipulation of representations, both sentential, and those related to external mediators [32.111, 112]. Model-based reasoning is applied to among others thought experiments, visual representations, and in analogical reasoning [32.113, 114].

As Giere [32.115] emphasizes, models are not only tools but they also play a central role in the construction of knowledge. “Models are important, not as expressions of belief, but as vehicles for exploring the implications of ideas (McClelland 2010)” [32.105]. One of the ways of acquiring knowledge besides deduction and induction is abduction that leads to knowledge discovery. Along with sentential and model-based theoretical abduction, [32.116] identifies *manipulative abduction* as thinking and learning through doing. Manipulative abduction is thus situated in the domain of extended cognition and presents an extra-theoretical behavior developed through manipulation of artifacts, such as written notes, diagrams, experimental set-ups, visual and other simulations, etc. One of the illustrative examples of extended cognition is diagrammatic reasoning [32.117, 118], [32.119]:

“What is interesting about diagrammatic reasoning is the interaction between the diagram and a human with a fundamentally pattern-matching brain. Rather than locating all the cognition in the human brain, one locates it in the system consisting of a human together with a diagram. It is this system that performs the cognitive task, for example, proving the Pythagorean theorem.”

Giere provides further examples of reasoning with pictorial representations and reasoning with physical and abstract models [32.96, p. 237]

“The idea of distributed cognition is typically associated with the thesis that cognition is embodied. In more standard terms, one cannot abstract the cognition away from its physical implementation.”

This agrees with *Fresco's* conclusions from his book *Physical Computation and Cognitive Science* [32.54].

Based on the idea that “*a complex system, as the cognitive one, and its transformations, can be described in terms of a configurational structure.*” [32.120], morphodynamical abduction is then the abduction expressed through the geometrical framework of configurational structure. *Magnani* in [32.121] explains that

“different mental states are defined by their geometrical relationships within a larger dynamical environment. This suggests that the system, in any given instant, possesses a general morphology we can study by observing how it changes and develops.”

This suggests the possibility of representing aspects of abductive reasoning in the framework of dynamical systems, as processes of natural computation.

In [32.121] the authors argue that:

“Creative and selective abduction can be viewed as a kind of process related to the transformations of the attractors responsible of the cognitive system behavior. In the context of naturalized phenomenology we have described anticipation and abduction

in the light of catastrophic rearrangement of attractors.”

This insight about the character of major qualitative shifts in understanding can be extended to aspects of scientific discovery as *Thagard* addressed for conceptual change and scientific revolutions [32.122].

In the context of model-based reasoning it is instructive to take software as an example of executable computational models that enables transformations from system requirements to design and implementation. Software is used as a cognitive tool of extended cognition, which facilitates cognitive information processing by automation of reasoning, performing cognitive tasks of computation, search, control, etc., that already has resulted in radically new conceptualizations such as cyber-physical systems and Internet of things.

## 32.7 Model-Based Reasoning and Computational Automation of Reasoning

Models have been historically used in scientific and engineering disciplines to handle large-scale, complex research and development enterprises. Modeling as an inherent human skill is tightly coupled with the use of natural language for communication [32.123]:

“Though we share the same earth with millions of kinds of living creatures, we also live in a world that no other species has access to. We inhabit a world full of abstractions, impossibilities, and paradoxes. We alone brood about what didn’t happen, and spend a large part of each day musing about the way things could have been if events had transpired differently.”

Models are typically exploited to design solutions as a preliminary step of the realization of an engineering project: the underlying aim is to anticipate relevant properties, design pitfalls, and other pertinent information that would be extremely expensive if discovered at advanced stages of a project. In modern times, none would build a bridge or a house without a model, at least to know in advance their expected mechanical properties and costs and time for completion, just to mention a few relevant parameters. The fact that most of the techniques exploit pictorial representations has to be directly interconnected to what is said so far, that is, modeling is an intrinsic human activity and our brain is exceptionally skilled in matching images with concepts, as argued in [32.117, 118].

Nowadays at the heart of scientific and engineering projects is software that is largely responsible for its function. The growing adoption of computational

devices and tools controlled by software in all aspects of human’s everyday life and its exploitation in mission-critical tasks inevitably contributed to the enormous magnification of nowadays software complexity. If the adoption of more and more advanced programming languages and techniques (first, second, third, and even fourth generation) can be conceived as progressive steps toward more abstract methods to develop software, they still meet the obstacles of code-centric approaches [32.124]:

“Conventional programming involves the manual translation of domain concepts living in the programmer’s head into a source program written in a concrete, general-purpose programming language such as C++ or Java. This translation inevitably causes important design information to be lost due to the semantic gap between the domain concepts and the language mechanisms available in the programming language. [...] Today, most designs are expressed in a concrete programming language meaning that the larger share of the design information is lost.”

In this respect, one of the main drawbacks of code is a limited understandability of the produced artifacts (even by the authors themselves), which seriously hinders the maintainability of the system. By considering that a complex software systems can be made up of millions of lines of code, have a life span of decades, and often merge in the solution expertise from diverse domains, it is clear that without proper modeling, the system will quickly run out of control, if it would be re-

alizable at all. Therefore, even though programming can be seen as a form of modeling of a system and its behavior, here we will refer to models as higher abstraction level representations, very often pictorial, of a software system [32.125]:

“Modeling, in the broadest sense, is the cost-effective use of something in place of something else for some cognitive purpose. It allows us to use something that is simpler, safer or cheaper than reality instead of reality for some purpose. A model represents reality for the given purpose; the model is an abstraction of reality in the sense that it cannot represent all aspects of reality. This allows us to deal with the world in a simplified manner, avoiding the complexity, danger and irreversibility of reality.”

From the 1980s, modeling techniques in software engineering have become more and more widespread. Their initial exploitation was confined to sole documentation/communication purposes, while from the late 1990s they have been progressively adopted to provide some form of automation. Interestingly, computing is perhaps the only domain (except for logic) that has *meta-products*, that is, it realizes products that are developed by means of the same methods used to realize the design/modeling tools (unlike, e.g., civil engineering where physics and computer graphics are exploited to model the final physical product, houses and bridges). It is not surprising that modeling techniques can be conceived as a derived product of description logics (DL), that is, a family of formal languages used for knowledge representation more expressive than propositional logic. However, as [32.126] argues, “these diagrammatic modeling languages provide no extensional, mathematical semantics, nor any automated reasoning facilities.”

The reasons of an evolution toward automated mechanisms are often connected with consistency problems: if a software system is documented through models and then implemented by hand, none can guarantee that what was coded is compliant with what was designed. Even more important, in future maintenance activities it will be very difficult to keep the consistency between models and code. These issues find their reasons in the gap between domain-specific description of the problem and programming language encoding of a solution, as interpreted by the programmer and narrowed down by the constructs available in the language (see the notion of agency explained later on). As a consequence, a paradoxical situation will appear in which modeling artifacts have been introduced as an additional effort that, however, leaves the initial problem unsolved – aiding in the maintenance of complex systems.

Modeling languages like the UML (unified modelling language), (object management group (OMG) [32.127]) are formal enough to be used for automated reasoning. They exploit pictorial, or better, diagrammatic representations of a system to document its structure and functions. They are typical examples of previously mentioned diagrammatic reasoning where diagrams are objects supporting distributed cognition. With UML being formal here we mean that models conforming, for example, to the UML have to adhere to a well-defined set of rules and constraints to produce models. Being more precise, a model has to adhere to a set of constraints defined by means of a metamodel, that is, a modeling language definition.

The most common way of defining a modeling language is to specify concepts and relationships between them. In general, language elements are interconnected through associations with multiplicities restricting possible source(s) and target(s) of a certain relation. Moreover, elements can contain other elements, and elements can specialize other elements. If a model adheres to all the production rules defined in the metamodel, it is said to conform to the metamodel. The metamodel itself has to adhere to precise rules to specify a language (like those we informally listed so far), which are typically referred to as the meta-metamodel. The abstraction hierarchy is limited at this point by prescribing that the meta-metamodel is defined by itself.

In order to improve the usability and readability of models, very often language concepts are not directly shown to users. On the contrary, they are in general amalgamated into information units and rendered in a more compact/intuitive way. Such utility elements, typically called *syntactic sugar* in programming languages terminology, introduce the distinction between abstract and concrete syntax of models. The former defines the structure of the model in terms of the metamodel it conforms to, while the latter represents how the model is rendered to the user. In this respect, the metamodel defines conformance rules in terms of the abstract syntax, while a certain abstract syntax can give place to multiple concrete syntaxes.

Modeling languages can be divided into two main categories: general purpose (GPL) and domain-specific (DSL). The former category refers to languages that have not been defined with a particular application domain in mind, and hence exploit general concepts to represent a certain real-life phenomena in abstract terms. The latter category instead is typically built bottom-up and exploits the vocabulary specific of a certain applicative field. When linking those categories to model-based reasoning, it is intuitively easier to grasp the *message* carried by a model when produced by a DSL, since it exploits concepts specific of a certain domain, very

often with the help of an adequate (pictorial) concrete syntax. On the contrary, GPLs' models are less intuitive since they re-encode certain phenomena through generic modeling concepts and their concrete syntax has to exploit very general modeling elements. However, the specificity of DSLs is also their Achilles' heel: whenever concepts need to be added and/or refined vast revisions can be required, in general to change users' rendering of elements, attached semantics, and so forth. For example, for a tiny language supporting the graphical definition of mathematical expressions, if we consider elementary school usage we could define the language taking into account only natural numbers. As soon as we want to extend the language to support real numbers everything needs to be revised: notably, negative or rational numbers not only need a different representation, but also enable additional operations.

The concepts exploited to define a language *implicitly establish ontology of an idealized user using models for a certain purpose*. In this respect, the specification of concepts, their relationships, and their graphical rendering through a concrete syntax are all conceived with this goal in mind. In the case of GPLs, ontology is indirectly derived as mapping between generic concepts and corresponding domain-specific items. Notably, the mathematical language mentioned above could be represented as a *package* containing four *classes*, each one identifying an arithmetical operation, and hence called *Addition*, *Subtraction*, *Multiplication*, and *Division*, respectively. In turn, each class would contain *attributes*, called, for example, *operand\_1*, *operand\_2*, and *result*. Moreover, each class would contain a *method do\_calculation* performing the appropriate operation on the operands and returning the result. It is worth noticing that in this case the GPL offers concepts like package, class, and so forth, by which it is encoding reality. On the contrary, a DSL could define a *Calculator* including the four operations, each of which requiring two input parameters and returning an output. If either exploiting a GPL or using a DSL, it is supposed that the user has a clear idea of the correspondence between the sign + and the addition operation, and so forth. Even more important, the user should make correct use of operands putting them in the correct order, especially when performing subtractions or divisions.

When talking about model-based reasoning we usually refer to semantics, that is, the meaning that is associated with concepts and relationships constituting a model [32.128]:

“a language consists of a syntactic notation (syntax), which is a possibly infinite set of legal elements, together with the meaning of those elements, which is expressed by relating the syntax to a se-

mantic domain. Thus, any language definition must consist of the syntax semantic domain and semantic mapping from the syntactic elements to the semantic domain.”

Semantics is distinguished in two main categories, namely structural and behavioral semantics. The former is based on the metamodel definition itself, while the latter focuses on the execution of models conforming to a given metamodel. Therefore, for instance if we consider again the mathematical expression language, we could define the subtraction operator as taking two natural numbers and producing one natural number. At this point we can also impose that the first input shall be greater than the second. Despite that we did not specify what a user would do with a model conforming to such a metamodel, it is quite intuitive that we are defining semantics by the metamodel, since we are narrowing down inputs and output to natural numbers (and we are also constraining the maximum number of inputs to two). Moreover, from an ontological perspective the terms *subtraction*, *operand*, and *result* should be self-explanatory about the concepts provided by the language.

Behavioral semantics adds the dynamics of model elements to the structural part, or the definition of the process related to the ontology defined with the language. Such description could be done in informal ways, even by means of natural language (this is for instance done for the specification of large portions of the UML). Therefore again taking into account the math example, the semantics of subtraction concept would be defined as *The subtraction operation subtracts the value of operand\_2 from operand\_1*. The main issues with informal approaches are their proneness to ambiguous interpretations and the impossibility to exploit them for automation purposes (e.g., interpretation, analysis, execution). A second possibility to give semantics to metamodel concepts is by means of a behavioral sublanguage embedded in the language itself. In some cases the structural part can be decorated with behavioral descriptions (e.g., scripts in a specific programming language); in other cases some portions of the language can be devoted to model behavior (for instance, the UML specification includes behavioral diagrams like state machines. Moreover, there exist UML extensions enabling behavioral description through so-called action languages). The model-driven research area introduced model transformations as another possible alternative, described in the following [32.129]:

“the definition of the semantics of a language can be accomplished through the definition of a mapping between the language itself and another language with well-defined semantics such as Abstract State

Machines, Petri Nets, or rewriting logic. These semantic mappings between semantic domains are very useful not only to provide precise semantics to DSLs, but also to be able to simulate, analyze or reason about them using the logical and semantic framework available in the target domain. The advantage of using a model-driven approach is that these mappings can be defined in terms of model transformations.”

Here model transformations are automatic mechanisms mapping models toward other models as well as streams of characters. In this respect, a transformation performs a semantic anchoring between the structural concepts defined in the metamodel and the corresponding elements generated as target of the transformation execution. From an ontological perspective, the transformation in this case conveys the definition of the process.

## 32.8 Model Transformations and Semantics: Separation Between Semantics and Ontology

Historically, the semantics of a model has been given through corresponding constructs in a programming language, and in some cases modeling languages have been even conceived bottom-up as abstraction of a programming approach. The underlying reason is that for software experts it was easier and less ambiguous to interpret a model by means of the corresponding algorithm implementing what is designed. Moreover, software was mainly used for pure computational purposes that did not act directly on the real world. Therefore, semantics in software engineering had an *indirect* relationship to the real world since it was revealed in terms of *data structures* and *computation actions*.

More recently, embedded software systems are becoming ubiquitous and have been gradually replacing hardware functions, thus requiring a variety of modeling approaches. Nowadays, physical behavior is often mixed with software models since embedded systems directly interact with the world – often referred to as cyber-physical systems. In turn, semantics also evolved from pure computation to combination of computation and interactions with the physical world. For example, a model of a power window in a car contains both a state machine to show how buttons are related with the position of the window, and a physical model of the force the motor applies to move the window. If the force exceeds a certain value the motor has to be stopped and buttons deactivated, since an object could be obstructing window movements.

Another relevant aspect of semantics is that *a model could have more than one interpretation* depending on the user’s (both human and machine) point of view. In other words, a model may carry multifaceted information that could be equivalently used to both perform analysis and to generate code. Notably, in the power window example, models serve both to generate the code for commanding the motor through buttons, and to verify that the window will never harm passengers in its movements.

Model transformations are the means to manipulate models, both to generate other models and to derive textual documents (including code). They are related to model-based reasoning because the correspondences established through transformations draw interconnections among concepts pertaining to different domains. Therefore, they can be exploited to map the concepts expressed in a source model toward a corresponding target for which the semantics is well known (e.g., code generation gives a precise operational semantics to the source model). This notably allows performing more or less automated considerations about the quality attributes of a certain system and to refine its specification if needed.

Despite the existence of model transformations, modeling gives inherently place to *ambiguities* and *problems of interpretation*. In the most trivial case, the agent writing the transformation is not the modeler, opening already at that point space for erroneous interpretations. One of the relevant ambiguity problems is related to *multi-view based modeling*: given the complexity of nowadays systems, they are often modeled by means of different points-of-view that describe the system from corresponding domain-specific perspectives. In general these different views are not completely orthogonal, rather they *overlap and combine* for certain aspects. Such overlaps introduce interpretation problems due to the fact that the same concept may have different semantics depending of the point-of-view it is used in. Even more, the combination of concepts coming from different views could constitute a higher order concept that is not representable in any one of the single views separately.

Further important issue is related to the management of *evolution*, which is one of the peculiarities of software systems in general. When dealing with models and their evolution, some problems come into play due to the level of abstraction. First of all, it is difficult to compare two versions of the same model at differ-

ent points in time and recognize precisely the kind of evolution they have been subject to. Notably, it is very difficult to distinguish between the deletion of an element and subsequent addition of a new one versus the simple modification of the same element from the older toward a newer version. Even if this could appear as a minor aspect, it has relevant consequences. In fact, in the former case whatever was derived from the removed element should be deleted as well, whereas in the latter situation interconnected elements should be tracked and updated accordingly. In turn, the *propagation of updates* poses interpretation problems as well. By recalling the simple evolution example related to the subtraction operation (from natural to real numbers) mentioned before it is not difficult to foresee what kind of problems developers will incur when trying to reflect the impact of change on different related elements. Notably, if a concept in the language was renamed, the question is should its concrete syntax also be revised? How? And what about transformation mappings written on the base of the previous version of the modified concept?

What can be seen as a promising trend to alleviate the issues described above is the introduction of a separation between what have been called as *structural* and *ontological* aspects of a certain language. The structural aspects refer to generic syntactic rules that are invariant with respect to the information carried by the language. On the contrary, the ontological aspects are domain specific and are strictly related to a particular application context [32.130]. In general, structural aspects are simpler to manage, since there is no domain semantics involved. On the contrary, ontological aspects embed the semantics of a certain domain, and therefore typically require user guidance. If we take an example of natural language, structural aspects are grammar rules for sentence construction, while the ontological part is the argument discussed in the text. In this respect, a better denomination would be *informative* and *cognitive* aspects of a language, respectively. In such a way, it would not only be clearer that the latter aspects include semantics details, but it would also make it possible to introduce the notion of *agency and agent*, to locate possible multiple interpretations due to agency (something that gets mixed in the term ontology).

A separation between semantics and ontology, by introduction of the model of *agent-centered ontology*, is due to the fact that ontology (all that exists) *depends on to whom it exists* (see the later discussion). For example for humans, invisible microscopic layers of physical reality did not exist before the invention of microscopes; birds collide with windows because they do not see glass – for them it does not exist before the collision. For them much of human civilization does not

exist otherwise than as physical objects. The simpler an agent in the world is, the simpler is its ontology, that is, all that exists and can exist for that agent. Living agents self-organize at increasing number of layers of agency [32.131]. The core is the basic physical structure of elementary particles and forces from which new layers of organization emerge – from physics to chemistry, biology, and cognitive layer. Humans, on the top of hierarchy, have the highest known number of levels of organization. Starting with the *model of layered agency*, from the basic physical primitives to cognitive functions we can define semantics for an agent. For an agent it is characteristic that it is capable of *acting in the world*.

The most fundamental is *physical agency* where agents act completely automatically by simply obeying physical laws. Chemical agency is a level above and it builds on basic physical agency of elementary physical constituents, taken in bigger chunks of molecules that interact with each other. Biological agency emerges from chemical ones when chemical structures and cycles are established, which enable stable self-sustaining and self-reproducing formations [32.84] like first viruses (in between crystal and living organism) and bacteria as simplest cellular organisms. Symbol-manipulation-based agency arises first with organisms possessing nervous system, which helps them to model and predict their environment. Social-level distributed cognition emerges in networks of agents, from simplest living organisms to humans and anticipated intelligent machinery that is currently being developed. On the highest level of organization, there are languages shared by a community of users, used for coordinating actions and control of environment. Here even programming languages belong.

Software is based on programming languages, which constitute logical framework and syntactic rules. With respect to agency and agents in modeling for SE, some consideration is in place. From the earlier sections of this chapter, it is clear that our cognitive mechanisms are shaped by our embodied pattern recognition capability, which in turn has been trained through individual life and experiences as well as based on evolutionary developments of the species. In this respect, model users are agents – the ones who design the language to specify models, the ones that abstract a certain real-life phenomena through the model, and the ones who map the information carried by a model back to a corresponding real-life domain. Agency depends on the background experience of a user that influences the interpretation of concepts represented through models. Notably, domain experts may have a deeper knowledge of certain aspects of the system that would introduce

ambiguities in (or erroneous interpretation of) the models exploited to design systems in their domain (earlier mentioned in the example of the arithmetic modeling language).

As an illustration take the picture shown in Fig. 32.3. If we consider its content as an abstraction of reality, typical human agent would give the interpretation of it as two road signs, both indicating an airport in half a mile. However, there would be some agents also noticing that the shape of the plane resembles an arrow. This added detail couldn't be ignored, since it gives place for further interpretations of the figure. Did the designer intend to convey that to reach the airport the driver should follow the direction pointed by the plane? In other words, is the orientation of the airplane making a difference in driving direction? If the agent designing such a picture did not know anything about the usage scenarios of those signs, of course all those further interpretations would be the erroneous product of agency. In this respect, designing a language has intrinsic pitfalls due to the fact that the agents creating a modeling language most probably will not be the ones using it to model a certain system. In turn, the agents modeling the system will most probably differ from the ones exploiting those models for other activities (testing, implementation, documentation, etc.). As a consequence, models will be inherently ambiguous unless a precise semantics is given. This is one of the main reasons why model-based approaches can miss their potentials if code generation (or other forms of precise semantics) is not provided. To avoid that, automatic derivation of code from model establishes a well-defined semantics free from misinterpretation, and once the mapping between models and code is proved as correct, it would guarantee the consistency between design and implementation.

By considering the distinction between *informative* and *cognitive* aspects of a language it would be possible to alleviate the inherent problems due to ambiguities carried by models. By approaching the problem in a model-based way, it would be necessary to introduce a new language able to express agency, or analogously to define a precise *agent-based ontology* clarifying the level of expertise of a certain agent. In this respect however, the current approach of model-based techniques goes in the direction opposite to a natural process of abstraction. In fact, in the latter, simple components are interconnected to build up higher order cognitive

**Fig. 32.3** Two similar road signs with possible ambiguous interpretations

concepts, while in the former a language is first defined and subsequently the user tries to represent certain reality through the concepts offered by the language. Therefore, a more natural approach would be to let the user model reality in the desired way and incrementally build the underlying language based on the concepts exploited in the modeling activity.

Moreover, partial model transformations could be defined for better specifying some of the cognitive aspects included in a model. Google search engine can be mentioned as an example of current proposal. The engine has been enhanced through the years and currently, thanks to user tracking (which is a machine learning process) it has the capability of anticipating search queries of a given user (agent). It is often enough to type the first three/four characters of a word to get as suggestion the exact sentence one was thinking about. Moreover, with the same accuracy the search engine is able to suggest a potentially more relevant query based on the one written by the user. In the same way, a modeling language should be able to create a customized profile for each user, by learning from the users' modeling operations, a corresponding adequate ontology. In this way, the tool could anticipate some of the users' needs and aid them in correct modeling choices. In other words, the tool would be able to close the gap between ontology of the idealized user of a modeling language and the agent-based one.

# 33. Computational Scientific Discovery

Peter D. Sozou, Peter C.R. Lane, Mark Addis, Fernand Gobet

Computational scientific discovery is becoming increasingly important in many areas of science. This chapter reviews the application of computational methods in the formulation of scientific ideas, that is, in the characterization of phenomena and the generation of scientific explanations, in the form of hypotheses, theories, and models. After a discussion of the evolutionary and anthropological roots of scientific discovery, the nature of scientific discovery is considered, and an outline is given of the forms that scientific discovery can take: direct observational discovery, finding empirical rules, and discovery of theories. A discussion of the psychology of scientific discovery includes an assessment of the role of induction. Computational discovery methods in mathematics are then described. This is followed by a survey of methods and associated applications in computational scientific discovery, covering massive systematic search within a defined space; rule-based reasoning systems; classification, machine vision, and related techniques; data mining; finding networks; evolutionary computation; and automation of scientific experiments. We conclude with a discussion of the future of computational scientific discovery, with consideration of the extent to which scientific discovery will continue to require human input.

Science is concerned with characterizing and explaining observations and phenomena. For most of history, it has been an exclusively human activity. However, the development of computers has had a substantial impact on science. The assessment and testing of scientific models has seen the application of computational methods, often with spectacular success. Among these major successes have been the development of numerical and simulation methods to compute the predictions of scientific models [33.1, 2].

A more ambitious endeavour is the use of computational methods to represent, in some sense, the formu-

lation of scientific ideas – the characterization of phenomena and the generation of scientific explanations, in the form of hypotheses, theories, and models. This is the focus of this review. What computational methods have been developed so far, and how have they been applied? What scope is there for further developments and applications?

We begin by discussing the evolutionary biological and anthropological roots of scientific discovery, and the establishment of scientific discovery as a human endeavor. We then set out important features of the nature of the scientific discovery process, and the

different forms of discovery. This provides a basis for considering the psychology of scientific discovery. This is followed by a discussion of computational discovery methods in mathematics, which, because of the close links between mathematics and the theoretical sciences, provides a useful prelude to computational discovery

in science. We then survey methods and applications in computational scientific discovery. We finally draw conclusions, with particular attention paid to what type of problems in scientific discovery computational methods are best suited to, and the future of computational scientific discovery.

### 33.1 The Roots of Human Scientific Discovery

Humans are capable of learning, that is, acquiring and processing information, so as to influence their future actions. This includes an ability to make inferences from limited observations. Scientific discovery, it has been claimed, uses similar inferential principles [33.3]. Why did natural selection favor the capacity for learning in animals? A major factor is likely to have been environmental variability [33.4]. There may have been something of a self-sustaining evolutionary process at work, with arms races between the learning capabilities of predators and prey, and competition for resources between members of the same species favoring the best learners. Animals with highly developed brains, particularly primates and corvids, exhibit the ability to innovate and to make tools to overcome new challenges [33.5–7]. Humans, however, stand out from other animals in the extent of their development of tools.

The precise evolutionary basis of human language is uncertain [33.8], but language facilitated the transmission and synthesis of useful information. Pre-agricultural communities are believed to have had a great deal of useful knowledge, largely gathered through trial and error. They demonstrated representational skills with the creation of art objects such as cave art (dating from approximately 40 000 years ago in Europe and Indonesia). Plant domestication is thought to have first occurred in the fertile crescent of Western Asia; the Sumerians of Mesopotamia are strong contenders for being the first to invent writing, somewhat before 3000 BC [33.9]. These developments led to highly ordered and stratified societies, with specialization of labor, significant technologies, and empirical knowledge of many important processes. The form of enquiry recognized today as general scientific explanation came later; the first search for the *causes and principles* of the natural world is attributed to Thales of Miletus around the beginning of the 6th century BC [33.10]. This notion was further developed by Aristotle, explaining what is less well known by means of what is better known and more fundamental, and

the requirement for explanations to be consistent with observations [33.11]. Aristotle's approach is a direct forerunner of the model of scientific discovery that is broadly accepted today, in which scientists propose new hypotheses and then devise experimental tests for them [33.12].

*Ernest Rutherford* remarked that “All science is either physics or stamp collecting” [33.13]. Although this could be said to be simplistic, it captures the essential truth that a great deal of science involves what may be termed *direct observational discovery*: Observing and characterizing phenomena, without the need for deep theoretical explanations. Thales of Miletus is credited with the discovery that when amber is rubbed with fur, it then attracts light objects – what is known today as static electricity [33.14]. The development of optical microscopy in the sixteenth and seventeenth centuries led to the discovery of bacteria, biological cells, and spermatozoa. These were clearly scientific discoveries of vital importance, but they were not in themselves deep theories. Some research in astronomy also has this character, such as the discovery in 1930 of Pluto by Clyde Tombaugh from examination of photographic plates. A deep theoretical understanding of gravitation was important for this discovery – anomalies in the motion of Uranus, not fully explained by the gravitational effects of Neptune, suggested the existence of a hitherto undiscovered planetary body – but the discovery itself was a direct observational discovery: It did not constitute the discovery of an observational law or of a theory.

These discoveries typify situations in which scientific discovery follows directly from technological advances. Thus, the development of x-ray crystallography [33.15] enabled the structure of proteins [33.16] and of deoxyribonucleic acid (DNA) [33.17] to be established. More recently, modern studies in molecular biology have led to a vast amount of data becoming available. This makes it worthwhile to consider data-driven scientific investigation [33.18], which is frequently computational and can complement the hypothesis-driven approach.

## 33.2 The Nature of Scientific Discovery

Scientific discovery involves a range of activities and methods. One general form, as described above, is direct observational discovery: simply finding and characterizing a phenomenon, such as the aforementioned discovery of what became known as static electricity [33.14]. *Langley* [33.19] describes the formation of taxonomies as the first stage of the discovery process. However, we do not consider direct observational discovery to be limited to the formation of taxonomies, as it may include discoveries that fit within existing taxonomies, such as the discovery of Pluto described above. Additionally, the formation of taxonomies is not always the first stage of scientific discovery; for example, the classification of organisms according to how recently they last shared a common ancestor depends on the prior theory that the organisms in question are descended from a common ancestor. In short, there are cases where direct observational discovery does not involve the formation of taxonomies, and cases where the formation of taxonomies is a late stage in the discovery process. We therefore consider direct observational discovery to be a basic form of scientific discovery. It generally occurs at the birth of a scientific field, but often continues as the field matures.

A different form of discovery, which generally comes after a field has matured sufficiently to have accepted terms for describing observations and quantitative measures of these observables, is concerned with finding empirical rules. Such a rule is a useful description of some aspect of the world to which a number of observations conform. Prominent examples are Kepler's laws of planetary motion, Weber's law (also known as the Weber–Fechner law) in psychology, which states that the just noticeable difference between two stimuli is proportional to the size of the stimuli, and the constancy of the speed of light in any reference frame, established by the Michelson–Morley experiment of 1887. This form of discovery can, if desired, be divided into those that involve qualitative rules on the one hand and quantitative on the other; an additional distinction concerns whether or not the rules involve unobserved entities [33.19].

Another category of discovery is theories. A theory is an underlying explanation, accounting for a set of observations by means of a causal process. For example, Newton's theory of gravitation explains Kepler's observations by means of a deeper, causal principle. The theory of evolution by natural selection, conceived by Darwin and Wallace, explains a wide range of observations regarding organisms' adaptations, and forms the basis of the modern science of behavioral ecology.

It should be recognized, however, that the distinction between different categories of scientific discovery is not absolute [33.3, 20]. Newton's theory of gravitation is a case in point: While we believe it is appropriate to call it a theory, one can also describe it as an empirical rule, albeit a deeper one with more explanatory power than Kepler's laws. A putative chemical structure can be regarded as a theory, and therefore the discovery of a chemical structure (such as the discovery by Watson and Crick of the double helix structure of DNA) can be regarded as discovery of a scientific theory, but it is not clear that there is a clear division between this discovery and direct observational discovery; in contrast, the discovery of the theory of evolution by natural selection is very different from a direct observational discovery.

Philosophers of science have been concerned mostly with the discovery of scientific explanations, that is, of empirical rules and theories. The essential characteristic of a scientific explanation is that it be logically coherent [33.21]. But how are scientific explanations (in the form of empirical rules or theories) generated in the first place? And how should a choice be made between competing empirical rules or theories?

Assessing potential explanations is problematic because there is no agreed objective method to assess a potential explanation against an alternative (nor against the possibility that no explanation so far advanced is a good explanation of the phenomenon in question). There are some generally agreed principles that make a potential explanation more likely to be accepted. These are that it is better if it fits the data more closely, better if it is more parsimonious, and better if it is more plausible. However, while metrics can sometimes be calculated for how well a theory fits the data, and for its parsimony, the question of plausibility is ultimately one for human judgment. There is also the problem of how much weight to put on all these factors. Humans appear to have developed pragmatic, context-specific methods of making acceptable inferences [33.3]: The psychology of scientific discovery is discussed in more detail in Sect. 33.3.

The process of finding an *explanation* for a specified phenomenon of interest has the characteristics of an inverse problem. These problems have the following form. There is some state of the world  $S$  which, in conjunction with certain physical laws, gives rise to a data set  $D$ . Given  $S$ , it is in principle straightforward to calculate  $D$ . This is known as the forward problem. The inverse problem is to calculate  $S$  from  $D$ . There may be no solution  $S$  that generates  $D$  exactly, or there

may be several. An example of such a problem concerns mirage data. A mirage is an optical distortion caused by meteorological conditions, which result in variation in the atmospheric refractive index [33.22]. The forward problem is to calculate what a mirage should look like from the refractive index profile. The inverse problem is to deduce the refractive index profile (and from this the temperature profile) from mirage data [33.23]. One approach involves a form of regularization: finding a refractive index profile to minimize a cost function [33.24]. This cost function includes an error term, which depends on how far the mirage data predicted by the proposed profile differs from the real data; computation of this term involves solving the forward problem for the proposed refractive index profile. Another term penalizes the proposed refractive index profile according to a measure of its implausibility. Vision problems are inverse problems [33.25]. A common characteristic of inverse problems is that, as with problems of scientific explanation, there is generally no clear, objective measure of the *best* solution; rather, ad hoc problem-specific measures are needed. As with the example of the inversion of mirage data [33.24], a feature of almost every computational approach to inverse problems is that a candidate solution is tested by solving the forward problem and calculating the data that would be predicted under this candidate solution.

Most inverse problems do not involve scientific discovery – for example, inverting mirages to find a temperature profile would not be considered scientific discovery – but the similarities between scientific discovery and inverse problems are clear, and indeed scientific discovery can be regarded as an inverse problem. It can be cast as follows: Given a suitable theoretical or empirical account of the relevant aspect of the world, specified in sufficient detail, it is possible to calculate what observations should follow from it: that is the forward problem. The inverse problem is to go from the observations to the empirical rule or the theory. It is therefore pertinent to consider the computational methods used in inverse problems. Computational optimization methods are widely used [33.24, 26]. Evolutionary computational methods have been applied [33.27–29]: These are particularly suited to problems in which there are several local optima, where standard optimization methods often get stuck at a local optimum. We will discuss evolutionary computational methods for scientific discovery in more detail in Sect. 33.5.

It must be remembered, however, that not all scientific discovery involves finding an explanation for a specified problem. Rich data sets allow data-driven research in which new entities are directly discovered, and new empirical rules suggested by data analysis [33.18]; we will describe in Sect. 33.5 how computational methods play a large part in these processes.

### 33.3 The Psychology of Human Scientific Discovery

At this point, it is pertinent to ask what is understood about how humans make scientific discoveries. This allows consideration of whether or not the human computational discovery process can be effectively simulated computationally. If it can, a further question arises: Does computational simulation or replication of the methods used in human scientific discovery give rise to effective practical tools for scientific discovery?

*Gillies* [33.30] describes two contrasting approaches to understanding scientific discovery. *Francis Bacon* [33.31] postulated a central role for induction in scientific discovery: Put simply, he regarded discovery as dependent, in a large part, on the simple application of logical rules to observations, with the development of theory strictly following the collection of data. In contrast, *Karl Popper* argued that observations are generally selective, and made within a theoretical context; he suggested that science proceeds through a process of conjecture and falsification [33.32]. On the question of where such conjectures come from, *Popper* [33.33] suggested that “there is no such thing as a logical method for having new ideas” [33.33, p. 37]. This line of think-

ing would seem to conflict with the modern notion that the human brain is effectively a computational device, though from a practical point of view it would also effectively apply if the human brain is computational, but too complex for understanding or meaningful simulation of brain activities that generate new ideas to be possible.

Where the aim is to explain a specified phenomenon, in the form of finding a suitable empirical rule or theory which is plausible and fits the data, the task can be described as a search process [33.20, 34, 35]. *Campbell* [33.34] and *Simonton* [33.35] consider a largely random search process, followed by a rigorous selection process. *Langley* et al. [33.20] put more emphasis on the concept of heuristic search, that is, using a search method which is intended to give a relatively high chance of finding a good solution quickly, compared to a purely random search of the same search space. In a study of how subjects learn to use an electronic device, *Klahr* and *Dunbar* [33.36] propose the concept of scientific discovery by dual search [33.34], involving a search in both hypothesis space and experi-

ment space. Klahr and Dunbar report that subjects vary in their approach to discovery: The principal approach of one group, the theorists, was to formulate hypotheses and then test them experimentally, while a second group, the experimenters, conducted many experiments without explicit hypotheses. This would seem to provide evidence that humans can use both *Popperian* and *Baconian* approaches to discovery. In the assessment of hypotheses, however, humans are prone to confirmation bias, that is, putting disproportionate weight on studies that would tend to confirm a favored hypothesis [33.37].

*Qin* and *Simon* [33.38] show how human subjects can discover a scientific law (Kepler's third law of planetary motion) by a process of exploring possible, though simple, algebraic relationships between two variables, and using the results of early explorations to make better-informed guesses of the relationship. This approach mimics the workings of the BACON computational scientific discovery method for finding scientific laws [33.39]. However, the participants in the experiment of *Qin* and *Simon* [33.38] were primed to expect that some sort of simple relationship between the variables existed. Kepler did not know for certain that such a relationship existed, so the extent to which the experiment of *Qin* and *Simon* represents the sit-

uation faced by Kepler is questionable. Nevertheless, *Qin* and *Simon*'s results do provide some support for the role of rule-based reasoning in scientific discovery. *Kulkarni* and *Simon* [33.40] developed the KEKADA computational system for explaining general scientific processes; it is able to replicate the discovery of *Hans Krebs*'s hypothesis for the urea–ornithine cycle [33.41], using rule-based methods, again providing some support for the idea that inductive methods are important in human scientific discovery. See Sect. 33.5 for more details about the BACON and KEKADA computational discovery systems.

Notwithstanding the *Baconian* view of discovery, it is generally held that at least some forms of human scientific discovery involve something which can be termed creativity. *Boden* [33.42] suggests that there are three forms of creativity. The first is *combinational* creativity: the new (unexpected) combination of familiar ideas. The second is *exploratory* creativity: the exploration of accepted, structured spaces. The third is *transformational* creativity, which involves ideas outside the rules of an accepted space. A capacity that contributes to creativity, and is particularly important in scientific discovery, is the use of analogy [33.3]; this has been the subject of cognitive modeling, with an emphasis on the role of memory [33.43].

## 33.4 Computational Discovery in Mathematics

Mathematics is not a scientific discipline, as it does not ostensibly deal directly with objects from the real world. However, as a formal language, mathematics is used to represent and discuss concepts in many scientific disciplines. This is most apparent in physics, where theories such as general relativity and the standard model for particle physics rely extensively on mathematical techniques for theoretical understanding and model construction (for an early discussion of this link, see *Wigner* [33.44]).

Many of the techniques found here are precursors of similar ideas used for computational discovery in other sciences, in particular the idea of using heuristic (rule-based) techniques to search a space of candidate solutions. Our selection of systems is intended to be indicative of the general techniques. For more details and coverage of additional systems in this area, see *Colton* [33.45], *Colton et al.* [33.46], and *Larson* [33.47].

### 33.4.1 Logic Theorist

Logic Theorist (LT) [33.48] was a program developed by *Newell et al.* to find proofs in elementary (proposi-

tional) logic. LT is programmed with some axioms and inference rules found in *Whitehead* and *Russell* [33.49], and develops proofs of several theorems found therein. It relies on a method that will also be seen in some systems in the next section: A space of possible solutions – in this case proofs – is explored using a class of methods known as heuristics. Heuristics can be defined as rules of thumb that are likely (but not certain) to provide a correct solution to a problem. Using heuristics has the advantage of cutting down the number of states that are visited during search. This makes it possible to carry out a highly selective search, sometimes called a heuristic search.

When started, LT stores in its memory a list of axioms, a list of operations, and the logical expression to be proved. It uses four rules of inference when searching for a proof. These are: substitution, which allows a variable to be replaced by a new variable or expression; replacement, where expressions, such as *implies*, are replaced by equivalent expressions using other connectives; detachment, which can split up compound statements when one part has been proved; and syllogism (chaining), which enables chains of inferences to be followed.

As in chess, where the legality of a move does not imply its quality, LT uses several proof strategies to make its search efficient. These strategies look for situations where the above rules of inference may be applied: For example, when wanting to show *a implies c* and knowing that *b implies c*, then proving *a implies b* would enable use of the syllogism inference.

Although intended as a program for proving logical statements, *Newell et al.* [33.48] also make some novel claims about the program's ability to simulate the behavior of human problem solvers, and were among the first authors to argue for the use of computer programs to aid in understanding psychological processes. See *Gobet and Lane* [33.50] for a discussion of LT's impact on psychology. Around the same time, a program was developed [33.51] that did not lay any claims to modeling human behavior, but used more intensive computational strategies to prove all the theorems in Chaps. 1–3 of *Whitehead and Russell* [33.49].

### 33.4.2 AM and EURISKO

Automated Mathematician (AM) [33.52, 53] is a program which uses heuristics to discover conjectures (and hence potential theorems) in mathematics. Unlike LT, it is unable to directly prove theorems. Instead, conjectures are created by modifying existing theorems, and tested empirically against specific examples. AM works within the set and number theory areas of mathematics, in part because it is easy for the computer to generate examples of, say, a conjecture about numbers. AM has been criticized [33.54], but serves as a model of how a mathematical discovery system can be designed.

AM begins with a basic set of concepts and can create well-known conjectures in set theory (such as subsets) and number theory (such as prime numbers, or Goldbach's conjecture). AM represents each concept in a frame, holding information including: its algorithm, examples, which other concepts it is related to by generalization or specialization, and other related concepts. A concept is then selected out of the current pool, based on a measure of *interestingness*, and adapted versions of the concept are created. These adaptations may be a specialization of the concept, a restriction of its domain, or similar. In addition, and crucially, a human observer may indicate a concept for the system to work on next.

As AM proved fairly successful in mathematics, a related system, EURISKO, was built to attempt to discover new search heuristics: EURISKO is a meta-discovery system, which discovers new ways for discovery to occur. As *Lenat and Brown* [33.55] explain, one of the discoveries of EURISKO was that AM's success was largely down to how mathematical concepts were represented. Replicating AM's success in other domains requires careful work on formulating the internal representation of the domain. In particular, changing the syntactic form of an expression should be reflected in meaningful changes to the semantics (to the meaning).

### 33.4.3 GRAFFITI

GRAFFITI [33.56] is a system for developing conjectures in an area of mathematics known as graph theory. A graph is a set of nodes interconnected by edges, and graph theory has important applications in many scientific areas, including physics, chemistry and computer science (see Sects. 33.5.1 and 33.5.5).

GRAFFITI, like AM, is used to generate conjectures but is unable to construct proofs. The conjectures are formed from a database of invariants of a graph, such as the diameter (greatest number of edges between any two nodes), rank (number of nodes minus the number of connected components), or chromatic number (the number of colors required to color a graph so that no two adjacent nodes are of the same color). Simple sums of these invariants are then generated, and tested against a database of known graphs.

As the conjectures can require considerable computational time to check, a pair of heuristics are used to try to focus on interesting conjectures. The *beagle* heuristic is used to check that the conjecture is not trivial, for example, that an invariant is less than itself plus 1. The *dalmation* heuristic is used to check that the conjecture is different to ones already in GRAFFITI's database.

If no counterexample can be found by the program, the conjecture is passed to the user. Conjectures are then published, and may be picked up and further analysed by graph theorists. GRAFFITI is one of the few systems proven to make conjectures which mathematicians find interesting, and has helped to advance the field. A substantial number of the conjectures have resulted in publications: a list may be found at [33.57].

## 33.5 Methods and Applications in Computational Scientific Discovery

We now turn to implementations of computational scientific discovery methods. Some of the methods are, in their present implementation, specific to particular domains, such as astronomy, chemistry, evolutionary biology, and psychology. Others are more general. Table 33.1 lists some principal examples of computa-

tional discovery methods. Below, we consider a number of discovery techniques. This is not intended to be an exhaustive list of all techniques and applications in computational scientific discovery. The main aim is to convey a sense of the range of methods and applications.

**Table 33.1** Principal examples of scientific discovery systems

System	Type of discovery	Domain	Main technique
DENDRAL [33.58]	Chemical structures (topological)	Chemistry/biochemistry	Partly rule-based, partly brute force exhaustive consideration of possible structures
MECHEM [33.59]	Chemical reaction pathways	Chemistry	Systematic search using defined components to a defined level of complexity; rule based/reasoning framework for controlling search
BACON [33.39]	Scientific laws	General	Rule-based/reasoning
GLAUBER [33.60]	Qualitative rules	Primarily chemical reactions, but potentially general	Rule-based/reasoning
KEKADA [33.40]	Scientific processes	General	Rule-based system that seeks to explain phenomena by recursively generating hypotheses; can also propose experiments
GOLEM [33.61]	Predicting three-dimensional structure of proteins	Biochemistry	Statistical classifier, using a machine learning method to determine the classification rules
<i>Storrie-Lombardie et al.</i> [33.62]	Classifying galaxies	Astronomy	Classifier based on a neural network, trained using backpropagation
<i>Shamir</i> [33.63]	Classifying galaxies	Astronomy	Classifier based on weighted proximity to a number of descriptors determined from test data
<i>Tiffin et al.</i> [33.64]	Candidate genes for disease causation	Biomedical	Data mining, combining gene expression data and biomedical literature
Warmr [33.65]	Potentially carcinogenic chemicals	Chemistry	Data mining combined with rule-based reasoning
GRAM [33.66]	Co-expressed genes and regulatory networks	Biomedical	Network generation from pairwise measures of expression, then incremental node addition
PC algorithm [33.67]	Causal relationships between variables	General	Network refinement by successive deletion and directional interpretation of edges
<i>Guindon and Gascuel</i> [33.68]	Deducing phylogenies from DNA	Evolutionary biology	Hill-climbing to improve estimated phylogenetic tree, based on maximum-likelihood methods applied to DNA data
<i>Frias-Martinez and Gobet</i> [33.69]	Process-based theories	Psychology	Evolutionary computation (genetic programming)
<i>Schmidt and Lipson</i> [33.70]	Scientific laws	General	Symbolic regression, based on genetic programming
Robot scientist [33.71]	Formulation and experimental testing of simple hypotheses	Biochemistry	Rule-based reasoning and control of a robot

### 33.5.1 Massive Systematic Search Within a Defined Space

The first significant achievement in computational scientific discovery was a system known as heuristic DENDRAL. This began in 1965, with the purpose of automatically finding structures in organic chemistry [33.58, 72]; an important motivation was to provide a test-bed for the applicability of ideas in the emerging field of artificial intelligence (AI). Heuristic DENDRAL relies on the idea of making intensive use of specific knowledge, together with harnessing computational power for searching. It systematically evaluates all the topologically distinct arrangements of a set of atoms consistent with the rules of chemistry. Later versions also consider three-dimensional geometry, and use data beyond mass spectrometry. Alongside heuristic DENDRAL is a sister system called meta-DENDRAL, the purpose of which is to learn the rules of mass spectroscopy from empirical data. While heuristic DENDRAL carries out computational scientific discovery directly, meta-DENDRAL is a method for developing a tool used in scientific discovery. It is therefore heuristic DENDRAL which is of more direct interest to the present study. The core of heuristic DENDRAL is a plan-generate-test algorithm. The planner devises hypotheses that reject or propose certain classes of chemical graph. A key feature of the planner is that it incorporates specialist knowledge to constrain the set of potential solutions considered by the generator. The generator was designed to exhaustively and efficiently generate all the possible chemical structures, within specified constraints. The testing part of the algorithm includes a prediction component. This takes a proposed structure and generates a predicted mass spectrum: This can be compared to the real data. This testing of a possible solution by comparing the predicted data it would generate to the real data involves a principle discussed in the consideration of inverse problems in Sect. 33.2: testing a proposed solution to an inverse problem by solving the forward problem for this solution, and comparing the predicted outcome to the real data.

It should be emphasized that heuristic DENDRAL is not just a number cruncher: The use of specialized knowledge to constrain the set of potential solutions considered – justifying the term *heuristic* – was very important to the success of this system. However, number crunching was also necessary: the capacity to use computational power to systematically evaluate a set of potential solutions which is too large a job to undertake manually.

Another system that makes good use of systematic search within a defined space is MECHEM [33.59]. This is concerned with finding chemical reaction path-

ways, that is, the steps involved in a chemical reaction. An example is a possible pathway in the urea–ornithine cycle, originally proposed by *Krebs* [33.41].

In this proposed pathway, the chemical species has been conjectured: It was not observed, nor was it part of the input data. The hypothesis-formation algorithm used in MECHEM makes use of two complexity parameters, specifying the number of steps and species to be contained in a hypothesis. Then the hypothesis generator finds the possible hypotheses within this constraint. If they are all rejected, then at least one of the complexity parameters is incremented. The MECHEM system also has a higher level (rule-based) decision system, allowing it to indicate that new experimental evidence should be sought, or that the problem be suspended.

### 33.5.2 Rule-Based Reasoning Systems

The BACON research program [33.20, 38], as with DENDRAL described above, originated in artificial intelligence research. BACON is a series of systems for discovering empirical rules, in the form of laws, by uncovering relationships within data sets. It makes use of rule-based induction, looking initially for simple relationships between variables, such as an invariant ratio or product. In what it achieves, BACON has a lot in common with regression, and can be considered a form of dimension reduction. Later versions of BACON go beyond simple regression and dimension reduction by generating properties representing intrinsic properties of entities; an example is the refractive index, generated in the discovery of Snell's law of refraction.

The GLAUBER discovery system [33.20, 60] uses a similar rule-based induction process to BACON, but is concerned with qualitative empirical rules. For example, it can discover the law that every acid combines with every alkali to produce some salt.

The KEKADA system [33.40] is a tool with the purpose of understanding scientific processes; it has been applied to the urea–ornithine cycle, replicating the steps undertaken by *Krebs* [33.41] to formulate his famous hypothesis describing how the cycle operates. In seeking to replicate how scientists act, it includes a *problem chooser* module: This determines which discovery task to attempt when there are several potential tasks on the agenda, according to considerations such as how important a task is, and how accurately it can be studied. It allows for a puzzling experimental finding to be added to the agenda for investigation. A hypothesis genera-

tor creates hypotheses when faced with a new problem. There are also rules to propose experiments whose findings could change confidence in existing hypotheses. The results of experiments feed into the system via hypothesis modifiers and confidence modifiers.

While rule-based reasoning can be considered to be the main discovery technique in the above systems, it should be noted that rule-based reasoning is also an important component of several other scientific discovery systems. Thus, for example, heuristic DENDRAL, described above, has a rule-based system to control which searches it carries out, while GOLEM, described below, uses rule-based reasoning to learn classification rules.

### 33.5.3 Classification, Machine Vision, and Related Techniques

Computerized processes for classification, alongside techniques for object/instance recognition, including machine vision methods, are becoming increasingly important. It is therefore not surprising that such systems have found applications in computational scientific discovery. The GOLEM system has been shown to successfully produce hypotheses about protein structure [33.61]. It uses machine learning to determine rules for predicting the structure. The basic algorithm takes a random sample of pairs of example residues, taken from all the proteins in the system, and computes common properties. These properties are then made into a rule. GOLEM therefore makes use of rule-based techniques, within the envelope of what is in effect a classification system.

In astronomy, data sets may include image data, and computational methods can be applied to problems such as the identification and classification of astronomical objects. *Storrie-Lombardie* et al. [33.62] use a neural network to classify galaxies into five types, based on 13 variables measured by machine, using a backpropagation algorithm to train the network. *Shamir* [33.63] describes the automatic classification of galaxies using a method which first converts each image to a number of low-level descriptors, and then uses discriminant analysis to find the descriptors which are most informative. A weighted distance between two feature vectors can then be computed; the predicted class of a test image is given by the class of the training image that has the smallest weighted distance to it. A similar approach has been applied to the classification of structures in biological images [33.73].

### 33.5.4 Data Mining

Methods used for finding patterns from large amounts of data, sometimes from disparate sources, have been

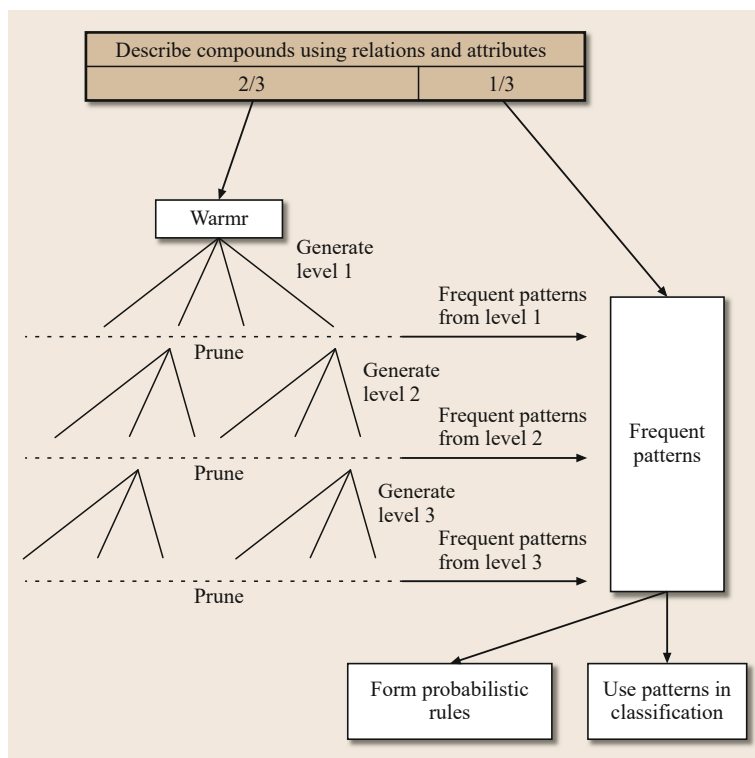

termed data mining [33.74, 75]. Scientific literature can be a useful source of such data [33.76]. For example, candidate genes for causation of disease can be determined from computational discovery of important statistical associations, using literature databases together with protein function [33.77] or gene expression [33.64] data. Computational data-mining techniques have also been used, in combination with rule-based methods, to identify candidate carcinogenic compounds, using a database of carcinogenetic tests of compounds [33.65] (Fig. 33.1). A deep commonality between machine learning (and classification) methods on the one hand and data mining techniques on the other is that both involve finding statistical associations in data. In machine learning, the emphasis tends to be on the techniques for finding associations within a given set of data, while data mining is often more concerned with techniques for extracting useful data from diverse or technically challenging sources. Machine-learning and data-mining approaches can be used together [33.78].

### 33.5.5 Finding Networks

Sometimes a set of entities interact together, in a way that governs some process. This is termed a network. An example is a gene network, that is, a set of genes and proteins that interact to govern a biological process [33.79]. Gene networks can be discovered through a computational process that combines different sources of evidence about interactions between genes and regulator proteins [33.66].

Finding networks frequently involves the use of optimization methods, to find a set of hypothesized interactions that maximizes some objective function, based on statistical measures of the strength of these interactions. The objective function can include a complexity penalty term, aimed at preventing overfitting and ensuring network sparseness [33.80]. Computational implementation of exhaustive search, clustering, or an optimization method which moves individual nodes to increase connectivity, can find networks of interacting molecules [33.81]. The structure and parameters of ecological networks, denoting how species interact in an ecosystem, can be estimated using computational methods based on an analysis of biological flows from prey to predator species [33.82, 83]. Combinatorial optimization techniques can be used to find the most important members of a social network [33.84].

It is often important to characterize probabilistic dependencies between variables in a network, and, where feasible, to seek evidence for causality. Probabilistic dependencies can be represented in a form of directed acyclic graph (i. e., where any relationship between two

**Fig. 33.1** Data-mining methodology for the Warmr system. The inputs are descriptions of compounds. Warmr goes through successive rounds of generating new patterns by adding to existing patterns and pruning patterns that do not occur frequently. At each level another logical condition is added to the pattern. The maximum level searched is limited by preset computer resources (after [33.65])

nodes A and B has a direction and there are no cycles) known as a Bayesian network (BN) [33.85]. In a BN, a node is conditionally independent of its nondescendants given its parents. One of the more successful computational approaches in finding such networks involves first connecting all nodes with edges, then deleting edges between variables that are independent, or conditionally independent on a subset of the remaining variables [33.67]; another step involves inferring the direction of the remaining edges from conditional dependencies. See *Haughton et al.* [33.86] for a review of computational methods. Such networks can provide evidence for causality [33.87, 88], though this approach has its critics [33.89].

Closely related to the discovery of networks is the discovery of ancestral relationships between entities. This is of particular interest in biology, for the discovery of phylogenetic relationships [33.90]. An important technique is the computational application of maximum likelihood methods, which seeks the phylogenetic tree that maximizes the probability of the observations given the tree [33.68, 91].

### 33.5.6 Evolutionary Computation

With the continuing development of faster computers, it has become possible to evaluate increasingly large

sets of candidate hypotheses, models, or theories for those which are consistent with available data, and which are admissible on other grounds such as parsimony and plausibility. How to generate the candidate hypotheses, models, or theories to be tested remains a serious challenge. Evolutionary computation is a process for searching a large space of potential candidate solutions by mimicking the Darwinian process of natural selection. The two main methods of evolutionary computation are genetic algorithms, a method for finding a set of parameters, and genetic programming, a method for finding an algorithm, in the form of a computer program. Here, we consider the application of genetic programming [33.92, 93] to scientific discovery. Genetic programming involves creating an initially random population of programs. In successive iteration cycles, a new population is generated by preferential selection of those individuals which are better with respect to a defined fitness function. In addition, a small amount of random change is introduced into the new programs (mutation); this helps the process explore new regions of the search space. New variants are also created by randomly combining two existing members of the population (crossover).

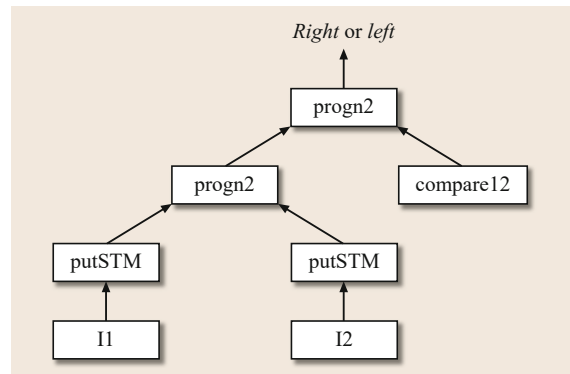

The development of process-based theories in psychology involves finding plausible psychological theories, constructed from basic processes, to explain the

results of psychological experiments. *Frias-Martinez* and *Gobet* [33.69] and *Lane et al.* [33.94] have applied genetic programming to this problem. A theory representation language allows a psychological theory to be represented by a computer program, built up from a set of operators corresponding to elementary psychological processes. Operators specify actions such as storing items in, or retrieving them from, short-term memory, and simple logical operations. This set of operators is based on previous theories in the psychological literature. In the genetic program, the fitness function measures how well predictions resulting from a candidate psychological theory fit a data set; it can also penalize theories that are too complex. *Frias Martinez* and *Gobet* [33.69] and *Lane et al.* [33.94] have shown that the technique can be used to generate theories to explain subjects' behavior in the delayed match to sample task [33.95], in which subjects must match a new image to one of two images they have seen previously. The theories developed using genetic programming generate predictions that fit the empirical data well. In addition, simple and surprising theories can be created [33.69]. Figure 33.2, adapted from [33.69], shows an example of such a theory. Input 1 is the new image, while input 2 is one of the previous images. The operators used in the theory are listed in Table 33.2. This capacity to generate unexpected theories offers the potential for these techniques to provide new insights into the psychological phenomena under study.

*Schmidt* and *Lipson* [33.70] describe a system for finding laws embedded in data sets. It uses a technique known as symbolic regression, and is based on genetic programming. A key test for a candidate law is that it should have good predictive ability, based on partial derivatives between pairs of variables. *Schmidt* and *Lipson* [33.70] represent an equation as a computer program. An initially random population of equations is created, and then a genetic programming algorithm is applied.

### 33.5.7 Automation of Scientific Experiments

A great deal of scientific experimentation involves labor-intensive cycles of setting up experiments, and collecting and analyzing data. The *robot scientist* [33.71, 96] automates this process, with the automation controlled by a computer algorithm. It iteratively collects and analyzes data and generates hypotheses,

**Fig. 33.2** Example of a theory generated by genetic programming. According to this theory, the delayed match to sample task is accomplished by comparing one of the new images to the original image; the second new image is not used (after [33.69])

**Table 33.2** Operators used in the theory shown in Fig. 33.2

Operator	Description
Progn2	Function: executes two inputs sequentially Input: Input1, Input2 Output: the output produced by Input2
PutSTM	Function: writes the input into short term memory (STM) Input: Input1 Output: the element written in STM (Input 1)
CompareI2	Function: compares positions 1 and 2 of STM and returns empty (NIL) if they are not equal or the element if they are equal Input: none Output: NIL or the element being compared

determined directly from data, for applications such as establishing which genes are involved in encoding enzymes. Some previous scientific discovery methods have incorporated in their logic the capacity to propose experiments [33.40, 59], but the robot scientist is probably the first practical application of a fully automated robotic system in which real world, rather than computational, experiments are formulated, executed, and analyzed.

Other automated systems, while arguably not as complete as the robot scientist, have been developed for the automation of the collection and analysis of data in hostile environments [33.97]. This applies in areas such as studies of underwater environments [33.98] and space exploration [33.99].

## 33.6 Discussion

The roots, nature, and psychology of scientific discovery (Sect. 33.1–33.3) provide a context for understanding the potential application of computational discovery systems, and their limitations. Section 33.4 has described examples of computational discovery systems in mathematics; these have characteristics, such as the use of logic, and of searching through large numbers of cases to find possible patterns, in common with scientific discovery systems.

The survey of scientific discovery methods in Sect. 33.5 has shown that computers can *do* scientific discovery, in the form of characterizing phenomena and generating scientific explanations. Yet the wholesale replacement of human scientists by computers is not on the horizon. Quite simply, computers are better suited to some aspects of the scientific discovery process than others.

What computers do particularly well is number crunching: carrying out large numbers of calculations and data operations, with great accuracy and at speed which exceeds human capability by several orders of magnitude. It follows that those areas where computational discovery methods have been most successful tend to be those for which number crunching can most readily be applied to discovery processes. The first significant discovery system, heuristic DENDRAL, illustrates this. The discovery of chemical topologies, and structures, involves consideration of a potentially enormous range of candidate solutions. Computational brute force enables a systematic search to be carried out, albeit within a limited parameter range. Rule-based methods for making the search methods efficient, and the facility to use specific knowledge to constrain the search, are important, but it is the number-crunching capacity of computers that made this approach feasible, even with the available computing power of the mid-1960s, when the system was first proposed. The later MECHEM system for finding chemical pathways similarly depends on number crunching to carry out a systematic search of possible pathways. This is not to suggest that humans use such forms of systematic search. As *Giza* [33.100] has argued, computational scientific discovery systems can proceed in a radically different manner from noncomputational methods, and employ criteria for choosing candidate discoveries that are different from those employed by human scientists.

The systems that are primarily rule-based, such as BACON [33.20], GLAUBER [33.60] and KEKADA [33.40], are those that come closest to attempting to replicate how humans carry out scientific discovery, at least to the extent that humans use inductive rules. It has been argued that this approach is not

successful, in that these methods have not discovered any new and important rules, generalizations, or laws: See *Gillies* [33.30] for a discussion of this claim. This does not detract from the possible use of such systems to shed light on understanding an important part of the basis for how humans make scientific discoveries. It does, however, suggest that systems that are primarily rule-based do not constitute the most practically important tools currently available for computational scientific discovery.

Classification, machine vision and data-mining methods provide important computational discovery tools, which fully utilize a computer's capability to process large amounts of information [33.65, 73]. These methods essentially involve detecting or recognizing patterns, which is similar in principle to finding conjectures in mathematics [33.52]. Automatic determination of network relationships is likely to prove to be increasingly important [33.80], and may benefit from future advances in statistical modeling and optimization techniques, but human input is required for problems where a strong degree of judgment and prior knowledge is required to construct causal relationships [33.89]. In the specific field of determining phylogenetic relationships, using established maximum-likelihood methods, computational discovery has been very successful [33.91].

The use of evolutionary computational methods in scientific discovery is relatively recent, and shows promise. The application to psychological theories [33.69] opens up the possibility of automatically discovering useful models involving a sequence of simple processes. The approach, however, requires human judgment in specifying the characteristics of operators used to construct models, in the extraction of data from published results, and in the interpretation of results. Automation of experimental procedures will continue to be important in hostile environments [33.97], and may find further application for relatively predictable cycles of hypothesis proposal and testing [33.71].

For computers to be really effective at the kinds of discovery methods that humans use will require basic developments in strong artificial intelligence, that is, computers which can replicate general human capacities. Is such a development likely? *Penrose* [33.101] has suggested that human consciousness may be dependent on nonalgorithmic physical processes, and not representable by a computational algorithm, and that this poses a serious barrier to strong AI; by way of example he draws on the way mathematical truth is discovered, arguing that there is no general algorithm for determining the truth of a mathematical proposition. Among the critics of this line of reasoning, however, is

Dennett [33.102], who suggests that people make use of reasoning methods that evolved for reasons related to survival, and that these may happen to work well for assessing mathematical propositions a high proportion of the time. Another possible barrier to strong AI is that inference depends on context [33.103, 104]: So far, humans have proved better than machines in being able to judge how to make good generalizations. Gillies [33.30] argues that humans have a *political superiority* to computers because computers are designed and built by humans in order to carry out human tasks; it follows that

“if a computer is designed to solve problems a, b, c, . . . , it is likely to give rise to further problems x, y, z, . . . which the computer system itself will not be able to solve, but which will need some human thinking for their resolution.”

In any event, the development of strong AI does not appear to be on the immediate horizon. There is no clear consensus on the prospects for strong AI in the medium and long-term future.

A recurring theme in this review has been that the application of computational scientific discovery systems requires human input – in areas such as judging putative causal relationships [33.89], judging the correct context for making generalizations [33.103, 104],

and specifying operators used for constructing evolutionary computational models [33.69]. An important open question is the extent to which such aspects of human judgmental skill could eventually be automated, but there does not seem to be a strong prospect of substantial automation of this sort in the near future.

The immediate trend will be for more development of discovery systems oriented to the kind of things computers do well. This is the case in several modern applications of AI, where problems are solved using the computer’s ability to use large quantities of data, rather than in mimicry of how humans do the same task. For example, *Google translate* does not try to construct models of what a sentence means, but instead scans the internet for data on how each sentence may be translated. In this way, the problem can be solved with a computer, but without employing a method that is human-like. Similarly, it is likely that areas of scientific discovery will be achieved by computers working in computer-like ways, with humans providing added value in terms of synthesis or creative insights. This harnessing of the complementary qualities of humans and machines is likely to increase the rate at which scientific discoveries are made [33.105].

In conclusion, computational scientific discovery methods are an increasingly important tool in science. But the role of the human scientist remains, for the foreseeable future, essential.

# 34. Computer Simulations and Computational Models in Science

Cyrille Imbert

Computational science and computer simulations have significantly changed the face of science in recent times, even though attempts to extend our computational capacities are by no means new and computer simulations are more or less accepted across scientific fields as legitimate ways of reaching results (Sect. 34.1). Also, a great variety of computational models and computer simulations can be met across science, in terms of the types of computers, computations, computational models, or physical models involved and they can be used for various types of inquiries and in different scientific contexts (Sect. 34.2). For this reason, epistemological analyses of computer simulations are contextual for a great part. Still, computer simulations raise general questions regarding how their results are justified, how computational models are selected, which type of knowledge is thereby produced (Sect. 34.3), or how computational accounts of phenomena partly challenge traditional expectations regarding the explanation and understanding of natural systems (Sect. 34.4). Computer simulations also share various epistemological features with experiments and thought experiments; hence, the need for transversal analyses of these activities (Sect. 34.5). Finally, providing a satisfactory and fruitful definition of computer simulations turns out to be more difficult than expected, partly because this notion is at the crossroads of difficult questions like the nature of representation and computation or the success of scientific inquiries (Sect. 34.6). Overall, a pointed analysis of computer simulations in parallel requires developing insights about the evolving place of human capacities and humans within (computational) science (Sect. 34.7).

For several decades, much of science has been computational, that is, scientific activity where computers play a central and essential role. Still, computational science is larger than the set of activities resorting to computer simulations. For example, experimental science, from vast experiments in nuclear physics at the European Organization for Nuclear Research (CERN) to computational genomics, relies heavily on computers and computational models for data acquisition and their treatment, but does not seem to involve computer simulations proper. In any case, there is a great and still proliferating variety of types of computer simulations, which are used for different types of inquiries and in different types of theoretical contexts. For this reason, one should be careful when describing the philosophy of computer simulations and unjustified generalizations should be avoided. At the same time, how much the development of computer simulations has been changing science is a legitimate question. Com-

puter simulations raise questions about the traditional conceptualization of science in terms of experiments, theories and models, about the ways that usual scientific activities like predicting, theorizing, controlling, or explaining are carried out with the help of these new tools and, more generally, how the production of scientific knowledge by human creatures is modified by computer simulations. Importantly, while the specific philosophical analysis of computer simulations is recent (even if it was preceded by the development of the philosophical study of scientific models) and computational science is a few decades old, the development of computational tools and mathematical techniques aimed at bypassing the complexity of problems belongs to a much older tradition. This means that claims about how much computer simulations change science, and how much a closer attention to computer simulations should change our picture of scientific activity, are questions to be treated with circumspection.

## 34.1 Computer Simulations in Perspective

When discussing philosophical and epistemological issues related to computational models and computer simulations, different chronologies should be kept in mind. The blossoming of the philosophy of models and simulations, within the philosophy of science is something recent (Sect. 34.1.1). The development of techniques aimed at extending our inferential and computational powers corresponds to a longer trend, even if the recent invention of powerful digital machines has changed the face of computational science (Sect. 34.1.2). Finally, the acceptance of computer simulations as legitimate scientific tools across the different fields goes at various paces (Sect. 34.1.3). This means that, even if computer simulations do change the face of science, much care is needed when analyzing the aspects of science which are actually changed, and how we should modify our picture of science when we adopt a computer simulation-based perspective (Sect. 34.1.4).

### 34.1.1 The Recent Philosophy of Scientific Models and Computer Simulations

While the use of computer simulations in the empirical sciences, in particular physics, developed after the construction of the (ENIAC) computer during World War II [34.1], and started changing how the empirical sciences were practiced, for decades computer-related discussions among philosophers were primarily focused on the development of artificial intelligence and the analysis of human cognition. Particularly active were debates in philosophy of mind regarding the question of the *computational theory of the mind*, that is, whether the mind can be likened to a digital computer, and in particular to a classical machine employing rules and symbolic representations [34.2–6]. However, within the mainstream philosophy of science, continued interest for computational science, compu-

tational models, and digital simulations of empirical systems as such did not really start until the early 1990s, with articles by *Humphreys* [34.7, 8], *Rohrlich* [34.9] or *Hartmann* [34.10]. (Such a description of the field is necessarily unfair to earlier works about the use of computer simulations in the empirical sciences. Particular mention should be given to the works of *Bunge* [34.11] or *Simon* [34.12].) An article by *Hughes* about the investigations of the Ising model [34.13], a special issue of *Science in Context* edited by *Sismondo* [34.14] and works by *Winsberg* [34.15–17], who completed his Ph. D. in 1999 about computer simulations, also contributed to the development of this field. Finally, in 2006, the *Models and Simulations* Conference took place, which was the first of what was to become a still active conference series, which has contributed to making the issue of computational science one of the fields of philosophy of science.

Philosophical works about scientific models, a very close field, were not significantly older. The importance of the notion of set-theoretic model had been emphasized by partisans of the model-theoretic view of theories in the 1970s, but, if one puts aside works by pioneers like *Black* [34.18] or *Hesse* [34.19], this did not launch investigations about scientific models proper. Overall, the intense epistemological study of models did not start until the 1980s, with in particular a seminal article by *Redhead* about scientific models in physics [34.20]. Members of the *Stanford School* also argued against the view that science was unified and that theories played a dominant role in scientific activities such as the selection and construction of models [34.21], and conversely emphasized the autonomy of experimental and modeling practices. This context was appropriate for an independent investigation about the role of models in science, which bloomed at the end of the 1990s [34.22] and was further fed by a renewal of interest for the question of scientific representation [34.23–25]. These investigations of models paved the way for new studies focused neither on theories nor on experiments. However, while the difficulty to explore a model was already acknowledged in works by *Redhead* and *Cartwright*, interest for the actual modes of its exploration, in particular by computer simulations, was not triggered. Indeed, the focus remained on the effects of the complexity of the inquiry on scientific representations, with studies about simplifications, approximations, or idealizations (Even *Laymon's* 1990 paper [34.26], in spite on its apparent focus on computer simulation, mainly deals with the nature of approximation and what it is to accept or believe a theory.), or how to articulate the model-theoretic view of theories and the uses of models and representations in actual scientific practices, by taking into

account scientific users, qua intentional cognitive creatures [34.27, 28], and their cognitively constrained ways to handle models by means of inferences, graphs, pictures or diagrams (*Kulvicki* [34.29], *Giardino* Chap. 22, this volume; *Bechtel* Chap. 27, this volume). Overall, in spite of the close connection within scientific practice between the uses of models and their computational explorations, the issue of computational models and computer simulations was not seen clearly as a fruitful field of inquiry of its own, this trend of thought being explicitly and vividly brought to the fore in 2008 in a deliberately provocative paper by *Frigg* and *Reiss* [34.30].

### 34.1.2 Numerical Methods and Computational Science: An Old Tradition

The second relevant chronology is that of the advancement in attempts to solve complex mathematical problems by developing computing machines and mathematical methods. Importantly, while the development of digital computers in the mid-twentieth century changed the face of scientific computation, humans did not wait for this decisive breakthrough to extend their mathematical and computational powers. Further, as *Mahoney* wrote it, “the computer is not one thing, but many different things, and the same holds true of computing” [34.31], and it is only in the twentieth century that different historical strands related to logic, mathematics, or technologies came together. On the one hand, early mathematical procedures, like Newton’s method to find the roots of real-valued functions, or Euler’s method to solve ordinary differential equations, were developed to provide numerical approximations for problems in numerical analysis. This field was already important to investigate physical systems but, with the advent of digital computers, it became a crucial part of (computational) science. On the other hand, mechanical calculating tools, such as abacuses or slide rules, were used from the Antiquity through the centuries. The invention by Pascal of a device (the *Pascaline*) to perform additions and subtractions, and the conceptualization by Babbage of mechanical computing systems fed by punched cards, were important additional steps. *Human computers* were also used. For example, in 1758, Clairaut predicted the return of Halley’s comet, by dividing the computational work with other colleagues [34.32]. Gaspard de Prony produced the logarithm and trigonometric tables in the early nineteenth century by dividing the computational tasks into elementary operations, which were carried out by unemployed hairdressers with little education. Human computers were used during World

War I to compute artillery tables and World War II to help with the Manhattan project [34.33, 34]. Finally, mechanical analog computers were developed for scientific purposes by engineers and scientists like Thomson or Kelvin, in the late nineteenth century, Vannevar Bush, between the two World Wars, or Enrico Fermi, in 1947, and such computers were used till the 1960s. Finally, even in the digital era, new technological change can have a large impact. For decades, access to computational resources was difficult and only possible in the framework of big projects. Typically, *Schelling's* first simulations of residential segregation [34.35] were hand made. An important recent step has been the development of personal computers, which has brought more flexibility and may have triggered the development of new modeling practices [34.36].

### 34.1.3 A More or Less Recent Adoption Across Scientific Fields

The development of computational science and the use of computational models and simulation methods vary from one field to another. Since the 1940s onward, computer simulations have been used in physics, and computers were also used in artificial intelligence as early as the late 1950s. However, some fields have resisted such methods, and still do, as far as commonly accepted mainstream methods are concerned. Typically, the development of computational models and computer simulations in the human and social sciences, with the possibility of analyzing diachronic interactions between agents (versus static models describing equilibria) is much more recent. As emphasized earlier, *Schelling's* initial dynamic model of segregation was first run manually in 1969. Attempts to use computational science to predict social and economic behavior were globally met with suspicion in the 1960s and 1970s, all the more since these studies were often carried out by scholars who did not belong to well-entrenched traditions in these fields (such as scientists studying complexity, including human behavior, in institutions like the Santa Fe Institute). Overall, in economics, computer simulations are still not accepted [34.37]. Similarly, the development of a specific (and still somewhat distinct) subfield using computational methods to analyze social phenomena is recent, with the edition by *Hegselmann et al.* of the volume *Modelling and Simulation in the Social Sciences from the Philosophy of Science Point of View* [34.38], the need felt to create, in 1998, the *Journal of Artificial Societies and Social Simulation* and the publication in 2005 of the handbook *Simulation for the Social Scientist* by *Gilbert and Troitzsch* [34.39].

### 34.1.4 Methodological Caveat

These different chronological perspectives call for the following comments.

First, philosophers should be careful when developing an epistemology of computational models and computer simulations. Modeling and simulating practices have been developed in various epistemic contexts in scientific fields in which well-entrenched theories are more or less present and which have different methodological and scientific norms. Thus, the role of computer simulations and their epistemological assessment can significantly differ from one case to another, and bold generalizations should be carefully justified or avoided. As just mentioned, the use of computer simulations is central and accepted in fields like climate science (even if it raises important problems) but is still regarded with great suspicion in fields like economics [34.37, 40].

Second, how much computational models and computer simulations correspond to epistemologically different practices, which should be described in terms of some *computational turn*, cannot be assumed, but should be investigated on a case-by-case basis regarding all potentially relevant aspects. This can be illustrated with the question of the tractability of scientific models. *Humphreys*, in his 2004 book *Extending Ourselves*, proposes the following two principles to analyze science: “It is the invention and deployment of tractable mathematics that drives much progress in the physical sciences”; and its converse version: “most scientific models are specifically tailored to fit, and hence are constrained by, the available mathematics” [34.41, pp. 55–56]. These two principles suggest both a continuist and discontinuist reading of the development of science. First, students of science need to assess which precise aspects of scientific practices have been changed by the development of computers and whether these changes should be seen as a scientific revolution, or simply as an extension of existing modes of reasoning [34.42]. In this perspective, questions about the tractability and complexity of models can no longer be ignored, and may be crucial to an understanding of how new branches of modeling and computational practices can develop and of how the dynamics of science can be qualitatively different [34.43]. At the same time, scientific practices were also constrained by the available mathematics before the advent of computers, and new findings in mathematics already paved the way for the development of new scientific practices. For example, *Lakatos* emphasizes that [34.44, p. 137]

“the greatness of the Newtonian programme comes partly from the development – by Newtonians of

classical infinitesimal analysis which was a crucial precondition for its success.”

From this point of view, a continuist reading is also required.

Third, the computational perspective may require partly revising the philosophical treatment of questions about science, and scientific representation in particular. Computer simulations are *actual* activities of investigation of scientific models, and, for this reason, the tractability and computational constraints that they face can hardly be ignored when analyzing them. They force us to adopt an in practice perspective, where what matters is not the logical content of representations (that is, the information which agents can access in principle, with unlimited resources), but the results and conclusions which agents can in practice reach with the inferential resources they have [34.41, §5.5]. By contrast, traditional analyses of scientific models adopt an in-principle stance: the question of their exploration and of the tractability of the methods used to explore them is one question among others, and is implicitly idealized away when discussing other issues. This implies surreptitiously smuggling in the unjustified claim that the distinction between what is possible in principle and what is possible in practice can be ignored for the investigation of these other issues, which may sometimes be controversial.

At the same time, philosophers of science draw their examples from the scientific literature, which, by

definition, presents successful investigations of models which must have been found to be, one way or another, tractable enough regarding the inquiries pursued. In brief, discussions about the scientific models which are found in scientific practices are ipso facto concerning computationally tractable models, or models having computationally tractable versions.

How much these remarks imply that existing analyses about scientific models have been discretely skewed, or on the contrary that the constraints of tractability have already been taken into account, needs to be ascertained, and the answer may be different depending on the question investigated. For example, for decades the question of the relations between fields has mainly been treated in terms of relations between theories. While this perspective is in part legitimate, recent investigations suggest that tractable models may also be a relevant unit to analyze scientific theoretical, methodological or practical transfers between fields [34.41, §3.3], [34.45, 46]. In any case, when discussing questions related to scientific representation, explanation, or confirmation, philosophers of science must watch out that answers may sometimes differ for the models that scientists work with daily (and which more and more require computers to be investigated), and for simple analytically solvable models, which philosophers more naturally focus upon, and which may have a specific scientific status regarding the construction of knowledge and the development of families of models in each field.

## 34.2 The Variety of Computer Simulations and Computational Models

Computer simulations involve the use of computers to represent and investigate the behavior of physical systems (Sect. 34.2.1). Beyond this simple characterization, various types of computer simulations can be met in science, each with its specificities, and, it is important to distinguish them to avoid undue extrapolations. Differences can be met at various levels of description. Computing machines can be digital or analog (Sect. 34.2.2). Digital computers are usually used to carry out numerical computations (Sect. 34.2.3), even if all computer simulations do not involve operations on numbers (Sect. 34.2.4). In both cases, computations may be deterministic or nondeterministic (Sect. 34.2.5). Finally, various types of mathematical and physical computational models can be met across science, such as equation-based models, agent-based models, coupled models or multiscale models, but, not all important computational methods or mathematical

frameworks are used to carry out computer simulations (Sect. 34.2.6).

My purpose in this section is to present and characterize different important types of simulations, which are used in scientific practice and will regularly be referred to in the following sections, and to highlight some specific epistemological questions related to them.

### 34.2.1 Working Characterization

In science, computer simulations are based on the use of computers. A computer is a physical apparatus which can reliably be used to carry out logical and mathematical operations. A computer simulation corresponds to the actual use of a computer to investigate a physical system *S*, by computationally generating the description of some of the states of one of the potential

trajectories of  $S$  in the state space of a computational model of  $S$  (*working characterization*).

This characterization is not meant as a full-blown definition (Sect. 34.6) but as a synthetic presentation of important features of computer simulations.

First, it emphasizes that the development of computers is a central step in the recent evolution of science, which was made possible by steady conceptual and technical progresses in the twentieth century. It can therefore be expected that computational aspects are often, though not necessarily always, central for the epistemological analysis of computational science and computer simulations (Sect. 34.3). Second, the working definition is meant to emphasize that all uses of computers in science cannot be seen as computer simulations. Typically, the use of computers to analyze big data is not considered as a computer simulation since the dynamics of the target system is not represented. Third, the characterization remains neutral regarding the question of whether in science there are simulations that are not based on the use of computers (whatever these could be). It is not incompatible with the claim that computer simulations are some sort of experimental activity, even if people willing to endorse such claims need to explain and justify in which sense the corresponding uses of computers can be considered as *experimental* (Sect. 34.5). Finally, since different types of computers exist, computer simulations may correspond to various types of objects. The working definition emphasizes that, in order to analyze actual science, the emphasis should be primarily on models of computations that can have an *actual* physical realization, and on physical systems that can be *used in practice* for scientific purposes – even if investigations about potential machines, and how some physical systems could instantiate them, may be relevant for foundational issues.

I now turn to the description of important types of computer simulations that have been, or still are, used in science and that figure in epistemological discussions about computer simulations.

### 34.2.2 Analog Simulations and Their Specificities

Analog computers were important tools for scientific computing till the late 1960s, during which with handbooks of analog computation were still being written [34.47, 48], and attempts were made in the early 1970s to link analog and digital computers. Analog simulations and physical analog systems are still occasionally used to investigate physical systems.

An analog computer is a physical machine which is able to carry out algebraic and integrodifferential

operations upon continuous physical signals. Thus, operations that would be difficult to program on a digital computer are immediately possible on an analog machine. The specificity of analog machines is that they contain physical elements whose dynamics decisively contribute to the dynamic instantiation of these mathematical operations. For a machine to be used as an analog computer, its physical dynamics must be explicitly known and completely under control so that there is no uncertainty about the operations which are carried out. While systems like wind tunnels cannot be made to compute several different dynamics, mechanical analog computers like the differential analyzer and electrical analog computers can be used as general-purpose computational tools.

Even if analog computers and analog simulations are seldom used nowadays, understanding them is epistemologically important. For instance, while quantum computation is an extension of classical digital computation, quantum analog computing, which involves no binary encoding, may prove useful for the purpose of the quantum simulation of physical systems [34.49]. Analog computers are considered to be potentially more powerful than digital machines *and* to be actually instantiated by physical systems, even if we are unable to use them to the full extent of their capacities because of analog noise or the impossibility of precisely extracting the information they process. The analysis of analog computability is also important for foundational studies aimed at determining which types of actual computers devices could be used for the purposes of computer simulations, how much resources we may need to simulate physical systems or what natural systems can compute [34.50–52]. For example, the General Purpose Analog Computer was introduced by Shannon as a model of the differential analyzer, which was used from the 1930s to 1960s.

Finally, understanding how analog computers work is important to understand analog simulations and how they differ from digital simulations. As is pitifully emphasized by *Arnold* [34.53, p. 52], the failure to distinguish properly between digital computer simulations and analog simulations can be (and has recently been) a major source of error in the philosophical discussions of computer simulations. Analog computers physically instantiate the mathematical dynamics which they are used to investigate. Therefore, the analog computational model that is analyzed is instantiated both by the physical computer and by the target system that is being simulated. Thus, the simulating and simulated processes share a common structure and are isomorphic [34.54], which need not be the case for digital simulations (Sect. 34.5.3). Importantly, this common structure is purely mathematical, and involves dimen-

sionless quantities [34.55, Chap. 8]. While the need to describe systems in terms of dimensionless quantities is a general one in the empirical sciences [34.56–58], and is also crucial for digital simulations, here it is specifically important to understand the type of reasoning involved in analog simulations. Indeed, the physical description of the simulating and simulated systems matter only in so far as one needs to justify that they instantiate a common dimensionless dynamical structure. In brief, such analogical reasoning does not involve any direct comparison between the physical material properties of the simulating and simulated systems: the mathematical structure mediates the comparison. In other words, even with analog simulations, an analysis of the similarities of the two systems is irrelevant once one knows which analog computation is being carried out by both systems.

### 34.2.3 Digital Machines, Numerical Physics, and Types of Equivalence

In digital machines, information is processed discretely, coded in binary digits (1 or 0), and stored in transistors. Computations involve the transition between computational states. These transitions are described in terms of logical rules between the states. If these rules can be described in a general form, they may be described in terms of equations involving variables. Digital computers can have various types of architecture with different computational performances. Traditionally, software was written for sequential computation, in which one instruction is executed at a time. In contrast, modern supercomputers are designed to solve tasks in parallel, and parallelism can be supported at different levels of architecture, which often implies the need to adapt algorithms, if not models, to parallel computation [34.59].

Digital machines can be used to develop different types of computer simulations. Much computational science is numerical: binary sequences code for numbers and computers carry out numerical operations on these numbers by processing the binary strings. Since computers can only devote limited memory to represent numbers (e.g., with floating-point representation), numerical science usually involves numerical approximations. In other words, computer simulations do not provide exact solutions to equations – even if the notion of an exact solution is not as straightforward as philosophers usually take it to be [34.60].

Different types of equivalence between computations, and, by extension, computer simulations, should be distinguished beyond equivalence at the bit level [34.61]. Logical and mathematical expressions and algorithms can be mathematically equivalent when they refer to, or compute, the same mathematical object

or some of its properties. Because of floating-point representation, round-off errors cannot be avoided in simulations. When algorithms result in small cumulative errors, they are stable and two such stable algorithms may be considered as numerically equivalent – although they need not be computationally equivalent in terms of their computational efficiency. Finally, based on the type of inquiry pursued, wider notions of representational equivalence can be defined at the computational model or computer simulation level. Typically, two computations yielding the same average quantity, or describing the same topology of a trajectory, may be considered as equivalent. Overall, this shows that analyses of the failures and predictive or explanatory successes of computer simulations must often be rooted in the technical details of computational practices [34.62]. From this point of view, an important part of computational science can be seen as the continuation of the numerical analysis tradition presented in Sect. 34.1.2.

### 34.2.4 Non-Numerical Digital Models

A large part of science gives a central role to scientific theories couched in terms of differential equations relating continuous functions with their derivatives. For this reason, much of computational science is based on finite-difference equations aimed at finding approximate numerical solutions to differential equations. However this theory- and equation-oriented picture does not exhaust actual practices in computational science. First, computer simulations can be carried out in the absence of theories – which turns out to be a problem when it comes to the explanatory value of computer simulations (Sect. 34.4). Second, even when equation-based theories exist, computational models are not necessarily completely determined by these theories and by mathematical results describing how to discretize equations appropriately (Sect. 34.3.2). Finally, even when well entrenched, equation-based, theories exist, digital, but non-numerical, computer simulations can be developed. This perspective was advocated in the 1980s by computer scientists like Fredkin, Toffoli, or Margolus. Building on the idea previously expressed by *Feynman*, that maybe “nature, at some extremely microscopic scale, operates exactly like discrete computer logic” [34.63], they wanted to develop “a less round-about way to make nature model itself” [34.64, p. 121] than the use of computers to obtain approximate numerical solutions of equations. The idea was to represent more directly physical processes by means of *physically minded* models, with interactions on a spatial lattice providing an emulation “of the spatial locality of physical law” [34.65] and to use exact models obeying discrete symbolic dynamics to dispense with numer-

ical approximations. In practice, this resulted in the renewed development of cellular automata (hereafter CA) studies and their use for empirical investigations. A CA involves cells in a specific geometry; each cell can be in one of a finite set of states, and evolves following a synchronous local update rule based on the states of the neighboring cells. The field of CA was pioneered in the 1940s by Ulam's works on lattice networks and von Neumann's works on self-replicating automata. It was shown over the decades that such models, though apparently over-simplistic, can not only be successfully used in fields as different as the social sciences [34.66] and artificial life [34.67], but also physics, in which they were shown in the late 1970s and 1980s to be mesoscopic alternate to Navier–Stokes macroscopic equations [34.68].

### 34.2.5 Nondeterministic Simulations

Another important distinction is between deterministic and nondeterministic algorithms. From the onset, computers were used to execute nondeterministic algorithms, which may behave differently for different runs.

Nondeterministic simulations involve using random number generators, which can be based on random signals produced by random physical processes, or on algorithms producing pseudorandom numbers with good randomness properties. Overall, the treatment of randomness in computer simulations is a tricky issue since generating truly random signals, with no spurious regularities which may spoil the results by introducing unwanted patterns, turns out to be difficult.

Monte Carlo methods, also called Monte Carlo experiments, are a widely used type of nondeterministic simulations. They were central to the Manhattan project, which led to the production of the first nuclear bombs and contributed heavily to the development of computer simulations. They can be used for various purposes such as the calculation of mathematical quantities like Pi or the assessment of average quantities in statistical physics by appropriately sampling some interval or region of a state space. These practices are hard to classify and, depending on the case, seem to correspond to computational methods, experiments, or full-blown computer simulations. *Metropolis* and *Ulam* [34.69] is a seminal work, *Galison* [34.70, 71] correspond to historical studies, and *Humphreys* [34.8], *Beisbart* and *Norton* [34.72]) to epistemological analyses.

### 34.2.6 Other Types of Computer Simulations

It is difficult to do justice to all the kinds of simulations that are seen in scientific practice. New com-

putational methods are regularly invented, and these often challenge previous attempts to provide rational typologies. Further, the features presented in the previous sections are often mixed in complex ways. For example, CA-based methods in fluid dynamics, which were not originally supposed to involve numbers or offer exact computations, were finally turned into lattice Boltzmann methods, which involve making local averages [34.73]. Here, I shall merely present types of computer simulations that are widely discussed in the philosophical literature.

#### Agent-Based Methods

Agent-based methods involve the microlevel description of agents and their local interactions (in contrast to global descriptions like balance or equilibrium equations), and provide tools to analyze the microscopic generation of phenomena. They are often opposed to equation-based approaches, but the distinction is not completely sharp, since equations do not need to describe global behaviors and, when discretized, often yield local update rules. Agent-based models and simulations are used across fields to analyze artificial, social, biological, etc., agents. CA models like the Schelling model of segregation can be seen as agent-based models even though most such agent-based also involve numbers in the descriptions of local interactions. Because they rely on microscopic descriptions, agent-based simulations are often at the core of debates about issues such as emergence [34.74], explanation [34.75], or methodological individualism in science [34.76].

#### Coupled and Multiscale Models

Extremely elaborate computational models, developed and studied by large numbers of scientists, are increasingly used to investigate complex systems such as Earth's atmosphere, be it for the purpose of precise predictions and weather forecasting or for the analysis of larger less precise trends of climate studies. While in fluid dynamics, it is sometimes possible to carry out *direct simulations*, where the whole range of spatial and temporal scales from the dissipation to the integral scale are represented [34.77, Chap. 9], such methods are too costly for atmosphere simulations, in which sub-grid models of turbulence or cloud formation need to be included (see *Edwards* [34.78] and *Heymann* [34.79] for accessible and clear introductions). Also, different models sometimes need to be coupled like in the case of global coupled ocean-atmosphere general circulation models.

These complex computer simulations raise a number of epistemological issues. First, in the case of multiscale or coupled models, the physical and computational compatibility of the different models can be

a tricky issue, and one must be careful that it does not create spurious behavior in the computer simulation (see *Winsberg* [34.16, 80], *Humphreys* [34.41, 81] for more analyses about such models). Second, since there are various ways of taking into account subgrid phenomena, pluralism in the modeling approaches cannot be avoided [34.82]. Importantly, the existence of different incompatible models need not be seen as a problem, and scientists can try to learn by comparing their results or elaborate ensemble methods to try to deal with uncertainties [34.83]. The development of investigations of such large-scale phenomena requires collective work, both within and between research teams. Typically, not only the interpretation of the models, their justification, the numerical codes [34.84], but also the standard of results [34.78, 85] must be shared by members of the corresponding communities. An important but still unexplored question is how much the collective dimension of these activities influences epistemologically how they are carried out. From this point of view, the epistemology and philosophy of computational models and computer simulations can be seen as another chapter of the analysis of the collective dimension of science.

## 34.3 Epistemology of Computational Models and Computer Simulations

Epistemologists analyze whether and how much knowledge claims are justified. In this case, it requires analyzing the specific roles played by computer simulations in the production and generation of items of knowledge (Sect. 34.3.1). Different levels of description and analysis can be relevant when investigating the epistemology of computer simulations, in addition to that of the computational model and how it is theoretically or experimentally justified (Sect. 34.3.2). Importantly, how computer simulations are justified, and why specific computational models are used by scientists, are overlapping (though not identical) questions. For example, field- or inquiry-specific explanations of the use of computer simulations fail to account for cross-disciplinary recurrences in the use of computational models, which may have more general mathematical or computational explanations (Sect. 34.3.3). Overall, computer simulations are one of the main sources of knowledge and data in contemporary science, even if the sense in which they produce new data and knowledge is often misunderstood (Sect. 34.3.4).

### Computational Methods versus Computer Simulations

Not all major families of mathematical and computational methods are used to produce computational models or computer simulations of empirical systems. Evolutionary algorithms are used for the investigation of artificial worlds, or of foundational issues about evolution, and they have important applications in the field of optimization methods. Artificial neural networks are used in the field of machine learning and data learning and to predict the behavior of physical systems out of large databases. Bayesian networks are helpful to model knowledge, develop reasoning methods, or to treat data. Overall, all these computational methods have clear practical applications. They can be used for scientific tasks, sometimes concurrently with computer simulations in the case of predictive tasks. However, no genuine representations of physical systems and their dynamics seem to be attached to their use – even if, as the development of CA-based simulations has shown, novel formal settings may eventually have unexpected applications for modeling purposes in the empirical sciences.

### 34.3.1 Computer Simulations and Their Scientific Roles

Science, as an institution, aims to reach epistemic goals of various sorts, both propositional (like reaching some epistemic states, typically justified true beliefs) and practical (like being able to reliably manipulate some physical systems). Epistemologically analyzing science requires the study of the reliability and efficiency of scientific procedures to reach these goals. Accordingly, to develop the epistemology of computer simulations, one first needs to single out their different scientific goals.

Even if they also serve pedagogical or expository purposes, most computer simulations can be described as activities aimed to develop knowledge. There exist various types of scientific knowledge (see *Humphreys* [34.81] for an overview), which raise specific problems, and, conversely, various types of knowledge can be produced by computer simulations.

Typically, items of knowledge may differ in how they are justified (theoretically, experimentally, inductively, etc.), and whether they were reached by a priori or a posteriori investigations. They may also differ regarding the activities needed to produce them and the type of information that they provide. For exam-

ple, predictive or explanatory knowledge, or knowledge about how systems behave and can be controlled are of different types. Some scientific roles can be general (*predicting*) and others are very specific. For example, computer simulations are used to develop evidential standards in physics by simulating detection procedures and identifying patterns of data (*signatures*) [34.86]. Overall, developing a coherent and fine-grained epistemology of computer simulations would require drawing a map of their various roles to see how much their epistemological features are general or contextual and role specific.

Let us now be more specific. In the twentieth century, the role of experiments, as sources of empirical evidence about nature and guides in the selection of theories, was repeatedly, if not exclusively, emphasized by empiricist philosophers of science. Conversely, activities which did not provide such evidence were mainly seen as serving theoretical purposes. Typically, models were first seen as being primarily of a theoretical nature [34.20, §5]. In this perspective, *Models as Mediators*, in 1999, represented a significant advance. Morgan and Morrison, by presenting a more precise “account of what [models] do” in science [34.20, p. 18], offered a more nuanced epistemological picture, where models were shown to have functions as diverse as investigating theories and the world, intervening, helping for measurement purposes, etc. Since an important role of computer simulations is to demonstrate the content of models [34.13] or unfold well-defined scenarios [34.87], computer simulations can be expected to have, or contribute to, similar roles to those described by Morgan and Morrison and to potentially share these roles with other demonstrative activities like argumentation or mental simulations.

Importantly, such a description of science, where items or activities as diverse as theories, models, computer simulations, thought experiments, or experiments may serve partly overlapping purposes, remains compatible with empiricism provided that experiments are seen as, in the architecture of knowledge, the only ultimate source of primary evidence about the nature of physical systems. It is also compatible with the claim that secondary, derived sources of knowledge, like theories, models, or simulations, can sometimes be more reliable than experiments to provide information about how systems behave, in particular in cases in which experimental evidence is hard to come by (Sect. 34.5.4).

Overall, it is unlikely that there is such a thing as *the* epistemology of computational models and simulations. If the various roles of computer simulations are specific cases of general functions, like demonstrating or unfolding, there may be such a thing as a general, but incomplete, epistemology of computer

simulations, corresponding to the general epistemological problems raised by such general functions. In any case, to complete the picture, one needs to go deeper into the analysis of the roles that computer simulations serve within scientific practices and how they fulfill these roles in various types of contexts. This program is not incompatible with the philosophical perspectives of some of the advocates of the so-called *practice turn* in science [34.88], and in particular of authors who put contextually described scientific activities at the core of their description of science [34.89, 90].

### 34.3.2 Aspects of the Epistemological Analysis of Computer Simulations

#### A Multilayered Epistemology

Epistemology analyzes the types of justifications that we have for entertaining knowledge claims, and investigates how and why we epistemically fail or succeed. In the case of computer simulations, failure may take place at various levels, from the material implementation of the computation to the physical model that is at the core of the inquiry, and at all the intermediate semantic levels of interpretation that are needed to use computers for the investigation of models (see *Barberousse* et al. [34.91] for a general description and *Grim* et al. [34.92] for a discussion of some specific failures found in computer simulations). Overall, the epistemology of computer simulations involves discussing the reasons that we have for claiming:

1. The computers that we use work correctly.
2. The programs or algorithms do what we want them to do.
3. The computer simulations, *qua physical representations*, correctly depict what we want them to represent.

Steps 1 and 2 correspond to questions related to engineering and computer science. I shall not discuss these at length but will simply illustrate them to show how serious they are in this context. For example, at the architectural level, parallel computing requires coordination the different cores of computers so that all potential write-conflicts in the memory are solved. At the program level, when trying to solve a problem P with an unknown solution S, scientists need to prove the correctness of the algorithms they use and to verify that the programs written do indeed execute these algorithms. Many such verification problems are undecidable, which means that no general versatile procedure can be found to make this verification for all cases. However, this does not imply that proofs of the correctness of the algorithm cannot sometimes be pro-

vided for specific problems. Overall, scientists in this field still actively investigate and debate how much algorithms can be verified (see *Fetzer* [34.93], *Asperti et al.* [34.94] and *Oberkampff and Roy* [34.95] for discussions). At a higher mathematical level, as we saw earlier, many computational methods provide numerical methods for approximately solving problems, and the stability of algorithms can be a source of concern, which means that analyzing computational errors is part of the epistemology of simulations [34.62].

Finally, one needs to assess whether the approximations in the solution, as well as the representational inadequacies of the model, are acceptable regarding the physical inquiry pursued. At this interpretational level, because of the variety of theoretical contexts in which computer simulations are carried out, there is no single and general way in which the reliability of the results they provide can be analyzed. The credentials of computer simulations will be different depending on whether a sound theory is being used, how much uncertainty there is about the initial conditions, how complex the target system is, whether drastic simplification assumptions have been made etc. Also, depending on what the simulation is used for, and what type of knowledge it is meant to provide, the justificatory requirements will be more or less stringent. It takes different arguments to justify that based on a simulation one knows how to represent, control, predict, explain, or understand the behavior of the system (see Sect. 34.4 for a discussion of the last two cases, and [34.96] for similar analyses). Similarly, precise quantitative spatial-temporal predictions are in need of much pointed justifications than computer simulations aimed at studying average quantities or qualitative behaviors of systems. Importantly, this discussion of the reliability of computer simulations overlaps significantly with that of the epistemology of physical models, and with how the results issued from approximate, idealized, coarse grained, or simply partly false models can still be scientifically valuable (see *Portides* Chap. 2, this volume; *Frigg and Nguyen* Chap. 3, this volume). However, in the present context, it is important to emphasize that, even if the content of models obviously constrains the reliability of the information that can be extracted from them, models do not by themselves produce results – only procedures which investigate them do. In this perspective, the epistemology of computer simulations is a reminder that reliability primarily characterizes practices or activities that produce knowledge and that models, taken alone, are not such practices. In other words, epistemological discussions about the reliability of models as knowledge providers make sense only by explicitly reintroducing such practices or when it can be assumed that reliably

extracting all their content is possible, an assumption that, in the framework of computational science, is often not plausible.

#### From Theoretical to Empirical Justifications

Computer simulations have often been viewed as ways of exploring theories by hypothetico-deductive methods. This characterization captures a part of the truth, since existing theories are often a starting point for the construction of computer simulations. In simple cases, computer simulations can mainly be determined by theories, like in the case of *direct simulations* [34.77] in fluid dynamics, which derive from Navier–Stokes equations, and in which all relevant scales are simulated and no turbulence model is involved.

However, taken as a general description, this view misrepresents how computer simulations are often produced and their validity justified. As emphasized by *Lenhard* [34.97], even when theoretical equations are in the background, computer simulations often result from some cooperation between theory and experiments. For example, in 1955 when Norman Phillips managed to reproduce atmospheric wind and pressure relations with a six-equation model, which arrangement of equations could lead to an adequate model of the global atmosphere was uncertain and the need for experimental validation was primordial to confirm his speculative modeling assumptions. Overall, the role of empirical inputs in simulation studies is usually crucial to develop phenomenological modules of models, parameterize simulations, or investigate their reliability based on their empirical successes [34.15, 17].

At the same time, since computer simulations are used precisely in cases where empirical data are absent, sparse, or unreliable [34.16], sufficient data to build up and empirically validate a computational model may be missing. In brief, in some cases, computer simulations can be sufficiently constrained neither by theories nor by data and are somewhat autonomous. From an epistemological point of view, this potential situation of theoretical and experimental under-determination is not something to be hailed, since it undermines the scientific value of their results (see also Sect. 34.4.2).

#### The Epistemology of Complex Systems

Because computer simulations are generally used to analyze complex systems, their epistemology partly overlaps that of complex systems and their modeling. It involves the analysis of simplification procedures at the representational or demonstration levels and of how various theoretical or experimental justifications are often used concomitantly. Overall, when it comes to investigating complex systems, obtaining reliable knowledge is difficult. Thus, any trick or procedure that

works is welcome and the result is often what Winsberg has labeled a *motley* epistemology [34.16].

At the same time, sweeping generalizations should be avoided. Philosophers studying computer simulations have too often cashed in their epistemology in terms of that of the most complex cases, such as computer simulations in climate science, which are characterized by extreme uncertainties and the complexity of their dynamics. But computer simulations are used to investigate systems that have various types and degrees of complexity, and whose investigation meets different sorts of difficulties. It is completely legitimate, and politically important, that philosophers epistemologically analyze computational models and computer simulations in climate science (see, e.g., [34.98] for an early influential article). However, to obtain a finer grained and more disentangled picture of the epistemology of computer simulations, and not to put everything in the same boat, a more analytic methodology should be applied. More specifically, one should first analyze how the results are justified in more simple cases of computer simulations where specific scientific difficulties are met independently. In a second step, it can be analyzed how adding up scientific difficulties changes justificatory strategies and when exactly more holistic epistemological analyses are appropriate [34.99]. In this perspective, much remains to be done.

### Epistemic Opacity

Epistemic opacity is present in computer simulations to various degrees and has various origins.

Models are often said to be white, gray, or black boxes depending on how they represent their target system. White-box models describe the fundamental laws or causal mechanisms of systems whereas black-box models simply correctly connect different aspects of their behavior. This distinction partly overlaps with that of theoretical and phenomenological models (see *Barberousse* and *Imbert* [34.100, §3.2] for sharper distinctions about these last notions). Computer simulations can be based on all types of such models, which may affect the understanding that they yield [34.101] (see also Sect. 34.4).

Opacity can also be present at the computational model or computational process level. *Global epistemic opacity* may arise from the complexity of the computation when it is not possible for an agent to inspect and verify all steps of the process [34.41, §3.7], [34.102]. It is in part contingent since it is rooted in our limitations as epistemic creatures, but it may be in part intrinsic in the sense that the complexity of the computation may be irreducible (see Sect. 34.4.3). Importantly, it is compatible with *local epistemic transparency*, when *any* step of the process can be inspected by a human mind – which

may prove useful in cases in which problems can be located by testing parts of the process and applying a dichotomy procedure. Local transparency requires that all details of the physical models and computational algorithms used be transparent, which may be more or less the case. Usually, computer simulations make heavy use of mathematical resource libraries such as code lines, routines, functions, algorithms, etc. In applied science, more or less opaque computational software can be proposed to simulate various types of systems, for example, in computational fluid dynamics [34.91, p. 567]. This raises epistemological problems since black-box software is built on physical models with limited domains of physical validity, and results will usually be returned even when users unknowingly apply such software outside these domains of validity.

Another form of epistemic opacity for individual scientists arises from the fact that investigating natural systems by computer simulations may require different types of experts, both from the empirical and mathematical sciences. As a result, no single scientist has a thorough understanding of all the details of the computational model and computational dynamics. Such type of opacity is not specific to computer simulations, since it is a consequence of the epistemic dependence between scientists within collaborations [34.103].

### 34.3.3 Selecting Computational Models and Practices

How do individual scientists decide to pursue specific theories, and, in particular, what types of sociological, psychological, or epistemic factors play a role in such processes? Conversely, do selected theories share specific features or properties? *Mutatis mutandis*, similar questions can be asked about other elements of science, such as research programs, experiments, models, practices, and, in the present case, computational models and computer simulations. Philosophers have mainly analyzed these questions by focusing on the explicit scientific justifications of individual practices, and the content of the representations involved. As we shall see, this is only a part of the story.

#### Explanation of Uses versus Justification of Uses

A helpful distinction is that between the explanation (and context) of use of a practice and its scientific justification within a scientific inquiry aimed at reaching specific purposes. To use words close to *Reichenbach's* [34.104, pp. 36–37], while the latter deals with the objective relation that scientists consciously try to establish between these given <activities> (simula-

tions, experiments, etc.) and the conclusions that are obtained from them, other aspects of material, computational, cognitive, or social natures, potentially unknown to the scientific agents involved in the inquiry, may play a role to explain that these activities were actually carried out. For example, in the case of the Millennium Run (a costly simulation in astrophysics), the results were made publicly accessible. Scientists who were not involved in the process leading to the decision to carry out this simulation could try to make the best of it since it was already there and milk it as much as possible for different purposes. Or, some scientists may decide to study biological entities like proteins or membranes by means of Monte Carlo simulations, because members of their teams happen to be familiar with these tools. However, once they have decided to do so, they must still justify how their computer simulations support their conclusions.

In the perspective of explaining actual scientific uses, one also needs to distinguish between explanations aimed to account for specific uses (e.g., *Why was the millennium simulation carried out in 2005 by the Virgo consortium?*) and those aimed to explain more general patterns, corresponding to the use of practices of a given type, within or across several fields of science (e.g., *Why are Monte Carlo simulations regularly used in this area of physics?*, *Why are they used regularly in science?*). Importantly, since different instantiations of a pattern may have different explanations, the aggregated frequency of a scientific practice, like that of the use of the Ising model across science, may be the combined effect of general transversal factors and of inquiry- or field-specific features [34.105].

#### Field-Specific versus Cross-Disciplinary Explanations

A tempting move has often been to answer that scientific choices are primarily, if not completely, theory driven – and are therefore field specific. After all, theories guide scientists in their predictive and explanatory activities by fueling the content of their representations of natural systems. However, a reason to look for additional elements of explanations is that the spectrum of actual modeling and computational practices is smaller than our scientific knowledge and goals would allow [34.21, 41, 106]. For example, why do the harmonic oscillator, the Ising model, the Lotka–Volterra model, Monte Carlo simulations, etc., play such prominent roles throughout science?

As highlighted by *Barberousse* and *Imbert* [34.105], a variety of significantly different explanations of the greater or lesser use of models of a given type, and of scientific practices, can be found, beyond the straightforward suggestion that there are

regularities in nature, which are mirrored by modeling and computational practices.

#### Local Factors

The explanation may be rooted in the specificities of modeling and computational activities. In particular, if explaining is better achieved by limiting the number of (types) of (computational) models [34.21, pp. 144–5], or explanatory argument patterns [34.107], it is no surprise that often the same computational models and practices are met. Also, scientists may feel the need to avoid dispersion of their efforts in cases when research programs need to be pursued for a long time before good results can be reached and it is more profitable to exploit a local mine than to go digging somewhere else [34.106, Chaps. 4 and 5], [34.21, pp. 143–4]. More generally, the recurrence of computational practices may be viewed as another example of the benefits of adopting scientific standards [34.108]. One may also, in the Kuhnian tradition, put the emphasis on the education of scientists, who are taught to see new problems through the lens of specific problems or exemplars [34.106, p. 189], and emphasize that this education has a massive influence on the lineages of models or practices which are later developed. This story can have a more or less contingentist version, depending on why the original models or practices at the lineage seeds are adopted in the first place, and why these uses are perpetuated and scientists do not emancipate from them after schooling.

Theories may also play an indirect role in the selection of computational models. For example, models naturally couched in the standard formalism of a theory may be easier to use, even if the same physics can also be put to work by using other models. *Barberousse* and *Imbert* [34.100] analyze the case of lattice methods for fluid simulations in depth, which, though significantly different from approaches based on Navier–Stokes differential equations, can be used for the same purposes, even if this requires spending time learning and harnessing new methods and formalisms, which physicists may be reluctant to do.

#### Computational and Mathematical Explanations

As seen in Sect. 34.1.4, *Humphreys* [34.41, 81], suggests that most scientific models are tailored to fit the available mathematics, hence the importance in scientific practice of tractable models (see *Humphreys*'s notion of computational template [34.41, §3.4], and further analyses in [34.45]). Even if one grants the potential importance of such mathematical and computational factors, cashing out in detail the corresponding explanation is not straightforward. *Barberousse* and

*Imbert* [34.105] emphasize that there are various computational explanations. The *objective computational landscape* (how intrinsically difficult problems are, how frequent easy problems are) probably influences how science develops, even if knowing exactly what it looks like and how it constrains scientific activity is of the utmost difficulty. However, the *epistemic computational landscape* (scientists' beliefs about the objective computational landscape) may just be as important since it frames modeling choices made by scientists.

Other potentially influential factors may also include how difficult it is to explore the objective landscape (and the corresponding beliefs regarding the easiness of this exploration), how much scientists, who try to avoid failure, are prone to resort to tractable models, or which techniques are used to select such tractable models (since some specific techniques, like polynomial approximations, may repeatedly select the same models within the pool of tractable models). Finally, modeling conservativeness may also stem from the computational and result pressure experienced by scientists, that is, how scarce computational resources are in their scientific environment and how much scientists need to publish results regularly.

#### Universality, Minimality, and Multiple Realizability

Other explanations may be offered in terms of how weak the hypotheses are to satisfy a model or a distribution. For example, the Poisson distribution is often met because various types of stochastic processes satisfy the few conditions that are required to derive it [34.41, pp. 88–89]. Relationships between models and how models approximate to each other may also be important. Typically, the Gaussian distribution is the limit of various other distributions (see however, *Lyon* [34.109] for a more refined analysis and the claim that in Nature Gaussian distributions are common, but not pervasive). More generally, models that capture universal features of physical systems and are rooted in basic properties, such as their topology, can be expected to be met more often. Therefore, for reasons having to do with the mathematics of coarse-grain descriptions, and the explanation of multiple realizability, many systems fall into the same class and have similar descriptions [34.110–112] when minimal, macro-level, or simply qualitative models are built and explored.

Importantly, all the above explanations are not exclusive. Typically, the emphasis on tractability may be a general one in the sense that models always need to be tractable if they are to be used by scientists.

### 34.3.4 The Production of 'New' Knowledge: In What Sense?

#### Be Careful of Red Herrings!

It is commonly agreed that computer simulations produce *new knowledge*, *new data*, *new results*, or *new information* about physical systems (*Humphreys* [34.41], *Winsberg* [34.113, pp. 578–579], *Norton* and *Suppe* [34.114, p. 88], *Barberousse* et al. [34.91, p. 557], *Beisbart* [34.115]). This can be considered as a factual statement, since contemporary science, which is considered to produce knowledge, relies more and more heavily on computer simulations.

At the same time, the notion of knowledge should not be a red herring. It is commonly considered that experiments, inferences, thought experiments, representations, or models can bring knowledge, which then generates the puzzle that widely different activities have similar powers. The puzzle may be seen as somewhat artificial since knowledge, especially scientific, can be of different types [34.81], and when *new* knowledge is produced, the novelty can also be of different types. In this perspective, it may be that what is produced by each of these activities falls under a general identical concept but is significantly different. From this point of view, the real question concerning computer simulations is not whether they produce *knowledge*, but in which particular sense they produce knowledge, what kind of knowledge they produce, what is specific to the knowledge produced by computer simulations, and what type of novelty is involved.

A comparison can be made with thought experiments, for which the question of how they can produce new knowledge has also been debated. Both activities correspond to the exploration of virtual situations, and do not involve direct interactions with the systems investigated. From this point of view, computer simulations and thought experiments can be seen as platonic investigation of ideas, with this difference that, for computer simulations, the mind is assisted by computers [34.41, p. 115–116]. Overall, computer simulations have been claimed to sometimes play the same role of unfolding as thought experiments [34.87], have sometimes been equated with some types of thought experiments [34.116], and it has been suggested that computational modeling might bring the end of thought experiments [34.117]. Importantly, even if thought experiments are perhaps less used in science than formerly, this latter claim seems implausible. The reason is that there are different kinds of thought experiments, and many reveal conceptual possibilities that have little to do with computational explorations. Arguably, the possibility to set up computer simulations would have added nothing to famous thought experiments such as

those made by Galileo, Einstein, Podolsky and Rosen, or Schrödinger. (I am grateful to Paul Humphreys for emphasizing this point.) In any case, a satisfactory account of these activities should account for both similarities and differences in how they work epistemologically and how they are used.

In any case, the question of how and what we can learn about reality by using these methods arises, even if the sources of puzzlement do not exactly touch the same points in each case. Indeed, how mental thought experiments work is more opaque than how computer simulations do. For this reason, their rational reconstruction as logical arguments [34.118, p. 354] is more controversial than that of computer simulations [34.115], and it is less clear whether their positive or negative epistemic credentials are those of the corresponding reconstructed argument [34.119]. (For example, if certain thought experiments are reliable because mental reasoning capacities about physical situations have been molded by evolution, development, or daily experiments, it is not clear that their logical reconstruction will more vividly make clear why they are reliable.) The situation is clearer for computer simulations since the process is externalized and is based on more transparent mechanisms (see however Sect. 34.3.2). Then, if computer simulations are nothing else than (computationally assisted) thinking corresponding to the application of formal rules, and their output is somewhat contained in the description of the computational model, how knowledge is generated is clearer but the charge of the lack of novelty is heavier.

#### The Need for an Adequate Notion of Content

Suppose that a physical system  $S$  is in a state  $s$  at time  $t$  and obeys deterministic dynamics  $D$ . Then, the description of  $D$  and  $s$  characterizes a mathematical structure  $M$ , which is the trajectory of  $S$  in its phase space and is known as such. If a computer simulation unfolds this trajectory, then it explicitly shows which states  $S$  will be in. At the same time, any joint description of one of these states and of the dynamics denotes the same structure  $M$ , which is known to characterize the evolution of  $S$ . So, from a logical point of view, no new content has been unraveled by the computer simulation, which can at best be seen as a means of producing new descriptions of identical contents. In brief, if knowledge is equated with that of logical content, computer simulations do not seem to be necessarily producing new knowledge. We may even be tempted to describe computer simulations as somewhat infertile and thereby perpetuate a tradition according to which formal or mechanical procedures to draw inferences, and rules of logic in particular, are sterile, as far as discovery is concerned, and can at best be used to present pieces of

knowledge that have already been found – a position defended by *Descartes* in 1637 in the *Discours de la Méthode* [34.120]. This kind of puzzle, though particularly acute for computer simulations, is not specific to them and is nothing new for philosophers of language – Frege and Russell already analyzed similar ones. However, this shows that, *pace* the neglect for linguistic issues in the present philosophy of science, without an adequate theory of reference and notion of content that would make clear what exactly we know and do not know when we make a scientific statement, we are ill-equipped to precisely analyze the knowledge generated by computer simulations [34.41, 121].

Computational science may also remain somewhat mysterious if one reasons with the idealizations usually made by philosophers of science. As emphasized in Sect. 34.1.4, idealizing away the practical constraints faced by users is characteristic of much traditional philosophy of science and theories of rationality. In the present case, it is true that “*in principle*, there is nothing in a simulation that could not be worked out without computers” [34.122, p. 368]. Nevertheless, adopting this *in principle* position is unlikely to be fruitful here since, when it comes to actual computational science, which scientific content can be reached *in practice* is a crucial issue if one wants to understand how computational knowledge develops and pushes back the boundaries of science (see *Humphreys* [34.41, p. 154] and *Imbert* [34.102, §6]).

Overall, it is clear that present computational procedures and computer simulations do contribute to the development of scientific knowledge. Thus, it is incumbent on epistemologists and philosophers of sciences to develop conceptual frameworks to understand how and in what sense computer simulations extend our science and what type of novelty is involved.

#### Computer Simulations and Conceptual Emergence

Computer simulations unfold the content of computational models. How to characterize the novelty of the knowledge that they bring us? Since the notion of novelty is also involved in discussions about emergence, the literature about this latter notion can be profitably put to work here.

Just as emergence may concern property instances and not types [34.123, 124, p. 589], the notion of novelty needed here should apply to tokens of properties instantiated in distinctive systems and circumstances, or to specific regularities the scope of which covers such tokens and circumstances. For example, the apparition of vortices in fluids is in a sense nothing new, since the behavior of fluids is covered by existing theories in fluid dynamics, no new concept is involved, and other phe-

nomena of this type are already understood for some well-studied configurations. At the same time, finding out that patterns of vortices emerge in configurations of a new type is a scientific achievement and the discovery of some new piece of knowledge.

Importantly, as emphasized by *Barberousse* and *Vorms* [34.125, p. 41], the notion of novelty should be separated from that of surprise. When the exact value of a variable is precisely learnt and lies within the range that is enabled by some physical hypothesis or principle, we have a kind of *unsurprising novelty*. *Barberousse* and *Vorms* give an example from experimental science, but computer simulations may also provide exact values for quantities, which agree with general laws (e.g., laws of thermodynamics) and are therefore partly expected.

In addition, computer simulations can provide cases of *surprising novelty*, concerning behaviors that are covered by existing theories like chaotic behavior for classical mechanics. Indeed, Lorenz attractor and behaviors of a similar type were discovered by means of computer simulations of a simplified mathematical model initially designed to analyze atmospheric convection, and this stimulated the development of chaos theory [34.125, p. 42].

This leads us to a type of novelty, related to what *Humphreys* calls conceptual emergence. Something is conceptually emergent relative to a theoretical framework *F* when it requires a conceptual apparatus that is not in *F* to be effectively represented [34.41, p. 131], [34.123, p. 585]. The conceptual apparatus may require new predicates, new laws and sometimes the introduction of a new theory. Importantly, conceptual emergence is not merely an epistemic notion. It does not depend on the concepts we already possess and the conceptual irreducibility is between two conceptual frameworks. Further, even if instances of the target pattern can be described at the microlevel without the conceptually emergent concepts, the description of the pattern itself, if it is made without these novel concepts, is bound to be a massive disjunction of microproperties, which misrepresents the

macro-pattern qua pattern. Also, the same conceptually emergent phenomena may arise in different situations and its description may therefore require an independent conceptual framework, just like the regularities of special science require new concepts, unless one is prepared to describe their content in terms of a massive disjunction of all the cases they cover [34.126].

Interestingly, various phenomena investigated by computational science are conceptually emergent. Even if computer simulations are sufficient to generate them, identifying, presenting, and understanding them may require further analyses of the simulated data, re-descriptions at higher scales and the development of new theoretical tools. For example, traffic stop-and-go patterns in CA models of car traffic, emergent phenomena in agent-based simulations, and much of the knowledge acquired in classical fluid dynamics seem to correspond to the identification and analysis of conceptually emergent phenomena. Effectively, it is by conceptually representing these phenomena in different frameworks that one manages to gain novel information about these systems, above and beyond our blind knowledge of the microdynamics that generates them.

It is important to emphasize that different types of novelty described above are also met in experiments exploring the behavior of systems for which the fundamental physics is known. In other words, the potential novelty of experimental results should not be overemphasized. Even if only experiments can *confound* us [34.127, pp. 220–221] through results which are not covered by our theories or models, many of the new empirical data that these experiments provide us with are no more novel than those produced by computer simulations. The statements describing these results are not *strongly referential*, in the sense that no unknown aspects of the deep nature of the corresponding systems would be unveiled by a radically new act of reference [34.87, pp. 3463–3464]. These statements derive from what we already know about the physical systems investigated, and the experimental systems unravel them for us. In this sense, they are merely *weakly referential*.

## 34.4 Computer Simulations, Explanation, and Understanding

Can scientists provide explanations by simulating phenomena? If the answer is based on the explanatory requirements corresponding to the existing accounts of explanation, it is hard to see why some computer simulations could not be explanatory (Sect. 34.4.1). Why the specificities of computer simulations should necessarily deprive them for their explanatory potential is also unclear (Sect. 34.4.2), which is compatible

with the claim that computer simulations are used for inquiries whose results are, on average, less explanatory (Sect. 34.4.3). Be this as it may, because they heavily rely on informational and computational resources, computer simulations challenge our intuitions about explanatoriness, and in particular the expectation that good explanations should enable scientists to enjoy first-person objective understanding of the sys-

tems they investigate (Sect. 34.4.4). Even if computer simulations fail to meet these expectations because of their epistemic opacity, understanding may sometimes be regained by appropriately visualizing the results or studying phenomena at a coarser level (Sect. 34.4.5). In any case, scientific judgments about such issues are influenced by disciplinary norms, which may sometimes evolve with the development of computational science (Sect. 34.4.6).

### 34.4.1 Traditional Accounts of Explanation

Philosophers of science have discussed intensively the issue of scientific explanation over the last decades. The seminal works of Hempel were published in the 1940s, when computational science started to develop. However, until recently, discussions about computer simulations and explanations did not interfere with each other – which could suggest that for theorists of explanation, *how* explanations are produced does not in fact matter. While it is true that many of the examples of explanatory inquiries analyzed in the literature are simple and, at least in their most elementary versions, do not belong to computational science, it is hard to see why computer simulations could not in some cases satisfy the requirements corresponding to major accounts of explanations. According to the deductive-nomological (hereafter DN) model, one explains a phenomenon when a sentence describing it is logically deduced from true premises essentially containing a scientific law [34.128, pp. 247–248]. For example, the explanation of the trajectory of a comet, by means of a computer simulation of its trajectory based on the laws of classical (or relativistic) mechanics together with the initial positions of all bodies significantly influencing its trajectory, seems to qualify as a perfect example of DN explanation – provided that computer simulations can be seen as deductions [34.91, 115].

Analog statements can be made concerning the causal and unificationist models of explanations. The computer simulation of the comet’s trajectory is a way to trace the corresponding causal processes, described in terms of mark transmission [34.129] or of conserved quantities such as energy and momentum [34.130]. Other causal theorists of explanation like Railton have claimed that explanatory progress is made by detailing the various causal mechanisms of the world and all the nomological information relevant to the investigated phenomenon; the corresponding “ideal explanatory text” is thereby slowly unveiled [34.131]. But, one should note that, because such ideal explanatory texts are necessarily complex, their investigation is almost inevitably made by computational means.

Similarly, computer simulations can sometimes be instantiations of argument patterns that are part of what *Kitcher* describes as the explanatory store unifying our beliefs [34.107]. For example, the computation of the comet’s trajectory can be seen as an instantiation of “the Newtonian schema for giving explanations of motions in terms of underlying forces” [34.132, p. 121, p. 179].

Be this as it may, computer simulations have often been claimed, both by scientists and philosophers, to be somewhat problematic concerning explanatoriness and lacking some of the features that are expected to go with the fulfillment of explanatory requirements. This reproach of unexplanatoriness can be understood in several senses.

### 34.4.2 Computer Simulations: Intrinsically Unexplanatory?

One may first claim that computer simulations in general, or some specific types of them, do not meet one’s favorite explanatory requirements. For example, agent-based simulations may be described as not usually involving covering laws nor providing explanatory causal mechanisms or histories [34.75, 133]. However, one should not ascribe to computer simulations reproaches that should be made to the field itself. If a field does not offer well-entrenched causal laws and one is convinced that explanations should be based on such laws, then the computer simulations made in such fields are not explanatory, but this has nothing to do with computer simulations in general. Also, some computer simulations are built with scientific material like phenomenological regularities, which potentially makes them unexplanatory, but this material could also be used in the context of explanatory inquiries involving arguments or closed form solutions to models. Thus, the problem comes from the use of this material and not from the reliance on one or another mode of demonstration – and claiming that computer simulations are unexplanatory is like blaming the hammer for the hardness of the rock.

For this reproach to be meaningful (and specific to computer simulations), it should be the case that other inquiries based on the same material are indeed explanatory, but that the corresponding explanations based on computer simulation are not, because of specific features of computer simulations or some types of them. It is not completely clear how this can be so. Computer simulations are simply means of exploring scientific models and hypotheses by implementing algorithms, which provide information about tractable versions of these models or hypotheses. Therefore, their explanatory peculiarity, if any, should be an effect of

specific features like the use of algorithms, coding languages, or external computational processes.

There is no denying that the need to format scientific models and hypotheses into representations that are suitable for computational treatment comes with constraints. For example, a recent challenge has been to adapt coupled circulation models and their algorithms to the architecture of modern massively parallel supercomputers. Similarly, when one uses CA models for fluid dynamics, the physical hypotheses must be expressed in the straightjacket of up-to-date rules between neighboring cells on a grid. Beyond these genuine constraints on computational practices, one should remember that, computational languages, provided they are rich enough, are content neutral in the sense that any content that can be expressed with some language can also be expressed with them. Similarly, computational devices like the computers we use daily are universal machines in the sense that any solution to a computational problem (or inference) that can be produced by other machines can also be produced by them. For these reasons, it is hard to see why, *in principle*, computer simulations should be explanatorily limited, since the theoretical content and inferences related to other means of inquiries can also be processed by them.

The case of CA models abovementioned exemplifies nicely this point. For several decades, CA models have been used under various names in various fields; from Schelling's investigations about spatial segregation in neighborhoods, analysis of shock waves in models of car traffic, models of galaxies, investigations of the Ising model, to fluid dynamics (see *Ilachinski* [34.134] for a survey). Because existing theories and scientific laws are not expressed in terms of CA, some philosophers have claimed that CA-based simulations were merely phenomenological [34.135, pp. 208–209], [34.9, p. 516]. Nevertheless, *Barberousse* and *Imbert* [34.100] have argued that such bold *general* statements do not resist close scrutiny. They present the case of lattice gas models of fluids and argue that, beyond their unusual logical nature, from a physical point of view, such mesoscopic models and computer simulations make use of the same underlying physics of conserved quantities as more classical models, and can be seen as no less theoretical than concurrent computer simulations of fluids based on macroscopic Navier–Stokes equations. Therefore, there is no reason why such computer simulations could not be usable for similar explanatory purposes.

Overall, there is no denying that *some* (and possibly many) computer simulations are not explanatory. Providing various examples of unexplanatory computer simulations is scientifically valuable, but it says nothing general about their general lack of explanatory power,

unless one shows why unexplanatoriness stems from specific features of (some types of) computer simulations qua simulations. In the absence of such conceptual analyses, one can simply conclude that some scientific uses of computer simulations, or some computational practices, turn out to be unexplanatory.

### 34.4.3 Computer Simulations: More Frequently Unexplanatory?

A different claim is that, given the current uses of computer simulations in science, they are more often unexplanatory than other scientific items or activities, even if this is partly a contingent matter of fact. The explanatoriness of computer simulations can be threatened in various ways. Computational models may be built on false descriptions of target systems or may lack theoretical support and simply encapsulate phenomenological regularities; they may have been spoiled by the approximations, idealizations, and modeling tricks used to simplify models and make them tractable; they may depart from the well-entrenched explanatory norms in a field or may not correspond to accepted explanatory methods. Clearly, none of these features is specific to computer simulations. However, it may be the case that because of their current uses in science, computer simulations more frequently instantiate them.

#### The Lure of Computational Explorations

Because they are powerful heuristic tools, and because other means of exploration are often not available, computer simulations are more often used to toy and tinker with hypotheses, models, or mechanisms and, more generally, to *experiment on theories* [34.135, 136]. This may especially be the case in fields where there is no well-established theory to justify (or invalidate) the construction of models, or where collected evidence is not sufficient to check that the simulated mechanisms correspond to actual mechanisms in target systems. For example, in cognitive science, competing theories of the mind and its architecture coexisted for decades, and even modern techniques of imaging like fMRI (functional magnetic resonance imaging), though empirically informative, do not provide sufficient evidence to determine how the brain works precisely in terms of causal mechanisms. Accordingly, in this field, developing a model that is able to simulate the cognitive performances of an agent does not imply that one has understood and explained how her brain works, and more refined strategies that constrain the functional architecture must be developed if one wants to make explanatory claims [34.4, Chap. 5]. The issue is all the more complex in this specific field since the inquiry may also involve determining (verses assuming)

whether neural processes are computations [34.137]. Similarly, in the social sciences, empirically validating a simulation is far from being straightforward and as a result the epistemic and, in particular, explanatory value of computer simulations is often questionable [34.138].

Overall, since computer simulations offer powerful tools to investigate hypotheses and match phenomena, it is a temptation for scientists to take a step further and claim that their computer simulations have explanatory value. In brief, computer simulations offer a somewhat natural environment for such undue explanatory claims.

### The Worries of Under-Determination

In the case of computer simulations, the higher frequency of inappropriate explanatory claims may be reinforced by the combination of several factors.

When toying with hypotheses, scientists are often interested in trying to reproduce some target phenomenology, so they often do not tinker in a neutral way. The specific problem with computer simulations is that, in many cases, getting the phenomenology right is somewhat too easy, and the general problem of under-determination of theoretical claims by the evidence is particularly acute.

First, computer simulations are often used in cases where data are scarce, incomplete, or of low quality (see, e.g., [34.78, Chap. 10] for the case of climate data and how making data global was a long and difficult process). The scarcity of data can also be a primary motivation to use computer simulations to inquire about a system for which experiments are difficult or impossible to carry out, like in astrophysics [34.139]. Furthermore, knowledge of the initial and boundary conditions out of which the computer simulations should be fed may also be incomplete, which leaves more latitude for scientists to fill in the blanks and possibly match data. As a result, confidence in the result of computer simulations like the Millennium Run and in their representational and explanatory success is in part undermined [34.139].

Second, computer simulations usually involve more variables and parameters than theories. For example, for a  $10 \times 10$  grid with cells characterized by three variables, the total number of variables is already 300. This raises the legitimate suspicion that, by tuning variables in an appropriate way, there is always a means to obtain the right phenomenology. (Ad hoc tuning is of course not completely straightforward, since the many variables involved in a computer simulation are usually jointly constrained. Typically, in a fluid simulation, all cells of the grid obey the same update rule and are correlated.) This possibility of tuning variables and parameters is indeed used in fields like machine

learning, which can be based, for example, on the use of artificial neurons. In such fields, one first combines a limited number of elementary mathematical functions (e.g., artificial neurons) that, when adequately parameterized, reproduce potentially complex behaviors found in databases (the learning phase). In a second step, one uses the parameterized functions (e.g., the trained neural network) on new cases in the hope that extrapolation and prediction are possible. In such cases, even if the right phenomenology is reproduced, and extrapolation partly works, it is clear that the trained neural network and the corresponding mathematical functions do not explain the phenomena. Overall, this means that the ability to reproduce some potentially complex phenomenon is far from being sufficient to claim that the corresponding computer simulation has explanatory power (see also [34.140] for the issue of the over-fitting of computer simulations to data).

Third, when scientists do succeed, they may be subject, as other human creatures, to confirmation biases, overweigh their success and tend to ignore the fact that various mechanisms or laws can produce the same data (or that other aspects of their computer simulations do not fit). While such biases are not specific to computational inquiries, they are all the more epistemologically dangerous since matching phenomena is easy.

### Complex Systems Resist Explanation

Because they are very powerful tools, computer simulations are specifically used for difficult investigations, which usually have features that may spoil their explanatory character [34.141, 142]. Typically, in the natural sciences, computer simulations and computational methods are centrally used for the study of so-called complex systems [34.143, 144], see also Chap. 35. Realistically investigating complex systems would imply taking into account many interrelated nonlinear aspects of their dynamics including long-distance interactions and, in spite of the power of modern computers, the corresponding models are usually intractable. Therefore, drastic simplifications need to be made in both the construction of the model and its mathematical treatment, which often threatens the epistemic value of the results.

Importantly, for the above reasons, the problem of the explanatory value of computer simulations can arise even in fields like fluid dynamics where the underlying theories are well known. It is no surprise that this problem is more acute in fields, such as the human and social sciences, in which no such theories are available, the investigated objects are even more complex, sound data are more difficult to collect and interpret, and the very nature of what counts as a sound explanation and genuine understanding is more debated [34.145, 146] especially in relation to computer simulations [34.133].

For these reasons, even if there are good arguments for claiming that computer simulations do not fare worse than other methods like analytic models or experiments (see [34.40] for the case of economics), it is not surprising that their potential explanatory power is undervalued.

Overall, it is plausible that often computer simulations have less explanatory power than other methods, and that this does not stem from their nature but from the type of uses they usually have in science. If this is the case, the question of the explanatory power of computer simulations is to be treated on a case-by-case basis by using the same criteria as for assessing the explanatory power of other scientific activities, *pace* the distrust that shrouds the use of computer simulations.

#### 34.4.4 Too Replete to Be Explanatory? The Era of Lurking Suspicion

Theories of explanation should capture our intuitions about what is explanatory. From this point of view, it is interesting to see whether computer simulations meet these intuitions, especially when they fulfill the explanatory requirements described by theories of explanations.

##### Computer Simulations and Explanatory Relevance

Good explanations should not include explanatorily irrelevant material. While determining whether some piece of information is explanatorily relevant to explain some target fact is a scientific task, finding a satisfactory notion of explanatory relevance is a task for philosophers. Despite progresses concerning this problem, current accounts of explanation still fall short of capturing this notion [34.147, 148]. At the same time, existing results are sufficient to understand why computer simulations raise concerns regarding explanatory relevance.

Scientific information, in particular causal laws, accounts for the behavior of phenomena. Thus, it is legitimate, when trying to explain some phenomenon, to show that its occurrence can be derived from a scientific description of the corresponding system. Nevertheless, even then, one may fall short of satisfying the requirement of explanatory relevance. This is clearly explained by *Salmon* in his 1989 review of theories of explanation, where he asks “Why are irrelevancies harmless to arguments but fatal to explanations?” and further states that “irrelevant premises are pointless, but they have no effect whatever on the validity of the argument” [34.149, p. 102]. While philosophers have mainly focused on the discussion of irrelevant unscientific premises, the problem actually lies deeper. Parts of the content of

laws or mechanisms, essentially involved in explanatory arguments, can be irrelevant to the explanation of aspects of phenomena that are covered by these laws or mechanisms [34.148]. So the problem is not simply to discard inessential (unscientific or scientific) premises, but also to determine, within the content of the scientific premises that are essentially used in explanatory derivations, what is relevant and what is not [34.102, 148, 150].

This problem is especially acute for computer simulations. Take a computer simulation that unfolds the detailed evolution of a system based on the description of its initial state and the laws governing it. Then all aspects of the computational model are actually used in the computational derivation. At the same time, all such aspects are not necessarily explanatorily relevant with respect to all facets of the computed behavior. Typically, some aspects of the computed behavior may simply depend on the topology of the system, on symmetries in its dynamics or initial conditions, on the fact that some initial quantity is above some threshold, etc.

Accordingly, the following methodological maxim may be proposed: *the more an explanation (resp. an argument) contains independent pieces of scientific information, the more we are entitled to suspect that it contains irrelevancies (regarding the target behavior).*

At the same time, one should remain aware that explaining some target phenomenon may sometimes irreducibly require that all the massive gory details involved in the simulation of the corresponding system are included. For example, as chaos theory shows it, explaining the emergence and evolution of a hurricane may essentially require describing the flapping of a butterfly’s wings weeks earlier.

An additional problem is that there is no general scientific method to tell whether a premise, or some part of the information it conveys, is relevant. Contrarily to what the hexed salt example [34.151] may perhaps suggest, irrelevant pieces of information within an explanation do not wear this irrelevance on their sleeves and are by no means easy to identify. This is the *problem of the lack of transparency, or of opacity, of irrelevant information.*

Overall, since they are based on informationally replete descriptions of their target systems, computer simulations legitimately raise the suspicion of being computational arguments that contain many irrelevancies, and therefore of being poor explanations – even when they are not.

##### Computer Simulations, Understanding, and Inferential Immediacy

Mutatis mutandis, similar conclusions can be reached regarding the issue of computational resources. Since

this issue is closely related to the question of how much computer simulations can bring about understanding, things shall be presented through the lens of this latter notion.

It is usually expected that explanations bring understanding. Theorists of understanding, while disagreeing on the precise nature of this notion, have explored its various dimensions, which provides a good toolkit to analyze how computer simulations fare on this issue.

Hempel cashes in the notion of understanding in terms of nomic expectability. From this point of view, taken as explanatory arguments, computer simulations seem able to provide understanding since, like other scientific representations, they can rely on nomological regularities. Further, in contrast to sketchy explanations, they make the nomic dependence of events explicit. Consider the explanation analyzed by *Scriven* that “the impact of my knee on the desk caused the tipping over of the inkwell” [34.152]. The *hidden strategy* described by *Woodward* [34.153] is to claim that the value of this latter nonnomological explanation is to be measured against an *ideal* explanation, which is fully deductive and nomological and describes the detailed succession of events that led to the stain on the carpet, even if this complete explanation is often inaccessible. From this point of view, a computer simulation can offer a way to approach such an ideal explanation, by providing an explicit deduction of the lawful succession of events that brought about the explanandum. However, an epistemic problem is that, once such a computer simulation has been carried out (and properly stored), it is possible to explicitly highlight any part of it, but it is not possible to scrutinize all parts because there are too many of them. This is one of the reasons why computer simulations are intrinsically opaque to human minds [34.41, §5.3], see also Sect. 34.3.2.

Be this as it may, causal theorists of explanation should agree that computer simulations often contribute significantly to developing our understanding by reducing uncertainty about the content of causal ideal explanatory texts, as requested in [34.131].

Computer simulations also seem to be able to provide unificatory understanding. For unificationists like *Kitcher*, understanding is a matter of “deriving descriptions of many phenomena using the same pattern of derivation again and again” [34.107, p. 423]. Since computer simulations offer more ways of deriving phenomena, by providing new patterns of derivation or instantiating existing patterns in more complex cases, at least some of them contribute to unification.

Things are less straightforward with *Woodward’s* account of explanation and understanding. *Woodward* argues that a good explanation provides “understanding

by exhibiting a pattern of counterfactual dependence between explanans and explanandum” [34.154, p. 13]. From this point of view, computer simulations fare well since, if one does not go beyond their domain of validity, they provide general patterns of counterfactual dependence between their inputs  $I$  and outputs  $O$ , which are obtained by applying  $t$  times their update algorithms ( $UA$ ), that is, more formally,  $O(t, I) = UA^t(I)$ .

Is there a philosophical catch? *Woodward* also requires that the pattern of counterfactual dependence be described in terms of a functional relation. But what is to count as a *function* in this context? Functions can be defined explicitly (by means of algorithms) or implicitly (by means of equations). The advantage of computer simulations is that they provide algorithmic formulations based on elementary operations of how the explanandum varies with the explanans. From this point of view, computer simulations are more explicit than models, which simply provide equations linking the explanans and the explanandum. However, the problem is that with computer simulations any kind of functional immediacy is lost, since it is computationally costly to carry out the algorithm. Indeed, *Woodward* usually describes straightforward examples of functional dependence like  $Y = 3X_1 + 4X_2$ . With such functions, we may feel that the description of the counterfactual dependence is *just there*, since, by *simply instantiating* the variables and carrying out the few operations involved, specific numerical relations are accessible. In such simple cases, a human mind can do the work by itself and answer the corresponding what-if-things-had-been-different (what-if) questions. In contrast, with a computer simulation, computing the output takes much computational power. So the tentative conclusion is that computer simulations provide understanding in *Woodward’s* sense, but this understanding is not immediately accessible, the degree of (non)-immediacy being described by the computational resources it takes to answer each what-if question. Importantly, an equation-based model may give the illusion of immediacy, since the equation presents a short description of how the variables are correlated. However, one should watch out that short equations can be unsolvable, and short descriptions of algorithms (like  $O(t, I) = UA^t(I)$ ) with simple inputs can yield complex behaviors that are computationally costly to predict [34.155].

Similar conclusions can be reached if one focuses on analyses of understanding proper. *De Regt* and *Dieks* propose to analyze understanding in terms of intelligibility, where this latter notion implies the ability to recognize qualitative characteristic consequences without performing exact calculations [34.156]. In this sense, understanding seems to be a matter of immediacy, as was already suggested by *Feynman*, who described it as

the ability to foresee the behavior of a system, at least qualitatively, or the consequences of a theory, without solving exactly the equations or performing exact calculations [34.157, Vol. 2, 2–1].

Depending on the cases, foreseeing consequences requires logical and cognitive operations to a greater or lesser extent. Thus, the above ideas may be rephrased in a more gradualist way, by saying that the less inferential or computational steps one needs to go through to foresee the behavior of a system or the consequences of a theory, the better we understand it. In this perspective, computer simulations fare terribly badly, since they involve going through many gory computational steps and, even once these have been carried out, scientists usually end up with no simple picture of the results and no inferential shortcuts that could exempt them from this computational stodginess for future similar investigations.

#### Understanding: What Do We Lose with Computer Simulations?

Before the advent of computational science, explanatory advances in science were always the direct product of human minds and pen-and-rubber methods. Therefore, any actual scientific explanation that satisfied the requirements for explanatoriness was also human sized, and the epistemic benefits logically contained within such explanations could actually be enjoyed by competent and informed epistemic agents. In [34.158, p. 299], *Hempel* states that an explanatory argument shows that “the occurrence [of an event] was to be expected” and he adds “in a purely logical sense.” This addition emphasizes that expectation should not be understood as a psychological notion nor refer to the psychological aspects of the activity of explaining. In the case of computer simulations, this addition is somewhat superfluous. Nomic expectability remains for scientists, since, based on computer simulations, they may know that they can entertain the belief that an event should happen. However, this belief is completely *cold*. Since the activity of reasoning is externalized in computers, it is no longer part of the proper cognition of scientists and does not come with the psychological side-effects associated with first-person epistemic activities, such as emotions or feelings of expectation, impressions of certainty and clarity, or the oft-mentioned aha or eureka feeling which usually comes with first-person experiences of understanding. In other words, with computer simulations, the mind is no longer the carrier of the activity of explanation, and simply records what it should believe. Unfortunately, epistemic benefits associated with the individual ability to carry out this activity are also lost. Since the explanatory argument can no longer be surveyed by a human mind, the details of the rela-

tions between the premises of the explanatory argument and its conclusion are opaque. Therefore, scientists are no longer able to encompass *uno intuitu* all aspects of the explanation and how they are related, to develop expectations about counterfactual situations (in which similar hypotheses are met), and the unificatory knowledge that only global insights can provide is also lost. Overall, with computer simulations the objective intelligibility that is enclosed in explanations and can be accessed by first-person epistemic appropriation of the explanatory arguments can no longer be completely enjoyed by scientists (see also [34.159] for further analyses about epistemic opacity in this context). In this perspective, the problem of computer simulations is not that they have less explanatory value but that *we cannot have epistemic access* to this explanatory value. In brief, this problem would not pertain to the logic of computer-simulation-based explanations but to their epistemology.

#### New Standards for Understanding?

The gradualist description regarding the need of cognitive and logical operations to foresee consequences (see Sect. 34.4.4 Computer Simulations, Understanding, and Inferential Immediacy) suggests that the boundary between cases where intelligibility is present or is lost is not completely sharp. Importantly, the ability to foresee consequences depends on various factors such as the knowledge of physical or mathematical theorems to facilitate deductions, the knowledge of powerful formalisms to facilitate inferences, how much the intuition of scientists has been trained to anticipate consequences of a certain type and has somewhat internalized inferential routines, etc., [34.102, §6.4]. In other words, at least in some cases, the frontiers of what has a computational explanation, but remains unintelligible to a human mind, can be pushed back to some extent.

This raises the question of how much the frontiers of intelligibility can be extended and whether the ideal of inferential or computational briefness for explanations should be considered as a normative standard. Two positions are possible. One may claim that genuine explanations should *always* yield the possibility for human subjects to access the corresponding understanding. Or one may claim that, as shown by computational science, we have gone beyond human-sized science, not all good explanations can be comprehended by human minds, and this is not a defect of *our* science, even if it is clearly an epistemic inconvenience.

A motivation for endorsing the former claim is that the lack of intelligibility of explanations often stems from epistemic flaws of the agents producing them and can be corrected. Typically, in science, results are often

laboriously proved and, with the advance of scientific understanding, shorter and clearer proofs, or quicker algorithms, are found.

Overall, it seems sound to adopt the following methodological maxim: *the more resources we need to produce (or check) an explanation (resp. an argument, a proof), the more we are entitled to suspect, in the absence of contrary evidence, that the explanation is unduly complex*. From this point of view, computer simulations do not seem flawless, since they make abundant use of computational and inferential resources. Accordingly, it is legitimate to suspect computer simulations of providing unduly complex explanations, which have simpler versions yielding the expected accessible understanding.

Nevertheless, this philosophical stance may be inappropriate in many cases. There is a strong suspicion that explaining phenomena often requires using an irreducible amount of resources. This idea of computational irreducibility has been vocally advanced, though not clearly defined, by Wolfram [34.155], and philosophers have toyed with close intuitions in recent discussions about emergence [34.74, 123, 124, 160–162]. Capturing the idea in a clear, robust and fruitful definition is a difficult on-going task [34.163]. However, there seems to be an agreement that this intuitive notion is not empty, which is what matters for the purpose of the present discussion. Overall, this means that in all such cases, asking for computationally simple explanations does not make sense, since such explanations do not exist. In this perspective, tailoring our explanatory ideals to our human capacities is wishful thinking, since in many cases, the inaccessibility of the usual epistemic benefits of explanations does not stem from our epistemic shortcomings.

This suggests that we may have to bite the bullet and say that, sometimes, computer simulations do bring full-fledged explanation and objective understanding, even if, because of our limited cognitive capacities, we cannot enjoy this understanding and the epistemic benefits harbored by such explanations. In other words, both of the above philosophical options are correct, though in different cases.

Ideally, one would like to be able to know when each of these two options should be adopted. Unfortunately, determining whether a computational process can be shortcut or a computational problem solved by quicker algorithms, seems to be in practice opaque (*problem of the lack of transparency of the optimality of the computational process*). This means that in most cases, when facing a computational explanation of a phenomenon, one does not know whether there are computationally or inferentially shorter versions of this explanation (and we are to be epistemically blamed

for being so explanatorily laborious), or whether one cannot do better (and the process is intrinsically complex).

Overall, because determining whether explanations are informationally minimal (regarding the use of relevant information) and whether arguments or computations are optimal is opaque, computer simulations are doomed to remain shrouded in suspicion about their explanatoriness, *even in cases in which there is no better (that is, shorter or less informationally replete) explanation*. In brief, the era of suspicion regarding the explanatoriness of computer simulations will not end soon.

#### 34.4.5 Bypassing the Opacity of Simulations

Even when computer simulations are epistemically opaque, some strategies can be tried to regain predictive power, control, and potentially understanding regarding the corresponding inquiries.

##### Understanding, Control and Higher Level Patterns

As emphasized by Lenhard [34.159], by *manipulating* computational models and observing which behavior patterns are obtained, scientists can try to control the processes involved and develop “a feeling for the consequences.” Lenhard suggests that this *understanding by control*, which is oriented toward design rules and predictions, corresponds to a pragmatic account of understanding, which is also involved in the building of reliable technological artifacts.

Other authors have emphasized that, even if the details of computer simulations cannot be followed by human minds, one may sometimes still obtain valuable insights by building coarse-grained representations of the corresponding target systems and analyzing whether macro-dynamics emerge when microinformation is thrown away [34.164]. Surprisingly, the existence of coarse-grained dynamics seems to be compatible with complex, potentially computationally irreducible, dynamics at the microlevel [34.165, 166], even if this by no means warrants that control or understanding can always be regained at the macro-level. Thus, the question arises as to when and how much epistemic virtues like predictive power, control, and potentially understanding, which are somewhat lost at the microlevel, can be partly recovered at the macro-level, and how the corresponding patterns can be detected. The treatment of such questions requires the analysis of logical and mathematical relations between descriptions of systems at different scales and, for this reason, it should gain from ongoing debates and research in the philosophical

and scientific literature about the emergence of simple behavior in complex systems.

### Visualization and Understanding

Another important issue is how to exploit macro-level patterns that are present in computer simulations to restore partial cognitive grasp of the simulated systems by humans. Given the type of creatures that we are, and in particular the high visual performance of the brain, using visual interfaces can be part of the answer. Indeed, the format of scientific representations partly determines what scientists can do with them – whereas, as emphasized by [34.41, p. 95], philosophers have often considered the logical content of a representation to be the only important element to analyze them. To go further into these issues, sharp analyses of representational systems and their properties are required. Tools and concepts developed in the Goodmanian tradition prove to be extremely useful [34.167]. For example, *Kulvicki* [34.29] highlights how much graphs and images can present information more immediately than symbolic representations can. This notion of immediacy is cashed in in terms of semantic salience, syntactic salience or extractability. *Vorms* further shows how taking into account formats of representation in the analysis of scientific reasoning is crucial, since inferences have different cognitive costs depending on the format of representation [34.168]. *Jebeile* [34.169] applies similar concepts to computational models and argues that visualization tools can have a specific explanatory role since they do not merely present computational data in more accessible ways, but also suggest interpretations that are not contained in the original data, highlight relations between these data, and thereby point at elements of answers to what-if questions.

Overall, the issue of how much visualization can convey objective understanding remains debated. For

example, *Kuorikoski* [34.164] acknowledges that visual representations are cognitive aids but emphasizes that they often merely bring about a *feeling* and *illusion* of understanding. So, there is the need of epistemological analyses which would make clear in which cases, and how, visual representations can be reliable guides and self-certifying vectors of knowledge, which partly enable their users to determine whether and how much they should trust them.

### 34.4.6 Understanding and Disciplinary Norms

All the above discussion has been based on general arguments about explanations and understanding. However, as already emphasized, explanatory norms sometimes differ from one field to another, economics being, at least in its mainstream branches, a paradigmatic case of a field in which simulation methods are shunned [34.37]. Similarly, the explanatory status of computer simulations and computational models varies across fields like cognitive sciences, artificial intelligence [34.137], artificial life [34.170] or within fields themselves (see, e.g., [34.171] for the case of computational chemistry and [34.79] for that of climate science).

This is not the place to discuss whether these variations regarding explanatory norms are deep, or whether they result from differences in theoretical contexts, in the degrees of complexity of the systems investigated, in the difficulties to collect evidence about them, in the scientific maturity and empirical success of these fields, etc. Such questions cannot be answered on the basis of armchair investigations. Field-specific studies of the explanatoriness of computer simulations, made by scholars who are in the same time acutely aware of present discussions about scientific explanation, are needed.

## 34.5 Comparing: Computer Simulations, Experiments and Thought Experiments

Computer simulations, experiments, and, to a lesser extent, thought experiments share various similarities, which calls for an explanation. Indeed, similarities between experimental activities and computational science are even found in mathematics, where some methods are claimed to be *experimental* (Sect. 34.5.1). Computer simulations, experiments and thought experiments can sometimes be seen as ways of carrying out similar activities, or activities having similar constraints (Sect. 34.5.2). Should an additional step be made, and computer simulations be considered as experiments?

A close scrutiny of the existing arguments in favor of this claim shows that it meets insuperable difficulties, both regarding the analysis of computer simulations and experiments. Further, the claim does not even seem necessary to account for the importance of the material aspects of simulations (Sect. 34.5.3). Finally, even if computer simulations can yield knowledge, which can sometimes be more reliable than that produced by experiments, unless a strong case against empiricism is properly made, computer simulations do not seem to seriously threaten the unique foundational role of exper-

iments as the source of primary evidence upon which science is built (Sect. 34.5.4). In any case, discussions about the relationships between experiments and computer simulations should remain compatible with the actual existence of hybrid (both computational and experimental) methods (Sect. 34.5.5).

When in the 1990s philosophers of science started investigating computer simulations, they soon realized that the object of their inquiry cross-cut traditional categories like those of theories, models, experiments or thought experiments. Similarities with experiments were particularly striking, since, among other things, computer simulations involved the treatment of massive data and statistical reasoning, required robustness analysis, and were claimed to yield new knowledge. As a result, computer simulations were suggestively dubbed by various authors as computer *experiments*, numerical *experimentation* or in-silico *thought experiments*, even though it was not always conceptually clear what these potentially metaphorical characterizations meant exactly.

All such similarities are worth analyzing and potentially call for explanations. They may be the sign of an identical nature between (some of) these activities, of common essential features, or may just be shallow or fortuitous. Clarifying this issue is also a way to analyze these activities more acutely by singling out what is specific to each or common to them and to determine to what extent epistemological insights can be transferred between them.

### 34.5.1 Computational Mathematics and the Experimental Stance

#### Experimental Proofs in Mathematics

Since aspects related to the representation of material systems are absent from mathematics, a comparison with this field can be hoped to be fruitful to *analyze* what exactly is experimental in computational science.

The mathematical legitimacy of computers for the production of proofs has been discussed for several decades. Computational proofs like that of the four-color theorem by Appel et al. [34.172, 173] were rapidly labeled *quasi-empirical* and discussions raged about how they should be interpreted [34.174, p. 244]. Such computational *proofs* can actually be seen as having roots in the older tradition of *quasi-empirical mathematics*, practiced for example by mathematicians like Euler, and philosophically defended by authors like Lakatos [34.175] or Putnam [34.176]. Interestingly, even in these contexts, the labels *empirical* or *experimental* were used to refer to various aspects of the activity of proving results.

Like experiments, computational proofs involve external processes, which are fallible. Their reliability can then be seen as being partly of a probable nature and needs to be assessed a posteriori by running these external processes several times and checking that the apparatus involved worked correctly. By contrast, proofs which can be *actively* and *directly* produced by humans minds, can provide a priori knowledge, the validity of which is assessed by (mentally) inspecting the proof itself, qua mathematical entity. Further, computational proofs, like experiments and empirical methods in mathematics, usually provide particular numerical results: as the computational physicist Keith Roberts writes it, “each individual calculation is [...] analogous to a single experiment or observation and provides only numerical or graphical results” (quoted in [34.70, p. 137]). Therefore, to obtain more general statements (and possibly theories), probabilistic inductive steps are needed. Overall, such debates illustrate the need to clarify the use in this context of labels like *experimental* or *empirical*.

#### The Experimental Stance

The case of computational mathematics also makes clear how scientists can adopt an experimental stance for inquiries where no physical process is investigated, and the nature of the object which is *experimented upon* is completely known.

Experimenting involves being able to trigger changes, or to intervene on material or symbolic dynamical processes, and to record how they vary accordingly. As noted by Dowling [34.136, p. 265] and Jebeile [34.169, II, §7.2], processes for which the dynamics is known can also work as black boxes, since the opacity of the process may stem either from our lack of knowledge about its dynamics, or from the mathematical unpredictability (or epistemic inaccessibility) of its known dynamics. In this perspective, contrarily to *Guala* [34.177], being a black box is not a specific feature of experiments.

Finally, when experimenting on a material or formal object, it is better that interactions with the object be made easy and the results be easily accessible to the experimenters (e.g., by means of visual interfaces) so that tinkering is made possible [34.136] and intuitions, familiarity, and possibly some form of understanding [34.159, 169, III] can be developed.

### 34.5.2 Common Basal Features

Some similarities of computer simulations and experiments (and thought experiments) may be accounted for by highlighting common basal features of these activities, which in turn account for the existence of their common epistemological features, such as the shared

concerns of practitioners of experiments and computer simulations for “error tracking, locality, replicability, and stability” [34.70, p. 142]. In this perspective, one should characterize the nature and status of these common basal features.

### Role or Functional Substitutability

Though computer simulations, thought experiments and experiments are activities of different types, they can sometimes be claimed to play identical roles. Typically, computer simulations are used to gain knowledge about how physical systems behave (hereafter *behavioral knowledge*) when experiments are unreliable, or making them is politically or ethically unacceptable [34.41, p. 107]. Importantly, acknowledging that computer simulations can sometimes be used as substitutes for experiments by no means implies that they can play *all the roles of experiments* (Sect. 34.5.4). Further, one should be aware that, at a high-level of abstraction, all activities may be described as doing similar things; therefore, these shared roles should be shown in addition to have nontrivial epistemological implications. For example, one may argue that *providing knowledge* or *producing data* are roles that are endorsed by computer simulations, thought experiments, or experiments. However, this may be seen as some partially sterile hand-waving. Indeed this points at a too abstract similarity if these activities produce items of knowledge of totally different types, and nothing epistemologically valuable can be inferred from this shared characterization (see [34.81] for a presentation of the different types of knowledge involved in science).

*El Skaf and Imbert* [34.87] make an additional step when they claim that these activities can in certain cases be *functionally substitutable*, that is, that we can sometimes use one instead of the other for the purpose of a common inquiry – which remains compatible with the fact that these activities do not play the roles in question in the same way, that they come with different epistemic credentials, provide different benefits, and therefore, as role holders, are not *epistemologically substitutable*. *El Skaf and Imbert*, in particular, claim that computer simulations, experiments, and thought experiments are sometimes used for the purpose of unfolding scenarios (see also *Hughes’* notion of demonstration in Sect. 34.6.1) and argue that investigations concerning the possibility of a physical Maxwellian demon were indeed pursued by experimental, computational and thought experimental means. The existence of such common roles then provides grounds for analyzing similarities in the epistemological structure of the corresponding inquiries.

*Morrison* [34.178] goes even further since she argues that some computer simulations are used *as mea-*

suring instruments and therefore that they have the same epistemic status as experimental measurements. She first claims that models can serve as measuring instruments, and then shows that this role can be fulfilled in connection with both computer simulations and experiments, which are similarly model shaped. An important part of her strategy is to relax the conditions for something to count as an experiment, by discretely giving primacy, in the definitions of scientific activities, to the roles which are played (here measuring) and by downplaying the importance of physical interactions with the investigated target systems in the definition of experiments (which are simply seen as *a way* to perform this measuring role). *Giere’s* rejoinder denies the acceptability of this strategy, and follows the empiricist tradition, when he claims that “a substitute for a measurement is not a measurement, which traditionally requires causal interaction with the target system” [34.179, p. 60]. Indeed, the potential additional pay-offs of experiments, as primary sources of radically new evidence, come from these causal interactions. Accordingly, their specificity is not due to their roles, qua information sources (since thought experiments, models, or theories are also information sources), but from the type of epistemological credentials that come with the corresponding information, and grounds our ultimate scientific beliefs. A different nonempiricist epistemology might be developed, but the bait must then be swallowed explicitly, and it must be explained why such an epistemology, in which activities are exclusively individuated on the basis of their function and the importance of other differences is downplayed, should be preferred. In any case, an account of how to individuate these functions would be needed, since at a high level of abstraction, various activities can be seen as performing the same function.

### Beyond Anthropocentric Empiricism

To practice science, humans need to collect observations and make inferences. Since human capacities are limited, various instruments have been developed to extend them and these instruments have been partly computational for decades. These parallel developments of observational and inferential capacities come with common epistemological features. In both cases, restricted empiricism, which gives a large and central role to *human* sensorial or inferential capacities in the description of how scientific activities are carried out, is no longer an appropriate paradigm to understand scientific practices. Indeed, the place of human capacities within modern science needs to be reconsidered [34.8, 41, 180]. Further, the externalization of observations and inferences comes at the price of some epistemic opacity and passivity for the practitioner, since, as humans, we

no longer consciously carry out these activities. Instead we simply state the results of experimental or computational apparatus. However, this also comes with gains in objectivity since observational and informational procedures are now carried out by external, transparent and controlled apparatus, which no longer have hidden psychological biases nor commit fallacies.

The development of computational instruments and computer simulations also raises similar epistemological problems. For example, the apparently innocuous notion of data seems to raise new issues in the context of computational science. Computer simulations, like models, have been claimed to be useful to *probe* physical systems and to be used as *measuring instruments* [34.178]. Whatever the interpretation of such statements (Sect. 34.5.3), it is a fact that both computer simulations and computational instruments provide us with *data*, which raises transversal questions.

A datum is simply the value of a variable. It can be taken to describe a property of any object. In this simple sense, data coming from experiments and computer simulations can play a similar role by standing for the properties of some target system within some representational inquiries. Furthermore, in both cases, their interpretation usually involves heavy computational treatments. In particular, mathematical transforms of various types serve to separate information from noise, remove artifacts, or recover information about a system property out of intertwined causal signals, like in computed tomography imaging techniques [34.121]. From this point of view, as emphasized by *Humphreys* [34.181], here one departs from a principle frequently used by traditional empiricists, and according to which “the closer we stay to the raw data, the more likely those data are to be reliable sources of evidence.”

At the same time, there are different types of epistemological data, and the need for their common study should not introduce confusion in their understanding. In science, one seeks to determine how much data reliably stand for their target, and which properties exactly they refer to. *Humphreys*’s remark above the computational treatment of data, reproduced above, highlights the fact that causal information concerning the source is crucial to treat and interpret data and to determine what empirical content they bring about this source (this is the *inverse inference problem*), given that data do not wear on their sleeves details of how they were produced. From this point of view, experimental and computational data have utterly different causal histories – so what gives its sense to the computational treatment is potentially of a different nature [34.91, 121]. Overall, more pointed comparative analyses of data obtained by computer simulations and computational instruments are still to be carried out, to understand their semantics

and epistemology and highlight both their nonaccidental similarities and specific differences (see [34.182] for the case of computational instruments).

Computational science must also face the challenge of data management. While the steps of *traditional* mathematical proofs and arguments, once produced, can be verified by scientists, things are usually different for computer solutions, even if they are merely executions of computational programs [34.91], or arguments [34.72]. Details of computer simulations are in general not stored since this would require too large amounts of memory (even if, in some cases like the Millennium Run, scientists may decide to keep track of the evolution of the computer simulation). In other words, like experimental science, computational science involves choosing which data to keep track of, developing powerful devices to store them, finding appropriate ways to organize them, providing efficient interfaces to visualize, search, and process them, and, more generally, developing new methods to produce knowledge from them. This also raises questions about how these data can or should be accessed by the scientific community, and which economic model is appropriate for them [34.183]. In brief, the epistemology of computer simulations here meets that of big data [34.184, 185], even if it cannot be assumed that on-going debates and analysis about the latter, because they are mostly focused on questions raised by empirically collected data, will naturally apply to, or be insightful for, the corresponding problems raised by computer simulations.

#### Different Activities, Similar Patterns of Reasoning

As noted by *Parker* [34.186], strategies developed to build confidence in experimental results, and described in particular by Allan Franklin, seem to have close analogs for the justification of results generated by computer simulations. Indeed, the interpretation of the results of computer simulations as evidence for hypotheses about physical systems can sometimes be made through an error-statistical perspective [34.187] as in the case of experiments [34.188].

Similar patterns of reasoning are also used to argue in favor of the existence of specific mechanisms or entities on the basis of patterns within data, modes of visualizations of these patterns, or our ability to manipulate the actual or represented systems and find pattern regularities in their behavior (see [34.71] for a description of the *homomorphic tradition*, in which visual forms are given much importance, in contrast to the *homologic tradition*, which is more based on logical relationships). More generally, visualization techniques, aimed to facilitate the reasoning about results present in

large databases, are crucial in the case of both experiments and computer simulations (Sect. 34.4.4).

Importantly, these similarities may have different explanations. For example, they may simply stem from the need to treat massive amount of data by efficient standard procedures, or be a consequence of features shared by experimental and computational data, independently of their quantity, like the presence of noise, or may correspond to the application of general types of evidential or explanatory arguments to data having different natures.

### The Reproducibility of Results

Reproducibility is a typical requirement for experiments, though it is one that is sometimes difficult to achieve because of the tacit knowledge involved in the carrying out of experiments [34.189]. Similar problems may arise with computer simulations. Even if the latter are nothing more than computations and are in principle reproducible, in practice reproducibility may sometimes be difficult, especially in the context of big science. For example, computer simulations may be too big to be reproduced (all the more since scientists have in general little incentive to reproduce results). Numerical codes may not be public (because they are not published or shared), and many of the computational details may be left tacit. Finally, computer simulations involving stochastic processes may not be exactly reproducible because the random numbers came from external physical signals or because the details of the pseudorandom number generator are not made public.

### Experimenters' and Simulationists' Regresses

Good scientific results are usually expected to be robust against various changes [34.190], in particular those related to implementation or material details, and this is why failure of exact reproducibility should not be a worry.

Still, when one faces an inability to reproduce a result, the problem may arise from a lack of robustness or flaw in the original experiment or computer simulation, or from a failure to reproduce it correctly. Accordingly, as emphasized by *Gelfert* [34.191], computer simulations are affected by a problem similar to that of the experimenter's regress [34.192], which is met when to determine whether an experimental apparatus is working properly scientists have no criterion other than the fact that it produces the expected results. As noted by *Godin* and *Gingras* [34.193], regresses like that highlighted by Collins are instances of well-known types of arguments already analyzed in the framework of ancient skepticism (more specifically, regresses or circular relations regarding justification). As such, they are specific neither to experiments nor to computer simulations –

even if solutions to these problems, as those described by *Godin* and *Gingras* or *Franklin* [34.194], may be partly activity specific. In any case, adopting a general comparative perspective provides a way to analyze more acutely what is epistemologically specific or common to scientific activities.

### 34.5.3 Are Computer Simulations Experiments?

Some authors go as far as claiming that, at least in *some* cases, what we call computer simulations *are* in fact experiments. In this perspective, Monte Carlo methods, sometimes labeled *Monte Carlo experiments* or *Monte Carlo simulations*, seem to be a philosophical test case (like analog simulations, Sect. 34.2.2). Such methods are used to compute numbers (e.g., pi), sample target distributions or produce dynamical trajectories with adequate average properties. They rely crucially on the use of randomness [34.8, 72]. They may look closer to experiments because they sometimes use physical systems, like a Geiger counter, to generate random events.

Still, *Beisbart* and *Norton* claim that Monte Carlo methods are not experiments, since randomizers can be replaced by computer codes of pseudorandomizers [34.72, p. 412]. This shows that these computer simulations do not require contact with the randomizer as an external object; therefore no direct empirical discovery about the nature of physical systems can be made by them and they should not be seen as having an experimental nature. In brief, in Monte Carlo simulations, the physical systems involved are simply used as computers to generate mathematically random sequences.

Beyond the analysis of specific cases, some authors have defended the bolder claim that all computer simulations are experiments (what *Winsberg* calls the *identity thesis* [34.195, §5]). While this goes against inherited scientific common sense (computations are not experiments!), the claim should be carefully examined. Indeed, in principle there is no impossibility here: while computations, logically defined, are not experiments, we need physical machines to carry them out. Therefore, in the end, computers, instruments and experimental systems are physical systems that we use for the purpose of doing science – and it all boils down to how we conceptualize in a coherent and fruitful way these external worldly activities. In brief, perhaps, after all, we would be better off revising our epistemological notions so that computer simulations are seen as genuine examples of experiments – a revisionary position with regard to the empiricist tradition since it ignores the specificity of experiments as primary evidential sources of knowledge.

In what follows, I review existing arguments in favor of the claim that computer simulations are experiments, and how these arguments have been criticized. Overall, as we shall see, in contrast to what is claimed in [34.195, §5], it is very dubious that discussions about the *identity thesis* are simply a matter of perspective and where the emphasis is placed. A minute, conceptually rigorous, and sharp treatment of this question can be found in [34.53, 72, 91, 196] and [34.169, Chap. 7].

### Problems with Analyses in Terms of Common Physical Structures

Some authors analyze computer simulations as manipulations of physical systems (the computers), which instantiate or realize models that are also instantiated or realized by the investigated physical systems.

*Norton and Suppe* [34.114] are good representatives of this tradition. They first try to describe formal relations between what they call a *lumped model*, the structure of the target system, and the programmed computer, which is supposed to embed the lumped model. They further argue that these relations account for the experiment-like character of computer simulations: instead of experimenting on real systems, computer simulations are used as physical stand-ins or analogs to probe real-world phenomena, and one thereby learns thing about the represented systems. This suggestive position has charmed various authors. It also has similarities with accounts of scientific representation made in terms of similarity [34.28], isomorphism, or weaker relationships between the representation and the target system [34.197, 198], even if the authors that defend the above view have not adopted so far this line of argument.

However, in the case of computer simulations, this view does not seem to resist close scrutiny, for reasons specific to computational activities. While in the case of analog simulations both the represented system and the analog computer instantiate a common mathematical structure (Sect. 34.2.2), such a claim cannot be made for digital computers. The general idea is that steps of computational processes are multiply realizable and that, conversely, how physical states of computers are to be interpreted is contextual and partly arbitrary [34.4]. It is true that for every step of a computation to be carried out in practice, one needs to use a physical machine that can be seen as instantiating the corresponding transition rule. However, physically different machines can be used to carry out different parts of a computation (for example when the computation is distributed). Furthermore, even if a single machine is used, different runs of the program will correspond to different physical processes, since the computer may process several tasks in the same time and contextually

decide how its memories are organized, and even within the same computation, a single part of the memory may be used at different steps to code for different physical variables [34.91, pp. 564–566], [34.196, pp. 81–84]. Overall, in the general case, the relation between the physical states of the represented target system and the physical states of the computer(s) that may be used to simulate its behavior is a many-many one, and the idea that the phenomenon is recreated in the machine “is fundamentally flawed for it contradicts basic principles of computer architecture” [34.196, p. 84]: in the case of a successful computer simulation, one can simply say that every step of the computation has been carried out by some appropriate physical mechanism, but there is no such thing as a computer instantiating the structure of the model investigated. (Note that the argument based on multiple realizability is in the spirit of those originally developed by *Fodor* [34.126] in his discussion of the reduction of the special sciences).

### Problems with Common Analyses in Terms of Intervention or Observation

Computer simulations have also been claimed to qualify as experiments “in which the system intervened on is a programmed digital computer” [34.199, p. 488], or to involve observations of the computer as a material system [34.114, p. 88]. *Winsberg* even goes as far as to claim that [34.195]

“nothing but a debate about nomenclature [...] would prevent us from saying that the epistemic target of a storm simulation is the computer, and that the storm is merely the epistemic motivation for studying the computer.”

Such claims can be answered along the same lines as the previous argument. There is of course no denying that when one runs a computer simulation one interacts with the interface of the computer, which triggers some physical change in the computer so that the right computation is carried out. Similarly, once the computation is finished, the physical state of the memory in which the result is stored, triggers a causal mechanism that produces changes in the interface so that the result can be read by the user. However, the definition of an intervention at the model level does not determine a specific intervention at the physical level of the computer. The reason is that, as emphasized above, even within the same computational process, the way that the intervened model variable is physically represented in the computer may vary, and how the computer, qua physical system, evolves precisely may depend on various parameters such as the other tasks that it carries out at the same time. In brief, the idea that actual com-

puter simulations, defined at the model level, could be seen as the investigation of the computer, qua physical machine, which is used to carry them out, seems to be riddled with insuperable difficulties.

Finally, one should mention that epistemic access to the physical states of the computer corresponding to the successive steps of a computation is usually not possible in practice [34.196, p. 81].

#### Problems with General Analyses in Terms of Epistemological and Representational Structure

Some authors have also argued that computer simulations and experiments share an epistemological structure, or epistemological aspects, and have used this claim to justify the identity thesis.

For example, it has been claimed that in both cases one interacts with a system to gain knowledge about a target system, and the internal and external validity of the processes needs to be checked. This type of analysis stems from a 2002 paper by *Guala* [34.177] in which he presents a laboratory experiment in economics aimed at investigating behavioral decision making by giving decisional tasks to real human subjects in the laboratory. In this case, a hypothesis about how agents behave in the laboratory is investigated (internal validity hypotheses); then, based on similarities between the experimental situation and the real-life situation, an external hypothesis is made about the behavior of agents in real life situations (external validity hypothesis). The notion of internal validity comes from social science and corresponds to the (approximate) truth of inferences about causal relationships regarding the system that is experimented on. External validity corresponds to the (approximate) truth of the generalization of causal inferences from an initial system, for which internal validity has been demonstrated, to a larger class of systems. *Guala* further claims that both computer simulations and experiments fit this epistemological description in terms of internal and external validity arguments, but cautiously concludes that their “difference must lie elsewhere” [34.177]. According to him, computer simulations and experiments are different, since in the latter case there is a material similarity between the object and the target, whereas, in the former case, there is a formal similarity between the simulating and the simulated systems (a claim which seems to be falling under the above criticism directed at Norton and Suppe and their followers).

*Guala*’s conceptual description is endorsed by most authors who try to picture computer simulations as some sort of experiment. For example, *Winsberg* accepts the description, but claims that the difference between experiments and computer simulations lies

in the type of background knowledge that researchers use to justify the external validity hypothesis [34.113, p. 587], a position which is again revisionary with regard to the empiricist tradition if this is the only specificity ascribed to experiments.

A serious worry is that describing the investigation of the computational model in terms of internal validity is problematic and artificial, since, as can be seen above, computer simulations cannot be considered as investigations of the causal behavior of the computer, qua physical system. For the same reason, the use of the notion of external validity is inappropriate, since for computer simulations inferences about the target system do not involve the generalization of causal relations taking place in the computer to other systems by comparing their material properties but involve the *representational* validity of the computational model.

A final problem is that the characterization of the methodology of experimental studies in terms of internal and external validity, though useful in the social sciences, is not a general one. Using it as an accepted general framework to compare experiments and computer simulations looks like a hasty extrapolation of the case of laboratory experiments in experimental economics, not to mention the fact that economics may be seen as a bold pick to build a general conceptual framework for experimental studies.

It is true that in experiments, the measured properties are often not the ones that we are primarily interested in and the former are used as evidence about these latter target properties. Typically, vorticity in turbulent flows is difficult to measure directly, and is often assessed by measuring velocity, based on imaging techniques. In more complex cases, the properties measured can be seen as a way to *observe* different and potentially remote target systems, as is vividly analyzed by *Shapere* with his case study of the observation of the core of the sun by the counting of  $^{37}\text{Ar}$  atoms in a tank within a mine on Earth [34.180]. Importantly, in all such cases, the measuring apparatus, the directly measured property, and the indirectly probed target system are related by causal processes. The uses of the collected empirical information then vary with the type of inquiry pursued. The evidence may be informational about the physics of a particular system, like the Sun. Or, it may be used to confirm or falsify theories (like in the case of the 1919 experiment by Eddington and the relativity theory). In some cases, *though by no means all*, it may be used to draw inferences about the nature or behavior of a larger class of similar systems – which are not related to the measured system by a causal relationships. If this latter case of reasoning about external validity is taken as paradigmatic for experiments, and the causal processes between the target experimented

systems (the source) and the measuring apparatus (the receptors), which are present in all experiments, are considered as a secondary feature, experimental activities are misrepresented. As Peschard nicely puts it “the idea that the experiments conducted in the laboratory are aimed at understanding some system that is outside the laboratory is a source of confusion” [34.200]. General conceptual frameworks that do not introduce such confusion are however possible. For example, *Peschard* proposes [34.200]

“to make a distinction between the *target system*, that is manipulated in the experiment or represented in the computer simulation, and the *epistemic motivation*, which in both cases may be different from the target system ”

(see also the distinction between the result of the unfolding of a scenario and the final result of the inquiry in [34.87]).

Overall, the common description provided by Guala, and heavily relied upon in [34.113, 199] to support versions of the *identity thesis* can be defended only by squeezing experiments and computer simulations into a straightjacket which misrepresents these activities, is not specifically fruitful, and meets insuperable difficulties.

#### Materiality Matters

Clearly, for both experiments and computer simulations, materiality is crucial. However, it does matter differently, and one does not need to endorse a version of the identity thesis to acknowledge the importance of materiality when claiming for example that, to understand computational science, the emphasis should be on computer simulations which can be in practice, and therefore materially, carried out by actual systems [34.41, 91].

For experiments, material details are relevant throughout the whole inquiry when producing, discussing and interpreting results, their validity and their scope (especially if one tries to extrapolate from the investigated system to a larger class of materially similar ones). By contrast, for computer simulations, material details are important to establish the reliability of the computation, but not beyond: only the mathematical and physical details of the investigation matter when discussing and interpreting the results of the computer simulation and the reliability of the inquiry.

#### 34.5.4 Knowledge Production, Superiority Claims, and Empiricism

The question of the epistemic superiority of experiments over simulations has also been discussed. *Parke*

[34.201] takes it for granted that “experiments are commonly thought to have epistemic privilege over simulations” and claims that this is in fact a context-sensitive issue. As we shall see, if one puts aside the question of the specific role of experiments as the source of primary evidence about nature, it is not clear whether the general version of the superiority claim has actually been defended, or whether a straw man is attacked.

#### Computer Simulations, Experiments and the Production of Radically New Evidence

Let us try to specify what the general superiority claim could be and how it has really been defended.

The obvious sense in which experiments may be *superior* is that they can provide scientists with primary evidence about physical systems, which originate in interactions with these systems, and cannot be the product of our present theoretical beliefs. It is unlikely that computer simulation can endorse this role. As *Simon* pithily puts it, “a simulation is no better than the assumptions built into it, and a computer can do only what it is programmed to do” [34.12, p. 14]. From this perspective, experiments have the potential to surprise us in a unique way, in the sense that they can provide results contradictory to our most entrenched theories, whereas a computer simulation cannot be more fertile than the scientific model used to build it (even if computer simulations can surprise us and bring about novel results, see Sect. 34.3.4). This is what *Morgan* seems to have in mind when she emphasizes that “[N]ew behaviour patterns, ones that surprise and at first confound the profession, are only possible if experimental subjects are given the freedom to behave other than expected,” whereas “however unexpected the model outcomes, they can be traced back to, and re-explained in terms of, the model” [34.202, pp. 324–5]. In brief, experiments are superior in the sense that, in the empirical sciences, they can serve a function which computer simulations cannot.

*Roush* [34.203] has highlighted another aspect regarding which experiments can be superior to simulations. She first insists that we should compare the two methods *other things being equal*, especially in terms of what is known about the target situation. Then, in any case in which there are elements in the experimenter’s study system that affect the results and are unknown, we may still run the experiment and learn how the target system behaves; by contrast, in the same epistemic situation, the simulationist cannot build a reliable computer simulation that yields the same knowledge. However, when all the physical elements that affect the result are known, a simulation may be as good as an experiment, and it is a practical issue to determine which one can in practice be carried out in the most reliable way.

Thus, for a quantitative comparison to be meaningful it should be related to roles which can be shared by experiments and computer simulations, such as the production of *behavioral* knowledge about physical systems, the relevant dynamics of which is known (Sect. 34.5.2).

### Grounds for Comparative Claims

Scientists and philosophers have emphasized over the last decades that computer simulations are often *mere simulations* [34.177], the results of which should be taken carefully. As seen above, economists *shun* simulation; similarly, *Peck* states that evolutionary biologists view simulations with suspicion and even contempt [34.204, p. 530]. Nevertheless, however well advised these judgments may be, they cannot by themselves support a *general* and *comparative* claim of superiority in favor of other methods, but at most the claim that, in fields where other methods are successful and computer simulations have little epistemic warrants or face serious problems, these other methods will usually or on average be more reliable (exceptions remaining possible).

Some authors have discussed the comparative claim by analyzing the power of the types of inferences made to justify knowledge claims in each case. In [34.199], *Parker* adopts *Guala*'s description of experiments (resp. computer simulations) as having material (resp. formal) similarities with their target systems (see the discussion in Sect. 34.5.3) and studies the claim that inferences made on the basis of material similarities would have an epistemic privilege. (*Guala* does not seem to endorse a comparative claim. He argues that material similarities are a specific feature of experiments, implying that the prior knowledge needed to develop simulations is different from that needed to develop experiments.) Again, the common description in terms of internal and external validity regarding the inferences from one physical system to another gives the semblance of a new problem. However, if, as suggested above, the material properties of computers matter only in so far as they enable scientists to make logically sound computations, and no similarity between systems is involved, the grounds and rationale for this discussion between the properties of the computer and those of the target system collapse. A way to save the argument is to claim that the aforementioned formal similarities are simply those between the computational model and the target system, but then the question boils down to the much more familiar comparison between model-based knowledge (here extracted by computational means) and some type of experiment-based knowledge.

On what grounds could the general privilege of experiment-based behavioral knowledge then be de-

fended? Since experiments and computer simulations are different activities, which are faced with specific difficulties, it is hard to see why computer simulations should always fare worse. Why could simulations based on reliable models not sometimes provide more reliable information than hazardous experiments? Indeed, it is commonly agreed that, when experiments cannot be carried out, are unreliable, or ethically unacceptable, computer simulations may be a preferable way to gain information [34.41, p. 107].

### Justified Contextual Superiority Claims

Interestingly, superiority claims can sometimes be made in specific contexts. *Morgan* presents cases in economics in which a precise and contextual version of the superiority claim may be legitimate [34.202].

Like *Guala*, *Morgan* discusses laboratory experiments in economics, that is, purified, controlled, and constrained versions of real world systems, which are studied in artificial laboratory environments (in contrast with field experiments, which “follow economic behavior *in the wild*” [34.202, p. 325]) and are aimed at investigating what is or would be the case in actual (nonsimplified) economic situations. Mathematical models can also be used for such inquiries and, in each case, scientists run the risk of describing artificial behaviors. *Morgan* then makes the following contextual claim that “any comparison with the model experiment is still very much to the real experiment’s advantage *here*” [34.202, p. 321] (my emphasis) on the grounds that, in this case, the problem of making ampliative analog inferences from laboratory system to real-world systems is nothing compared with the problem of the realism of assumptions for models exploring artificial models [34.202, pp. 321–322]. She does not justify this point further, but a plausible interpretation is that, in such cases, mathematical models necessarily abstract away essential parts of the dynamics of decision making, which arguably are preserved in experiments because of the material similarity between the laboratory and real agents. In brief, while material similarity plays a role in her argument she does not make the general claim in the core of her paper that material similarity will *always* provide more reliable grounds for external validity claims than other methods (even if her formulation is less cautious in her conclusion).

Overall, such sound contextual comparative judgments require two premises: first that in some context computer simulations are not reliable (or have reliability  $r$ ) and second that in the same context material similarities provide reasonably reliable inferences (or have reliability  $s > r$ ). (Indeed, analogical reasoning based on material similarities, in which one reasons based on systems that are representative of or for larger

classes of systems [34.127], can sometimes be powerful ways to make sound – though not infallible! – contextual inferences. As emphasized by *Harré* and *Morgan*, “shared ontology [...] has epistemological implications” [34.202, p. 323], since “the apparatus is a version of the naturally occurring phenomenon and the material setup in which it occurs” [34.205, pp. 27–8]. After all, different samples of the same substance obey the same laws, even if contextual influences may change how they behave and any extrapolation is not possible.)

### 34.5.5 The Epistemological Challenge of Hybrid Methods

Whether computer simulations and experiments are ontologically, conceptually, and epistemologically distinct activities or not, it is a fact that jointly experimental and computational *mixed* activities have been developed by scientists. Their study was pioneered by *Morgan*, who presents various types of hybrid cases in economics [34.206] and biomechanics [34.127]. For example, she reports different mixed studies aimed at investigating the strength of bones and carried out by cutting slices of bone samples, photographing them, creating digital 3-D images, and applying the laws of mechanics to these experiment-based representations. *Morgan* further attempts to provide a principled typology of these activities. This proves difficult because “modern science is busy multiplying the number of hybrids on our epistemological map” and because the qualities of hy-

brids “run along several dimensions” [34.127, p. 233]. Overall, sciences illustrate “how difficult it is to cut cleanly, in any practical way, between the philosopher’s categories of theory, experiment and evidence” [34.127, p. 232], and, we may add, computer simulations or thought experiments.

Should these hybrid methods lead philosophers to reconsider the conceptual frontiers between experiments and computer simulations? We can first note that their existence may be seen as a confirmation that the traditional picture of science, in which theoretical, representational or inferential methods on one hand and experimental activities on the other play completely different but complementary roles, is not satisfactory (Sect. 34.5.2). Then, if one grants that activities like experiments, thought experiments and computer simulations can sometimes play identical roles, it is no surprise that they can also be jointly used to fulfill them. Similarly, a group of four online players of queen of spades sometimes involve virtual players – but most people will be reluctant to see this as sufficient grounds for claiming that bots are human creatures.

In any case, these hybrid activities raise epistemological questions. What, if anything, distinguishes a computer simulation that makes heavy use of empirical data from a measurement involving the computational refinement of such data [34.53, 121]? How much should the results of these methods be considered as empirical? Overall, what type of knowledge and data is thereby generated (see [34.53] for incipient answers)?

## 34.6 The Definition of Computational Models and Simulations

The main definitions of computer simulations are critically presented: Humphreys’s 1994 definition in terms of computer-implemented methods, Hartmann’s 1996 definition in terms of imitation of one process by another process, Hughes’s DDI (denotation, demonstration, interpretation) account of theoretical representation, and finally Humphreys’s 2004 definition, with its emphasis on the notion of a computational template (Sect. 34.6.1). The questions that a satisfactory definition should answer are then discussed, in particular which notions should be primitive in the definition, whether computer simulations should be defined as logical or physical entities, whether they correspond to success terms, how the definition should accommodate the possibility of scientific failure and the pursuit of partly open inquiries, or to what extent computer simulations are social, intentional, or natural entities (Sect. 34.6.2).

I come back finally to the issue of the definition of computer simulations. Providing a definition may look at first sight to be easy, since what computers are is well-known and clear cases of computer simulations are well identified. However, a sound definition should also be helpful to analyze less straightforward cases and be fruitful regarding epistemological issues related to computer simulations, not least by forcing philosophers to clarify the various intuitions which are entertained across scientific fields about these methods.

It is not difficult to present definitions that accommodate *some* types of computer simulations or *some* particular (or field specific) uses of computer simulations. Nevertheless, failing to distinguish between what is typical of computer simulations in general and what is specific to particular cases can lead (and has led) to heedless generalizations (Sect. 34.5.3). Things are all the more tricky as the very same types of computer

simulations, qua formal tools (e.g., agent-based, CA models, equation-based simulations, etc.) can be used in different epistemic contexts for different purposes, and require totally different epistemological analyses. The case of CA-based computer simulations exemplifies the risk of too quick *essentialist* characterizations. While it was believed that these models were appropriate for phenomenological simulations only [34.9, 135], their use in fluid dynamics has shown that they could supply theoretical models based on the same underlying physics as traditional methods [34.100].

The following section is organized as follows. Existing definitions and the problems they raise are presented first, and then issues that a good definition of computer simulations should clarify are emphasized.

### 34.6.1 Existing Definitions of Simulations

#### Computer-Implemented Methods

As emphasized by Humphreys, a crucial feature of simulations is that they enable scientists to go beyond what is possible for humans to do with their native inferential abilities and pen-and-paper methods. Accordingly, he offered in 1991 the following working definition [34.7]:

“A computer simulation is any computer-implemented method for exploring the properties of mathematical models where analytic methods are unavailable.”

This definition requires that we possess a clear definition of what counts as an analytic method, which is not a straightforward issue [34.60]. Further, as noted by Hartmann et al. [34.10, pp. 83–84], it is possible to simulate processes for which available models are analytically solvable. Finally, as acknowledged by Humphreys, the definition covers areas of computer-assisted science that one may be reluctant to call computer simulations. Indeed, this distinction does sometimes matter in scientific practice. Typically, economists are not reluctant to use computers to analyze models but shun computer simulations [34.37]. Since both computational methods and computer simulations involve computational processes, their difference must be either in the different types (or uses) of computations involved either at the mathematical and/or the representational level.

#### One Process Imitating Another Process

Hartmann proposes the following characterization, which gives the primacy to the representation of the temporal evolution of systems [34.10, p. 83]:

“A model is called *dynamic*, if it [...] includes assumptions about the time-evolution of the system.

[...] Simulations are closely related to dynamic models. More concretely, a simulation results when the equations of the underlying dynamic model are solved. This model is designed to imitate the time-evolution of a real system. To put it another way, a simulation imitates one process by another process. In this definition, the term process refers solely to some object or system whose state changes in time. If the simulation is run on a computer, it is called a computer simulation.”

This definition has been criticized along the following lines. First, as noted by Hughes [34.13, p. 130], the definition rules out computer simulations that do not represent the time evolution of systems, whereas arguably one can simulate how the properties of models or systems vary in their phase space with other parameters, such as temperature. Accordingly, a justification for the privilege granted to the representation of temporal trajectories should be found, or the definition should be refined, for example, by saying that computer simulations represent successive aspects or states of a well-defined trajectory of a system *along a physical variable* through its state space. Second, the idea that a specific trajectory is meant to be represented may also have to be abandoned. For example, in Monte Carlo simulations, we learn something about *average values* of quantities along sets of target trajectories by generating a potential representative of these trajectories, but the computer simulations are not aimed at representing any trajectory in particular. One may also want a computer simulation to be simply informative about structural aspects of a system. Overall, the temporal dynamics of the simulating computer is a crucial aspect of computer simulations since it “enables us to draw conclusions about the behavior of the model” [34.13, p. 130] by unfolding these conclusions in the temporal dimension of our world, but the temporal dynamics of the target system may not have to be represented for something to count as a computer simulation.

Third, the definition is probably too centered on models and their solutions [34.207], since it equates computer simulations with the solving of a dynamic model that represents the target system. This is tantamount to ignoring the fact that describing computer simulations as mathematical solutions of dynamic models is not completely satisfactory. What is being solved is a computational model (as in Humphreys’s definition [34.41], see below), which can be significantly different from, and somewhat independent of, the initial dynamic model of the system, which usually derives from existing theories. Effectively, different layers of models, often justified empirically, can be needed in-between [34.13, 97, 208]. For this reason, the repre-

sentational relation between the initial dynamic model and the target system, and between the computational system and the target system, are epistemologically distinct.

Finally, the definition may be reproached for entertaining a recurrent confusion about the role of materiality in computer simulations (Sect. 34.5.3), by describing the representational relation as being between two physical processes, and not between the computational model and succession of mathematical states which unfold it (*in whatever way they are physically implemented and computed*) and the target system.

### Computer Simulations as Demonstrations

*Hughes* does not propose a specific definition of computer simulations since he believes that computer simulations naturally fit in the DDI account of scientific representation that he otherwise defends [34.13, p. 132]. According to the DDI, which involves denotation, demonstration, and interpretation as components [34.13, p. 125]:

“Elements of the subject of the model (a physical system evincing a particular kind of behavior, like ferromagnetism) are *denoted* by elements of the model; the internal dynamic of the model then allows conclusions (answers to specific questions) to be *demonstrated* within the model; these conclusions can then be *interpreted* in terms of the subject of the model.”

The demonstration can be carried out by a physical model (in the case of analog simulations) or by a logical or mathematical deduction, such as a traditional mathematical proof, or a computer simulation. Further, according to *Hughes*, in contrast to Hartmann’s account, “the DDI account allows for more than one layer of representation” [34.209, p. 79]. Overall, a virtue of this account is that it emphasizes the common epistemological structures of different activities by pointing at a similar demonstrative step, which excavates the epistemic content and resources of the model (see also [34.210] for refinements, [34.87] for an analysis which extends the idea of demonstration, or *unfolding*, to thought experiments and some types of experiments, and [34.72] for the related idea that computer simulations are arguments). While as a definition of computer simulation, *Hughes*’s sketchy proposal has somewhat been neglected (see however [34.208]) it is a legitimate contender and it remains to be seen how much a more developed version of it would provide a fruitful framework for philosophical discussions about computer simulations.

### Computer Simulations as the Concrete Production of Solutions to Computational Models

In order to answer problems with the previous definitions, *Humphreys* proposed in 2004 another definition of computer simulations, which is built along the following lines [34.41]. He defines the notion of a theoretical template, which is implicitly defined as a general relation between quantities characterizing a physical system, like Newton’s second law, Schrödinger’s equation, or Maxwell’s equations. A theoretical template can be made less general by specifying some of its variables. When the result is *computationally tractable*, we end up with a computational template. (Thus, what qualifies as a computational template seems to depend on our computational capacities at a given time.) When a computational template is given (among other things) an interpretation, construction assumptions, and an initial justification, it becomes a computational model. Finally, *Humphreys* offers the following characterization [34.41, pp. 110–111]:

“System S provides a core simulation of an object or process B just in case S is a concrete computational device that produces, via a temporal process, solutions to a computational model [...] that correctly represents B, either dynamically or statically. If in addition the computational model used by S correctly represents the structure of the real system R, then S provides a core simulation of system R with respect to B.”

Another important distinction lies between the computer simulation of the behavior of a system and that of its dynamics [34.41, p. 111] since, even when the computational model initially represents the structure and dynamics of the system, the way its solutions are computed may not follow the corresponding causal processes. Indeed, in a computer simulation, the purpose is not that the computational procedure exactly mimics the causal processes, but that it efficiently yields the target information from which an appropriate dynamic representation of the target causal processes can finally be built for the user. For reasons of computational efficiency, the representation may be temporally and spatially dismembered at the computational level (e.g., by computing the successive states in a different order), as may happen with the use of parallel processing, or of any procedure aimed at partially short cutting the actual physical dynamics.

The space here is insufficient to analyze all the aspects of the above definition and to do justice to their justification – all the more so since further complications may be required to accommodate even more

complex cases [34.208]. Suffice it to say that this elaborate definition, which is aimed at providing a synthetic answer to the problems raised by previous definitions, is one of the most regularly referred to in the literature.

### 34.6.2 Pending Issues

#### Simulating or Computing

Giving a definition of computer simulations implies choosing which notions should be regarded as primitive and how to order them logically. Some authors first define the notion of simulation and present computer simulations as a specific type of simulations. For example, *Bunge* first defines the notion of analogy, then that of simulation, and finally that of representation, as sub-relation of simulation. For him, an object  $x$  simulates another object  $y$  when (among other things) (1) there is a suitable analogy between  $x$  and  $y$  and (2) the analogy is valuable to  $x$ , or to another party  $z$  that controls  $x$  (see [34.11, p. 20] for more details).

A potential benefit of this strategy is that it becomes possible to unify in the same general framework various different types of analogous relations between systems such as organism versus society, organism versus automaton, scale ship versus its model, computer simulations of both molecular and biological evolution, etc. Similarly, *Winsberg* [34.195, §1.3] suggests that the hydraulic dynamic scale model of the San Francisco Bay model should be viewed as a case of simulation (see [34.211] for a recent presentation and philosophical discussion of this example in the context of modeling). While scale models can obey the same dimensionless equations as their target systems and be used to provide analog simulations of them, *Winsberg's* claim is not uncontroversial and may require an extension of the notion of simulation. Indeed the model and the Bay itself do not exactly obey the same mathematical equations. For example, distortions between the vertical and horizontal scales in the model increase the hydraulic efficiency, which implies adding copper strips and the need for empirical calibration. Therefore, this is not exactly a case of a bona fide analog simulation (Sect. 34.2.2) but of a complex dynamical representation between closely analogous systems. In any case, if one adopts such positions, it is then a small step to describe other cases of analogical reasoning between material systems (and possibly cases of experimental economics, in which the dynamics of the analogous target system is not precisely known and external validity is to be assessed by comparing the material systems involved) as cases of simulations (Sect. 34.5.3).

At the same time, unification is welcome only if it is really fruitful (and is, of course, not misleading). As seen above, the problem with such analyses is that

they tend to describe computer simulations as involving a representational relationship between two material systems and to misconstrue how computers work (see again Sect. 34.5.3). They thereby tend to misrepresent the epistemological role of the physical properties of computers and the fact that computational science involves two distinct steps; one in which computer scientists warrant that the computer is reliable and another in which scientists use computations and do not need to know anything about computers qua physical systems. A way out of this deadlock may be to use a flexible notion of simulation, which can be applied to relations between physical *or* logical–mathematical simulating processes and the target simulated physical processes. Then, the question remains as to what exactly is gained (and lost) from an epistemological point of view by putting in the same category modes of reasoning of such different types – if one puts aside the emphasis on the obvious similarities with analog simulations, which are a *very specific* type of computer simulation (Sect. 34.2.2). Overall, it is currently far from clear whether this unificatory move should be philosophically praised.

#### Abstract Entities or Physical Processes

Arguably, computations are logical entities that can be carried out by physical computers. Then, the question arises should computer simulations also be seen as abstract logical entities, or should they be seen as material processes instantiating abstract computations? *Hartmann's* definitions present computer simulations as processes, whereas *Humphreys's* definition is more careful in the sense that the computing systems simply *produce* the solution or *provide* the computer simulation. Clearly, to analyze computational science, it is paramount to take into account material and practical constraints since a computer simulation is not really a part of *our* science and we have no access to its content unless a material system *carries* it out for us. At the same time, just like the identity of a text is not at the material level, the identity of a computing simulation (and the corresponding equivalence relationship between runs of the same computer simulation) is defined at the logical (if not the mathematical) level and the physical computer simply presents a token of the computer simulation. From this point of view, the material existence of computer simulations and the in principle/in practice distinction emphasized by *Humphreys* [34.41] have epistemological, not ontological, significance, that is, they pertain to what we may learn by interacting with actual tokens of computer simulations [34.91, p. 573] but not to the nature of computer simulations. Similarly the identity of a proof seems to be at the logical level, even if a proof has no existence

nor use for us unless some mathematician provides some token of it.

### Success, Failure, and the Definition of Computer Simulations

A computer simulation is something that reproduces the behavior or dynamics of a target system. The problem with characterizations of this type is that they make computer simulation a success term and if a computer simulation mis-reproduces the target behavior, it is no longer a computer simulation. This problem is a general one for representations, but is specifically acute for scientific representations (*Frigg* and *Nguyen* Chap. 3, this volume). Indeed, while anything in art can be used to represent anything else, scientific representations are meant to be informative about the natural systems they represent. This is part of their essential specificities and, arguably, a definition according to which any process could be described as a scientific computer simulation of any other process is not satisfactory. At the same time, one does not want something to be a computer simulation, or a scientific representation, based on whether it is scientifically successful and exactly mirrors its target (remember that, for some scientific inquiries, representational faithfulness is not a goal and may even impede the success of the investigation [34.212] and [34.23, Chaps. 1 and 3]).

An option is to say that something is a scientific representation if it correctly depicts what its user wants it to represent. However, this may raise a problem for computer simulations that were carried out and had subsequent nonintended uses, like the millennium simulation. It may also raise a problem for fictions, which strictly speaking seem to represent nothing [34.25, p. 770].

Finally, failed representations, which do not represent what their producers believe them to depict, are also a problem. Representational inquiries can fail in many ways, and failures are present on a daily basis in scientific activity, from theories and experiments to models and simulations. For this reason, descriptions of scientific activities should be compatible with failure, especially if they are to account for scientific progress and the development of more successful inquiries. Indeed, it would be weird to claim that many of the computer simulations that scientists perform and publish about are actually not computer simulations. Further, whether a genuine computer simulation is carried out should be in general transparent to the practitioner, and this cannot be the case if computer simulation is defined as a success term and scientific failure is frequent (see also [34.213, pp. 57–58]).

Overall, a question is to determine where the frontier should lie between unsuccessful or failed computer

simulations, and potential cases in which something that was believed to be a computer simulation by scientists actually is not. This in turn requires knowing how computer simulations can fail specifically [34.92] and which failures are specific to them. In brief, one needs to be able to decide on a justified basis which failures disqualify something from being a computer simulation and which ones simply alter its scientific, epistemic, or semantic value. This analysis may also have to be coherent with analyses about how other types of scientific activities such as experiments and thought experiments can fail [34.214], especially when these activities play similar or identical roles.

An option to consider is that something is a computer simulation based on criteria that do not involve empirical success, and that it qualifies as an empirical success depending on additional semantic properties and on whether it correctly represents the relevant aspects of its (real or fictional) target system(s). This option is potentially encompassing enough (the scientifically short-sighted student can be said to perform a computer simulation), but discriminating between good and bad computer simulations is still possible. It is compatible with the fact that research inquiries are often open and scientists need not know in advance what in their results will have representational value in the end. Finally, it is also compatible with a different treatment of representational and implementation failures. Indeed, the possibility of being unsuccessful at the representational level is consubstantial to empirical inquiries and is in this sense *normal*. By contrast, an implementation failure is simply something that should be fixed. It corresponds to a case in which we did not manage to carry out the intended computation, whereas computing is not supposed to be a scientific obstacle, and we learn nothing by fixing the failure.

### Natural, Intentional, or Social Entities?

A similar but distinct issue is to determine which type of objects computer simulations are, *qua token physical processes carried out by computing devices* – a question which is close to that of the nature of physical computers and is also related to that of the ontology of model (*Gelfert* Chap. 1, this volume).

Arguably, they are not simply natural objects which are defined by some set of physical properties and exist independently of the existence of the agents using them. Indeed, because computations can be multirealized and some runs of computations built by patching different bits of computation on physically different machines, it is unlikely that all computations can be described in terms of natural kind predicates (massively disjunctive descriptions not being allowed here) [34.126].

Further, for both computations and computer simulations, pragmatic conditions of use seem to matter. To quote *Guala* commenting on the *anthropomorphism* of Bunge's definition (see above), [34.177, p. 61]

“it makes no sense to say that a natural geyser *simulates* a volcano, as no one controls the simulating process and the process itself is not useful to anyone in particular.”

Indeed, even if any physical system can be seen as computing some (potentially trivial) functions (see below), any physical object cannot be *used* as a (general) computer, and we may have to endorse a position along the lines of Searle's notion of social objects [34.215], or of any analysis doing the same work: a physical object X counts as Y in virtue of certain cognitive acts or states out of which they acquire certain sorts of functions (here computing), given that these objects need to demonstrate appropriate physical properties so that they may serve these functions for us. A specificity of computer simulations is that, unlike entrenched social objects, such as cars or wedding rings, a small group of users may actually be enough for a physical system to be seen as carrying out a computer simulation. Thus, the evolution of a physical system (like a fluid) may count for some users as an analog computer, which performs a computer simulation, and for other users as an experiment, even if experiments and computer simulations are in general objects of different types, and this case is unlikely to be met in practice (Sect. 34.5.3).

In any case, what is needed for something to be used as a computer or a computer simulation is not completely clear. The physical process must clearly be recognized as instantiating a computer model. Control is useful but not necessarily mandatory (e.g., we may use the geyser to simulate a similar physical system, even if the geyser would not count as a controlled *versatile* analog computer). The possibility to extract the computed information is clearly useful – an issue that matters for discussions about analog and quantum computer simulations, and of course cryptography.

An alternative position is not to mention users in the definition and to claim that, pace the peculiar case of man-made computations (which may make use heavily of the possibility offered by multiple realizability, see Sect. 34.5.3), physical processes are the one-piece physical instantiations of running computer models (resp. computer simulations) and, as such, are computations (even if, sometimes, trivial ones). See [34.216] for a sober assessment of this pancomputationalist position. In this perspective, one may say that it is a practical problem to create artificial human-friendly computers which can *in addition* be controlled and the informa-

tion of which can be extracted. While such positions may be palatable for those, like *Konrad Zuse*, *Edward Fredkin* and their followers [34.64, 217, 218], who want to see nature as a computer, it is not clear that such pan-computationalist theses, whatever their intrinsic merits for discussing foundational issues like the computational power of nature or which types of computers are physically possible, serve the purpose of understanding science as it is actually practiced.

An important distinct question is whether intentional or pragmatic analyses should also be endorsed regarding computational models and computer simulations, *qua representational mathematical entities*, that is, how much the intentions of users and conditions detailing how their use by scientists is possible, should be part and parcel of their definitions. Arguably, a scientific model is not simply a piece of syntax or an entity which inherently and by itself represents, completely or partially, a target system in virtue of the mathematical similarities it intrinsically possesses with this system. In order to understand how scientific representations and computer simulations work and actually play their scientific role, their description may have to include captions, legends, argumentative contexts, intentions of users, etc., since these elements are part of what makes them scientifically meaningful units. Indeed, how one and the same mathematical model represents significantly varies depending on the inquiry, subject matter and knowledge of the modelers. This is particularly clear in the case of computational templates, which are used across fields of research for different representational and epistemological purposes [34.41, §3.7], and which are scientific units at the level of which different types of theoretical and conceptual exchanges take place within and across disciplines [34.45]. Overall, this issue is not specific to computer simulations but can be raised for other scientific representations [34.23, 168, 219–221]. Thus, this point shall not be developed further.

### Computer Simulations and Computational Inquiries

How should computer simulations be delineated? Computer simulations do not wear on their sleeves how they were built, contribute to scientific inquiries, should be interpreted and how their results should be analyzed. Accordingly, authors like Frigg and Reiss distinguish between computer simulations in the narrow sense (corresponding to the use of the computer), and in the broad sense (corresponding to the “entire process of constructing, using and justifying a model that involves analytically intractable mathematics” [34.30, p. 596]). See also the distinction between the unfolding

of a scenario and the computational inquiry involving this unfolding at its core [34.87], or the description of how the demonstration activity is encapsulated in other activities in the DDI account of representation [34.13].

Whatever the choice which is made, there is tension here. As underlined above, an analysis of the identity of scientific representations cannot rest on the logical and mathematical properties of scientific models and their similarities with their physical targets, and indications about how these representations are to be interpreted cannot be discarded as irrelevant to the analysis of their nature and uses. At the same time, computer simulation, qua computational process, and the arguments that are developed by humans about it, are activities of different natures and play different roles. Therefore an encompassing definition should not lead to blur the specificities of the different components of computational inquiries (just like a good account of thought experiments should not blur that they crucially involve mental activities at their core and are part of inquiries also involving scientific arguments).

### 34.6.3 When Epistemology Cross-Cuts Ontology

Whatever the exact definition of computer simulations, it is clear that they are of a computational nature, involve representations of their target systems and that their dynamics is aimed at investigating the content of these representations.

Importantly, whereas the investigation of scientific representations is traditionally associated with the production of theoretical knowledge, the nature of com-

puter simulations does not seem to determine the type of knowledge they produce.

Clearly, computer simulations can yield theoretical knowledge when they are used to investigate theoretical models. At the same time, even if computer simulations are not experiments (Sect. 34.5.3), they produce knowledge, which may qualify as empirical in different and important senses. As we have seen, computer simulations provide information about natural systems, the validity of which may be justified by empirical credentials rooted in interactions with physical systems for aspects as various as the origin of their inputs, the flesh of their representations of systems (see in Sect. 34.5.5 the examples by Morgan about the studies of the strength of bones), the calibration or choice of their parameters, or their global validation by comparison with experiments (Sect. 34.3.2). However, information about the dynamics represented cannot completely be of empirical origin, since it involves the description of general relations between physical states, and general relations cannot be observed.

From this point of view, computer simulations may be seen as a mathematical mode of demonstrating the content of scientific representations that is in a sense neutral regarding the type of content that is processed: empirically (resp. theoretically) justified representations in, empirically (resp. theoretically) justified information (or knowledge) out. This suggests that when analyzing and classifying types of scientific data and knowledge, the ways that they are produced and processed (experimentally or computationally) and where their reliability comes from (e.g., theoretical credentials or experimental warrants) are, at least in part, independent questions.

## 34.7 Conclusion: Human-Centered, but no Longer Human-Tailored Science

Computer simulations and computational science keep developing and partly change scientific practices (Sect. 34.7.1). Human capacities no longer play the role they had in traditional science, hence the need to analyze the articulation of computational and mental activities within computational science (Sect. 34.7.2). This requires in particular studying computational science for its own sake, which however should not be seen as implying that computer simulations always correspond to scientific activities of radically new types (Sect. 34.7.3). In any case, whatever the exact relations between computer simulations and traditional activities like theorizing, experimenting or modeling, it is a fact that recent investigations about computer simulations

have shed light on epistemological issues which were de facto not treated in the framework of previous philosophical studies of science (Sect. 34.7.4).

Before the development of computers, humans were involved at every step of scientific inquiries. Various types of devices, tools, or instruments were invented to assist human senses and inferential abilities, and they were tailored to fit human capacities and organs. In brief, science was for the most anthropocentric science, that is to paraphrase *Humphreys* [34.41, §1.1] “science by the people for the people,” and analysts of science, from Locke, Descartes, Kant to Kuhn, or Quine offered a human-centered epistemology [34.123, 124, p. 616]. Similarly, theories and models needed to be couched

in formalisms which made their symbolic manipulation possible for humans (hence the success of differential calculus), problems were selected in such a way that they could be solved by humans, results were retrieved in ways such that humans could survey or browse them, etc.

### 34.7.1 The Partial Mutation of Scientific Practices

The use of computers within representational inquiries has modified, and keeps modifying, scientific practices. Theorizing is easier and therefore less academically risky, even in the absence of well-entrenched backing-up theories; solutions to new problems become tractable and how scientific problems are selected evolves; the models which are investigated no longer need to be easily manipulated by human minds (e.g., CA are well adapted for computations, but ill-suited to carry out mental inferences [34.43]; the exploration of models is primarily done by computers, making mental explorations and traditional activities like thought experiments are somewhat more dispensable [34.117] and [34.41, pp. 115–116]; the treatment of computational results, as well as their verification, is made by computational procedures; the storage of data, but also their exploration by expected or additional inquirers, are also computer based. Finally, the human, material, and social structure of science is also modified by computers, with a different organization of scientific labor, the emergence in the empirical sciences of computer-oriented scientists, like numerical physicists and computational biologists or chemists, or the development of big computational pieces of equipment and centers, the access to which is scientifically controlled by the scientific community (like for big experimental pieces of equipment).

### 34.7.2 The New Place of Humans in Science

Overall, the place and role of humans in science has been modified by computational science. Arguably, human minds are still at the center of (computational) science, like spiders in their webs or pilots in their spacecrafts, since science is still led, controlled, and used by people. Thus, we are in a hybrid scenario in which we face what *Humphreys* calls the anthropocentric predicament of how, we, as humans, can “understand and evaluate computationally based scientific methods that transcend our own abilities” [34.42, p. 134]. In other words, interfaces and interplays between humans and computers are the core loci from

which computational science is controlled and its results skimmed by its human beneficiaries. More concretely, scientific problems still need to be selected; computational models, even if designed for computers, need to be scientifically chosen (e.g., CA-based models of fluids were first demonstrated to yield the right Navier–Stokes-like behavior by means of traditional analytic methods [34.43]; results of computer simulations, even if produced and processed by computers, need to be analyzed relative to the goals of our inquiries; and ultimately scientific human-sized understanding needs to be developed for new fundamental or applied scientific orientations to be taken.

### 34.7.3 Analyzing Computational Practices for Their Own Sake

Over the last three decades, philosophers of science have emphasized that in most cases computer simulations cannot simply be viewed as extensions of our *theoretical* activities. However, as discussed above, the assimilation of computer simulations with experimental studies is still not satisfactory. A temptation has been to describe the situation as one in which computer studies lay in-between theories and experiments. While this description captures the inadequacy of traditional characterizations based on a sharp and exclusive dichotomy between scientific activities, it is at best a metaphor. Further, this one-dimensional picture does little justice to, let alone help one understand, the intricate and multidimensional web of complex and context-sensitive relations between these activities.

An alternative is to analyze computational models, computer simulations, and computational science for their own sake. Indeed, computer simulations clearly provide a variety of new types of scientific practices, the analysis of which is a problem in its own right. Importantly, this by no means implies that these practices require a radically new or autonomous epistemology or methodology. Similarly mathematical and scientific problems can be genuinely independent, even when *in the end* they can be reduced by complex procedures to a set of known or solved problems. Indeed, the epistemology of computer simulations often overlaps piecewise with that of existing activities like theorizing, experimenting, or thought experimenting. Disentangling these threads, clarifying similarities, highlighting specific features of computational methods, and analyzing how the results of computer simulations are justified in actual cases is an independent task for naturalistic philosophers, even if one believes that, in principle, computer simulations boil down to specific mixes of already existing, more basic activities.

### 34.7.4 The Epistemological Treatment of New Issues

In practice, the analysis of computer simulations has raised philosophical issues, which were not treated by philosophers before computational studies were taken as an independent object of inquiry, either because they were ignored or unnoticed in the framework of previous descriptions of science, or because they are genuinely novel [34.96, 124, 207]. This a posteriori justifies making the epistemological analysis of computational models and computer simulations a specific field of the philosophy of science. How much computer simulations will keep modifying scientific practices and how much their philosophical analysis will finally bring about further changes in the treatment of important issues like realism, empiricism, confirmation, explanation, or emergence, to quote just a few, remains an open question.

**Acknowledgments.** I have tried to present a critical survey of the literature with the aim of clarifying discussions. I thank the editors for providing me the op-

portunity to write this article and for being so generous with space. I also thank T. Boyer-Kassem, J.M. Durán, E. Arnold, and specifically P. Humphreys for feedback or help concerning this review article. I am also grateful to A. Barberousse, J. P. Delahaye, J. Dubucs, R. El Skaf, R. Frigg, S. Hartmann, J. Jebeile, M. Morrison, M. Vorms, H. Zwirn for stimulating exchanges over the last couple of years about the issue of models and simulations and related questions. All remaining shortcomings are mine.

Various valuable review articles, such as (J.M. Durán: A brief overview of the philosophical study of computer simulations, *Am. Philos. Assoc. Newslett. Philos. Comput.* **13**(1), 38–46 (2013), W.S. Parker: Computer simulation, In: *The Routledge Companion to Philosophy of Science*, 2nd edn., ed. by S. Psillos, M. Curd (Routledge, London 2013)), have been recently written about the issue of computer simulations. (P. Humphreys: Computational science in Oxford bibliographies online, (2012) doi:10.1093/OBO/9780195396577-0100) presents and discusses important references and may be used as a short but insightful research guide.

# Simulation

## 35. Simulation of Complex Systems

Paul Davidsson, Franziska Klügl, Harko Verhagen

Understanding and managing complex systems has become one of the biggest challenges for research, policy and industry. Modeling and simulation of complex systems promises to enable us to understand how a human nervous system and brain not just maintain the activities of a metabolism, but enable the production of intelligent behavior, how huge ecosystems adapt to changes, or what actually influences climatic changes. Also man-made systems are getting more complex and difficult, or even impossible, to grasp. Therefore we need methods and tools that can help us in, for example, estimating how different infrastructure investments will affect the transport system and understanding the behavior of large Internet-based systems in different situations. This type of system is becoming the focus of research and sustainable management as there are now techniques, tools and the computational resources available. This chapter discusses modeling and simulation of such complex systems. We will start by discussing what characterizes complex systems.

### 35.1 Complex Systems

What makes a system *complex* can be formulated from various points of view. In daily speech, *complex* may be primarily a relative notion depending on what a human observer may experience as not so easy to grasp or control. A formal definition capturing what a complex system is, with the necessary general validity, turns out to be difficult to formulate. There is currently no generally accepted definition of the term *complex system* [35.1]. Since there are many sources of complexity, very different systems can be described as complex ones. There are many different notions of *complexity*. In computer science complexity has two major facets: information complexity (how large is the minimal description of the information that fully capture it?) or computation complexity (how much time [space] does an algorithm need for solving a problem in relation to the problem size?). Yet, these technical terms

do not match the intuition of a complex system being difficult to understand, verify or control. Ladyman et al. [35.1] collect various definitions from different domains. Those definitions focus on structures, on the effect of initial conditions, self organization and informal *complicatedness*. Based on the analysis of these definitions, they discuss a list of features that we will tackle in the next section as they form the core properties of complex systems. None of them alone forms a definitory aspect, but combinations give an important impression of what a complex system might be.

Over the years there have been a number of approaches aimed at capturing complex systems. Originating in physics, the idea of self-organized criticality [35.2] was central for the analysis of complexity. *Critical attractor* and *nonequilibrium system* are the

central terms in the related vocabulary. A second related approach is termed *complex adaptive systems*, originating more from biology, based on the idea that complexity arises from many entities adapting to their local environment.

### 35.1.1 Features Associated with Complex Systems

Following the discussion above, an intuition of what is a *complex system* can be best imparted by describing the features of complex systems. None of the features alone capture a complex system and a complex system does not need to exhibit all of them. A complex system in physics may have a completely different shape compared to a complex system in biology or social science. Nevertheless, a combination of those features can be identified at any complex system that we will consider in the following.

#### Nonlinearity

Nonlinearity is one of the most frequently identified properties of a complex system. It basically describes that when combining results/solutions/behavior from multiple elements into one system, these do not add in a linear way, but rather in a nonlinear way due to interactions between elements. Examples of nonlinear systems are systems in which saturation occurs. Prominent are also systems in which a small change causes a big effect somewhere else. Weather, economies, social systems form examples for this kind of *chaotic* system.

Nonlinear phenomena are hard to model, capture and analyze mathematically. Often simulation is a last resort for handling the complexity, yet not each simulation paradigm is suitable.

#### Distributedness, Scale and Interaction

Many systems coined as complex ones, especially in biology or social science, are large and distributed. That means they contain a huge number of entities that are distributed in some way. This may not just refer to geographic distribution, but also to an entity taking a position in a network of relations. The important idea is that there is a form of local interaction, an entity or component interacts with a (selected) number of others distributed over some form of more or less abstract environment. Scale also plays an important role simply because a small system can be overlooked, in a huge one perceiving what happens where in that distributed system obscures the overall dynamics, or as *Auyang* [35.3, p. 11] coins it:

“The relational network is chiefly responsible for the great variety of phenomena in the world. It is

also responsible for the difficulty in studying large composite systems.”

Clearly, the origins of complexity are not merely in the number of entities capable of participating in an interaction, but there is some form of trade-off between the complexity of interaction and the number of interacting entities. Clearly the interaction of hundreds of millions of humans creates a complex system of epidemic spread [35.4], but there are also examples for systems with only a few entities, but complex interactions; for example the model describing the *emergence of political actors* [35.5] contains only 10 entities deciding about whether to pay tribute or not based on decisions taken before. Although there are only a few entities, their decision making and interaction is based on several feedback loops resulting in a complex system.

#### Multiple Levels of Observation, Self Organization, Emergence

*Auyang* [35.3] assumes that complexity arises from large-scale composition. The idea of a system composed of many interacting entities may lead to complexity even if the interaction does not lead to nonlinearity. In such a system, there are at least two levels of observation: the individual entity and the overall system level. The behavior and pattern observable on the latter originate from actions and interactions among the lower level entities, between the entities and their environment as well as if there is some manifestation on a high level (some form of *organization*) this may also impact on the lower level entities.

Two additional concepts are relevant in relation to the multilevel feature of complex systems: self organization and emergence. Self organization denotes some process in which local interactions of lower-level entities produce some form of sustainable regularity from an initially unordered situation. Often random fluctuations are responsible for locating the produced regularity. In his famous book *Kauffman* [35.6] discusses self organization in biological systems based on (evolutionary) adaptation, clearly distinguishing true self organization from organization following some predefined scheme expressing some intention to build structure. A key to self organization is that local decision making is adaptive to a changed environment; that means the local behavior is not fully predefined but at least conditional to environmental conditions. Prominent examples for self-organizing systems can be found in many natural systems, percolation processes in physics, genesis of structures in biology, bird flocking, etc. The principles are also used in technology, mainly in systems such as swarm robotics or biologically inspired optimization.

A related concept, capturing phenomena or patterns originating from local interaction on a lower level is emergence. In addition to self organization, it contains some associated aspect of *astonishment*. As this is often very subjective, the actual definition of the term *emergence* is partially controversial. *The whole is more than the sum of its parts* forms the intuitive characterization. This idea fascinated researchers from Aristotle to Holland [35.7]. More formal approaches for defining emergence are based on the idea that the description of the overall phenomenon uses different vocabulary than the description of the description of the lower-level entities producing the phenomenon. Well-known examples are the Mexican wave in cheering audiences in which the individual spectators stand up depending on their neighbors' actions so that a wave forms, or traffic jams originating from too high density of vehicles. The congestion travels into the opposite direction than the individual vehicles. *Darley* [35.8] discusses the dilemma of relating the definition of emergence to some limited understanding by an observer and defines emergence as a phenomenon that is best predicted by simulation.

#### Adaptivity, Flexible Decision Making and Feedback Loops

The features tackled so far mostly address the system level, but there is an important aspect also in the individual entities' behavior making up the complex system: For producing a complex system, decision making and interaction of the lower-level entities requires some degree of freedom. The entities must be able to adapt

their decision making to their local context. Only if the entities can adapt, feedback loops can be formulated and something complex (unexpected) can be produced. Flexible decision making refers to the next action the entity chooses to perform possibly being related to the extent with which an entity does something or referring to the selection of the interaction partner. Adaptivity hereby means a change in the behavior in reaction to some immediate environmental context, for example governed by some rules that control an entity to change its movement direction before bumping into a suddenly occurring obstacle. True learning is different from adaptive behavior: it changes the behavior program itself – for example, the entity learns a new rule about how to deal with obstacles. Learning can also happen on the system (population) level in the form of evolution combining the production of new entities with a fitness-based selection and/or survival.

### 35.1.2 Summing Up

The last section attempted to capture the idea of a *complex system* based on particular features. The main assumption hereby is a complex system originates from multilevel systems in which phenomena and patterns on the overall system level are produced by entities that are capable of flexible behavior and interaction.

Complex systems – as characterized here – are best analyzed and their overall behavior is best predicted using simulation. In the following, we will focus on different approaches and different motivations to modeling and simulating complex systems.

## 35.2 Modeling Complex Systems

Already in the early days of computer development, modeling and simulation were used in different research areas to predict the behavior of complex systems. Such models were typically based on differential equations and focused on describing phenomena on the overall system level. For instance, models of predator-prey populations could fairly accurately reproduce empirical data, but were limited in the sense that the models did not capture the actual low-level entity behavior and decision making, as well as the interaction between entities, but were based on the assumption that all low-level units were homogeneous. The development of individual-based modeling offers a possible solution to this problem with its (seemingly) natural mapping onto interacting, individual entities with incomplete information and capabilities, leading to models without global control, with decentralized data, asynchronous

computing, and inclusion of heterogeneities. These models also offer the possibility of studying the dynamics of the interaction processes instead of focusing on the (static) results of these processes [35.9, 10].

The main task of computer simulation is the creation and execution of a formal model of the behavior of the system being simulated. *Formal* means here that the model is represented using a formal language with so clearly defined syntax and semantics that the model can be executed using a computer. In scientific research, computer simulation forms a research methodology that can be contrasted to empirically driven research. As such, simulation belongs to the same family of research as analytical models. One way of formally modeling a system is to use a mathematical model, and then attempt to find analytical solutions enabling the prediction of the behavior of the system from a set of

parameters and initial conditions. Computer simulation, on the other hand, is often used when simple closed-form analytic solutions are not possible, which is typically the case for complex systems.

Computer simulation consists of three main steps:

1. Designing a model of an actual or theoretical system
2. Executing the model on a computer, and
3. Analyzing the execution output.

Although there are many different types of computer simulation, they typically attempt to generate a sample of representative scenarios for a model in which a complete enumeration of all possible states would be prohibitive or impossible. In this chapter we will describe simulation as a tool for understanding the behavior of complex systems. For a deeper philosophical treatment of the concept of simulation, we refer to Chap. 34 of this book by *Imbert*.

### 35.2.1 Macro-Level Versus Micro-Level Simulation

As indicated above, we can identify two main approaches to modeling of complex systems:

- Macro-level (or equation-based) simulation, which is typically based on mathematical differential or difference models. It views the overall system with its set of (the population) individual entities as one structure that can be characterized by a number of variables.
- Micro-level simulation, in which the behaviors and decision making of the specific individual entities are explicitly modeled. In contrast to macro-level simulation, it views the overall system behavior as emerging from the interactions between individuals. Thus only with micro-level simulation, the idea that complex effects need not have complex causes, can be explored. Micro-level simulation is sometimes referred to as multi-agent-based simulation (MABS), or agent-based simulation.

As argued by *Parunak* et al. [35.11], micro-level simulation is most appropriate for domains characterized by a high degree of localization and distribution and dominated by discrete decisions. Equation-based modeling, on the other hand, is most naturally applied to systems that can be modeled centrally and in which the dynamics are dominated by physical laws rather than information processing. Clearly, in many cases an abstract view onto aggregate dynamics as provided by macro-level simulation may be sufficient. However, for simulating complex systems micro-level approaches are more relevant. In the following sections we will

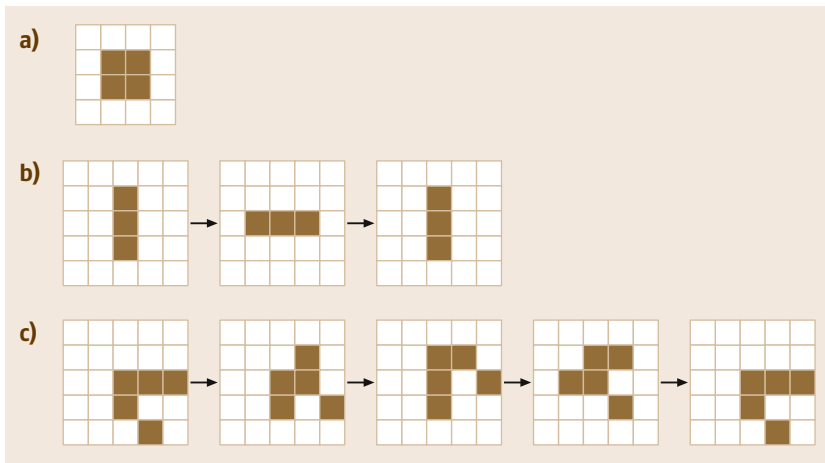

describe common ways of implementing micro-level simulations.

#### Cellular Automata

Individual-based modeling can be traced back to von Neumann, who in the 1950s invented what was later termed *cellular automata* [35.12]. The core definition of a cellular automaton refers to a model of a system that is discrete in time, space and state, yet the term is often used in a broader way denoting to models with discrete space (cells). In principle, such a simulation model consists of a grid of cells, i.e., entities, each in one of a finite number of states. The state of a cell at time  $t$  is a function of the states of a finite number of cells (called its neighborhood) at time  $t - 1$ . These neighbors are a selection of cells relative to the specified cell, and do not change. Every cell has the same rule for updating, based on the values in this neighborhood. Each time the rules are applied to the whole grid a new generation is created. These were used by *Conway* [35.13] in the 1970s when he constructed the well-known *Game of Life*. It is based on very simple rules determining the life and death of the cells in a virtual world in the form of a two-dimensional (2-D) grid just based on the state of a few neighbors, but was able to produce astonishing macro-level dynamics as shown in Fig. 35.1.

Inspired by this work, researchers developed more refined models, often modeling the social behavior of groups of animals or artificial creatures based on local interactions. With respect to human societies, *Epstein* and *Axtell* [35.14] developed in the 1990s one of the first agent-based models, called *Sugarscape*, to explore the role of social phenomena such as seasonal migrations, pollution, sexual reproduction, combat, and transmission of disease. This work is in spirit closely related to one of the best-known and earliest examples of the use of simulation in social science, namely, the *Schelling* model [35.15], in which cellular automata were used to simulate the emergence of segregation patterns in neighborhoods based on a few simple rules expressing the preferences of the agents. Another pioneer from the 1950s worth mentioning is *Barricelli* [35.16], who to some extent used agent-based modeling for simulating biological systems.

The cellular automata models closely resemble the models used in statistical physics, which has inspired physicists to include the simulation of social phenomena in large-scale social systems in their research agenda. In this area, sometimes referred to as sociophysics, phenomena such as opinion spreading in a society and competition between languages have been studied. These models originally described the behavior of atoms and molecules, which are quite simple objects,

**Fig. 35.1a–c** Macro-level phenomena produced by purely local rules determining the state (white = dead, alive = dark) of a cell based on the neighbors' state in the Game of Life

and the macro-level phenomena caused by their interaction (rather than by complex behavior of the individual as in the case of humans). Thus, in these models little attention is paid to individual variation and the individual decision making is rather primitively modeled. A prominent example of sociophysics is the work of *Galam* [35.17].

Another prominent example of a model in which local interactions lead to interesting macro-level behavior is the Boid model by *Reynolds* [35.18], which simulates coordinated animal motion such as bird flocks and fish schools. The underlying spatial representation and consequently the state of the entities in form of direction of movement are continuous values. So it is not a cellular automata in the narrow sense, yet belongs to the same category of models that generate complex system behavior from locally interacting, simple entities.

### Dynamic Micro-Simulation

One of the first, and most simple, ways of performing micro-level simulation in social science is often called *dynamic micro-simulation* [35.19, 20]. It is used to simulate the effect of the passing of time on individuals. Data from a (preferably large) random sample from the population to be simulated is used to initially characterize the simulated individuals. Some examples of sampled features are: age, sex, employment status, income, and health status. A set of transition probabilities are used to describe how these features will change over a given time period, e.g., there is a probability that an employed person will become unemployed over the course of a year. The transition probabilities are applied to the population for each individual in turn and then repeatedly reapplied for a number of simulated time periods. Sometimes it is necessary to also model changes in the population, for example birth, death, and

marriage. This type of simulation can be used to, for example, predict the outcome of different social policies. However, the quality of such simulations depends on the quality of:

- The random sample, which must be representative, and
- The transition probabilities, which must be valid and complete.

### Micro-Level Simulation in Technical Domains

Also for socio-technical systems, that means for systems in which people and technology interact, a number of micro-level modeling and simulation techniques exist. Examples are complex production lines in which human workers cooperate with machines executing more or less automated process steps. Formulating a complex system using for example a Petri nets and queuing system is based on a process-oriented point of view of locally interacting entities and is particularly apt for entities traveling through a complex system in a more or less automated way not involving individual reasoning and on-the-fly adaptation.

Petri nets hereby have been accepted as a powerful formal modeling tool for dealing with performance and functionality issues in systems with distributed concurrent processes based on local behavior – for example complex software systems (see as an introduction [35.21]). According to its basic definition, the core of a Petri net (of the type condition-event net) model is a bipartite graph consisting of a finite set of places connected with elements from a finite set of transitions. Places can hold tokens (one or more tokens with or without colors) that *travel* from place to place when a transition *fires*. The colors of the token represent its internal state and allow formulating behavior depending on internal state.

Queuing systems are used for performance analysis in distributed systems in which entities are traveling through a system, for example patients through a hospital or jobs through a production system (see for introduction: [35.22]). Also queuing systems models are graphs with two different types of nodes: servers and queues. The servers represent resources that the jobs have to be processed by. If the server is busy, the job has to wait in the queue in front of that resource. Every queue may have its special queuing discipline. Connections between the different elements are either deterministic (without branching) or probabilistic (branching or merging).

These micro-level models and simulations are used for complex socio-technical systems – with a focus on technology – that benefit from a distributed, process-oriented point of view. In contrast to cellular automata, space is abstracted to times that a token or job needs for traveling between places or servers. Simulated time is usually handled event-based, that means simulated time is advanced to times in which change happens that triggers other changes. A general formalism for object-oriented modeling and simulation is Discrete Event System Specification (DEVS) [35.23], which is possible to use for micro-level modeling and simulation for complex systems. Based on the concept of eventually coupled *systems*, the underlying abstractions are quite generic and thus can be used without doubt, but they are not specifically supportive for modeling complex systems. Below, we will introduce agent-based simulation – a micro-level modeling approach for complex systems that is more general than these more formalized modeling and simulation paradigms.

### 35.2.2 Purpose of Modeling Complex Systems

Modeling and simulation of complex systems can be done for different purposes, such as:

- Supporting theory building and evaluation
- Supporting the engineering of systems, e.g., validation, testing, etc.
- Supporting planning, policy making, and other decision making and
- Training, in order to improve a person's skills in a certain domain.

It is possible to distinguish between four types of end users: *scientists*, who use the models in the research process to gain new knowledge or verify hypotheses; *policymakers*, who use it for making strategic decisions; *managers* (of systems), who use it to make operational decisions; and *other professionals*, such as architects, who use it in their daily work. Below we describe how

these types of end users may use modeling and simulation of complex systems for different purposes.

#### Supporting Theory Building and Evaluation

In the context of theory building, a simulation model can be seen as an experimental method or as a theory in itself [35.24]. In the former case, simulations are run to test the predictions of theories, whereas in the latter case simulations in themselves are formal models of theories. Using a formal language for describing ambiguous, natural language-based theories helps to find inconsistencies and other problems, and thus contributes to theory building.

Simulation may also be used to evaluate a particular theory, model, hypothesis, or system, or compare two or more of these. Moreover, simulation can be used to verify whether a theory, model, hypothesis, system, or software is correct. Using simulation studies as an experimental tool offers great possibilities. For instance, many experiments with human societies are either unethical or even impossible to conduct. Experiments in silico, on the other hand, are fully possible. These can also breathe new life into the ever-present debate in sociology on the micro-macro link [35.25].

#### Supporting the Engineering of Systems

Many large-scale technical systems are distributed and involve complex interactions between humans and machines. The idea is to model the behavior of human users in terms of software entities (see next section). In particular, this seems useful in situations where it is too expensive, difficult, inconvenient, tiresome, or even impossible for real human users to test out a new technical system. Of course, also the technical system, or parts thereof, may be simulated. For instance, if the technical system includes hardware that is expensive and/or special purpose, it is natural to simulate also this part of the system when testing out the control software. An example of such a case is the testing of control systems for *intelligent buildings*, where software entities simulate the behavior of the people in the building [35.26].

#### Supporting Planning, Policy Making, and Other Decision Making

In simulation for decision making the focus is on exploring different possible future scenarios in order to choose between alternative actions. Besides this type of prediction, modeling of complex systems may be used for analysis; to gain deeper knowledge and understanding of a certain phenomenon.

An area in which several studies of this kind have been carried out is disaster management, such as experiments concerning different roles and the efficiency of reactions to emergencies [35.27]. Here also software

entities are models of humans. Based on individuals' observations, personal characteristics and skills, past experience and role characteristics, and social network, the entities create a plan to execute. The effect of adding a role (floor warden) in a fire alarm scenario upon the evacuation efficiency in an abstract environment is analyzed. Sometimes environmental information is based on GIS (geographical information system) data, thereby tying the simulation closer to the physical reality [35.24]. In yet another study, real-world data were used for both the environment and the software entities' internal decision-making model to analyze the effect of different insurance policies on the willingness of modeled humans to pay for a disaster insurance policy [35.28].

Another application area for this type of simulation study is disease spreading. Again, software entities are used to represent human beings and the simulation model is linked to real-world geographical data. One study [35.29] also included software entities that represent towns acting as the epicenter of disease outbreak. The town entity's behavior repertoire consisted of dif-

ferent containment strategies. The simulation model can be quickly adapted to local circumstances via the geographical data (given that there is data on the population as well) and is used to determine the effects of different containment strategies.

A third area where social simulation has been used to support planning and policy making is traffic and transport. An example of this is the simulation of all car travel in Switzerland during morning peak traffic [35.30].

### Training

The main advantage of using modeling and simulation for training purposes is to be part of a real-world-like situation without real-world consequences. Especially in the military the use of simulation for training purposes is widespread. Also in medicine, where mistakes can be very expensive in terms of money and lives, the use of simulation in education is on the rise.

An early product in this area was a tool to help train police officers to manage large public gatherings such as crowds, demonstrations, and marches [35.31].

## 35.3 Agent-Based Simulation of Complex Systems

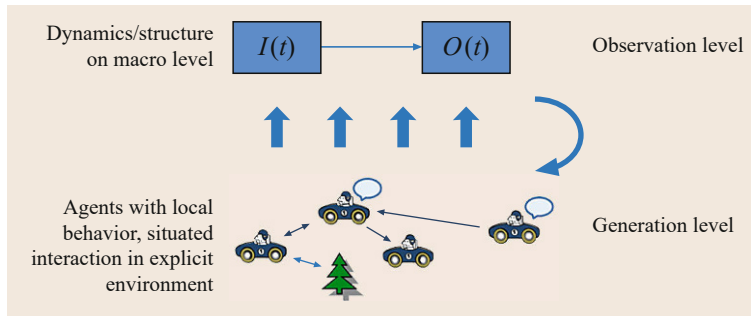

A special case of micro-level modeling is agent-based modeling. Multi-agent systems [35.32] consist of interacting entities embedded into a shared environment are coined as *agents*. Agents are characterized by some kind of agency and autonomy. There are many entities that can be referred to as *agents*, see [35.33] for a famous example describing a thermostat as an agent. Less controversial examples of agents are autonomous robots and human beings. Agency contains hereby notions of situatedness – being embedded into a (local) environment that is accessible to the agent by sensors and manipulatable using sensors. A second important aspect of agency relates to the agents' social abilities. This means that the agent is capable of interacting with other agents, taking part in conversations, coordinating activities, etc. Autonomy is the most difficult aspect as it relates to different aspects ranging from the agent is capable of executing a particular sequence of actions without human interventions to the agent learns and adapts its behavior without external control.

Agent-based models mostly focus on the emergence of macro-level properties from the local interaction of adaptive agents that influence one another [35.9, 34]. However, simulations in computational organization theory [35.35, 36], for example, often try to analyze the influence of macro-level phenomena on individuals. Given that complex systems are characterized by com-

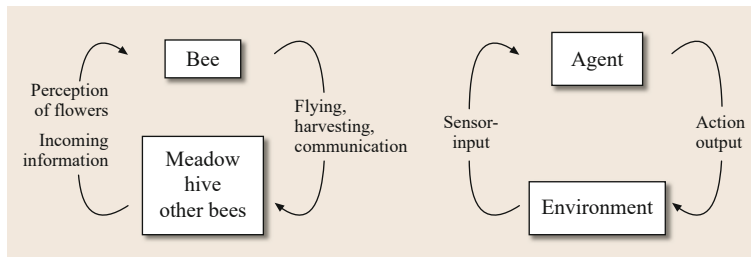

plexity in the interaction of entities that in themselves are and behave in an understandable way and that agents are the computational implementation of such entities, it is clear that agent-based modeling is a suitable paradigm for implementing and studying complex systems. It is supported by their generative nature [35.36]. Figure 35.2 illustrates the general principle.

There are mainly two reasons for the increasing popularity of agent-based simulation: the intuitiveness and the flexibility of the paradigm. The ontological correspondence between agents and original actors facilitates understanding of the model. The unit of description is the active entity in the model: real pedestrians are mapped to agents in crowd simulation or households in demographic models. Figure 35.3 illustrates this using the example of a bee and the general concept of an agent.

The second major advantage is the freedom of design. Agent-based models can contain heterogeneous entities, heterogeneous spatial environments or arbitrary complex agent decision making. This flexibility basically allows remodeling of any other micro-level model using an agent-based simulation. In other simulation paradigms, heterogeneity of entities or space, structural variation (entities leaving or entering the system) or context-dependent and flexible individual decision making are hard to achieve in a direct way.

**Fig. 35.2** The principle of agent-based simulation

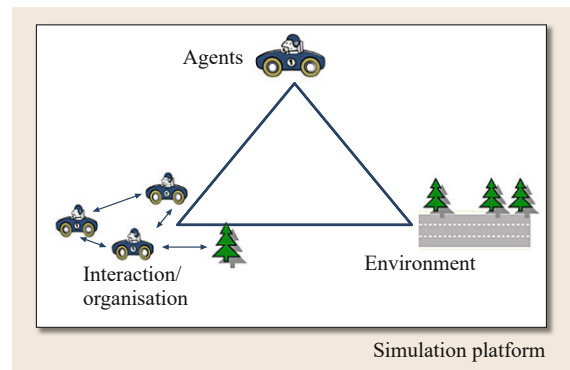

**Fig. 35.3** Correspondence of concepts between real-world actors (such as bees) and agents

### 35.3.1 Elements of Agent-Based Simulation Models

Let us now focus on how the system to be simulated is modeled. This depends on the type of system that should be simulated and for what purpose the simulation is done. A model of a system consists of a set of entities and an environment (in which the entities are situated). The entities are either individuals (agents) that have some decision-making capabilities, or objects (resources) that have no agency and are purely physical. There are a number of characteristics that can be used to differentiate between different types of models. We will first look at how individuals are being modeled, then on the interaction between the individuals, and finally how the environment is being modeled. Figure 35.4 summarizes these three basic aspects of agent-based simulation. In the following, the different elements of an agent-based simulation model are discussed. Section 35.3.2 deals with the engineering aspects also manifested in the simulation infrastructure used.

#### Model of an Individual

A model of an individual could range from being very simple, such a one binary variable (e.g., alive or dead) that is changed using only a single rule, to being very complex. The complexity of the model for a given simulation should be determined by the complexity of the individuals being simulated. Note that in complex systems very complex collective behavior could be achieved from very simple individual models, if the number is sufficiently large.

**Fig. 35.4** Illustration of the three elements of an agent-based model. A fourth relevant part is the simulation platform that will be discussed in Sect. 35.3.2, *More Issues in Engineering Agent-Based Simulations*

We can distinguish between modeling of the state of an individual and the behavior of the individual, i.e., the decisions and actions it takes. The state of an individual, in turn, can be divided into the physical and the mental state. The description of the physical state may include, for example, the position of the individual, and if it is a person being simulated features such as age, sex, and health status. The physical state is typically modeled as a feature vector, i.e., a list of attribute and value pairs. However, this is not always the case as in some domain the physical state of individual is not modeled at all, for example the *Principles of Synthetic Intelligence* (PSI) agent by Künzel and Hämmer [35.37] that was used to give stu-

dents theoretical insights in the area of psychological theory.

Whereas the physical state often is simple to model, the modeling of the mental state is typically much more complex, especially if the individuals modeled are human beings. A common approach is to model the beliefs, desires, and intentions of the individual, for instance by using the belief–desire–intention (BDI) model [35.38, 39]. Such a model may include the social state of the individual, i. e., which norms it adheres to, which coalitions it belongs to, etc. Although the BDI model is not based on any experimental evidence of human cognition it has proved to be quite useful in many applications. There has also been some work on incorporating emotions in models of the mental state of individuals [35.40] as well as obligations (cf. the beliefs, obligations, intentions and desires (BOID) model [35.41] which extends the BDI with obligations).

The modeling of the behaviors (and decisions) of the individuals can be done in a variety of ways, from simple probabilities to sophisticated reasoning and planning mechanisms. As an example where the former is used, we can mention dynamic micro-simulation as described in Sect. 35.2.1, *Dynamic Micro-Simulation*, which was one of the first ways of performing individual-based simulation and is still frequently used. In traditional micro-simulation, the behavior of each individual is regarded as a *black box*. The behavior is modeled in terms of probabilities and no attempt is made to justify these in terms of individual preferences, decisions, plans, etc. Thus, better results may be gained if also the cognitive processes of the individuals were simulated. Opening the black box of individual decision making can be done in several ways. A basic and common approach is to use decision rules, for instance, in the form of a set of situation-action rules. That is, if an individual and/or the environment is in state X then the individual will perform action Y. By combining decision rules and the BDI model quite sophisticated behavior can be modeled. Other models of individual cognition used in agent-based social simulation include the use of Soar (a computer implementation of Allen Newell’s unified theory of cognition [35.42]), which was for example used in Steve for generating a believable simulated tutor [35.43]. Another unified theory of individual cognition for which a computer implementation exists is Adaptive Control of Thought-Rational (ACT-R) [35.44], which is realized as a production system. A less general example is the Consumat model [35.45], a meta-model combining several psychological theories on decision making in a consumer situation. Also, nonsymbolic approaches such as neural networks have been used to model the agents’ decision making [35.27].

As we have seen, the behavior of individual could be either deterministic or stochastic. Also the basis for the behavior of the individuals may vary. We can identify the following categories:

- The state of the individual itself: In most social simulation models the physical and/or mental state of an individual plays an important role in determining its behavior.
- The state of the environment: Also the state of the environment surrounding the individual often influences the behavior of an individual. Thus, an individual may act differently in different contexts although its physical and mental state is the same.
- The state of other individuals: One popular type of simulation where the behaviors of individuals are based on the state of other individuals is those using cellular automata. As introduced above, the state of each cell is updated as a function of the states of a particular set of neighbors. In this case, information about the state of other individuals can be seen as gained through observations. Another possibility is to gain the knowledge through communication and in this case the individuals do not have to be limited to the neighbors.
- Social states (norms etc.) as viewed by the agent: For simulation of social behavior the agents need to be equipped with mechanisms for reasoning at the social level (unless the social level is regarded as emergent from individual behavior and decision making). Several models have been based on theories from economy, social psychology, sociology etc. An example of this is provided by *Guye-Vuillème* [35.46] who has developed an agent-based model for simulating human interaction in a virtual reality environment. The model is based on sociological concepts such as roles, values, and norms and motivational theories from social psychology to simulate persons with social identities and relationships.

In most simulation studies, the behavior of the individuals is static, i. e., the decision rules or reasoning mechanisms do not change during the simulation. However, human beings and most animals do have an ability to adapt and learn. To model dynamic behavior of individuals through learning or adaptation can be done in many ways. For instance, both ACT-R and Soar have learning built in. Other types of learning include the internal modeling of individuals (or the environment) where the models are updated more or less continuously.

Finally, there are some more general aspects to consider the modeling of individuals. One such aspect is whether all the agents share the same behavior or they behave differently, i. e., representation of behavior is ei-

ther individual or uniform. Another general aspect is the number of individuals modeled, i. e., the size of the model, which may vary from a few individuals to billions of individuals. Moreover, the population of individuals could be either static or dynamic. In dynamic populations, changes in the population are modeled, typically births and deaths.

#### Model of the Interaction Between Individuals

In dynamic micro-simulation each simulated individual is considered in isolation without regard to their interaction with others. However, in many situations the interaction between the individuals is crucial for the behavior at system level. Thus, in such cases better results will be achieved if the interactions between individuals were simulated. Two important aspects of interactions are who is interacting with whom, i. e., the interaction topology, and the form of interaction.

A basic form of interaction is physical interaction (or interaction based on spatial proximity). As we have seen, this is used in simulations based on cellular automata, e.g., in the Game of Life, introduced in Sect. 35.2.1, *Dynamic Micro-Simulation*. Another example is the Boids model [35.18], which simulates coordinated animal motion such as bird flocks and fish schools in order to study emergent phenomena. In these examples, the interaction topology is limited to the individuals immediately surrounding an individual. In other cases, as we will see below, the interaction topology is defined more generally in terms of a (social) network. Such a network can be either static, i. e., the topology does not change during a simulation, or dynamic. In these networks the interaction is typically language based. An example of this is the work by *Verhagen* [35.47] where agents that are part of a group use direct communication between the group members to form shared group preferences regarding the decisions they make. Communication is steered by the structure of the social network regardless of the physical location of the agents within the simulated world.

#### Model of the Environment

The state of the environment is usually represented by a set of (global) parameters, for example temperature. In addition, there are a number of important aspects of the environment model, such as:

- **Spatial explicitness:** In some models, there is actually no notion of physical space at all. An example of a scenario where location is of less importance is, for example, *innovation networks* [35.48] in which the individuals are high tech firms that each have a knowledge base that they use to develop artifacts to launch on a simulated market. The firms are able

to improve their innovations through research or by exchanging knowledge with other firms. However, in many scenarios location is very important, and in those each individual (and sometimes each object) is assigned a specific location at each time step of the simulation. In this case, the individuals may be either static (the entity does not change location during the simulation) or mobile. The location could either be specified as absolute positions in the environment, or in terms of relative positions between entities. In some areas the simulation software is integrated with a geographical information system (GIS) in order to achieve a closer match to reality, see [35.49].

- **Time:** There are in principle two ways to address time, and one is to ignore it. In static simulation time is not explicitly modeled; there is only a *before* and an *after* state. However, most simulations are dynamic, where time is modeled as a sequence of time steps. Typically, each individual may change state between each time step.
- **Exogenous events:** This is the case when the state of the environment, for example the temperature, changes without any influence or action from the individuals. Exogenous events, in case they are modeled, may also change the state of entities, for example, decay of resources, or cause new entities to appear. This is a way to make the environment stochastic rather than deterministic.

### 35.3.2 Engineering Agent-Based Simulations

#### Factors to Consider When Choosing a Model

In contrast to some of the more traditional approaches, such as system dynamics modeling, agent-based modeling does not yet have any standard procedures that can support the model development. During the last decade some attempts in this direction have been proposed. For example, *Grimm* et al. [35.50] proposed a structure for documenting an agent-based simulation model originally in the area of ecological systems. However, it is often the case that the only formal description of the model is the actual program code. However, it may be useful to use the unified modeling language (UML) to specify the model [35.51].

Some of the modeling decisions are determined by the features of the system to be simulated, in particular those regarding the interaction model and the environment model. The hardest design decision is often how the mental state and the behaviors of individuals should be modeled, in particular in the case when the individuals are human beings. For simpler animals or machines, a feature vector together with a set of transitions rules

is often sufficient. Depending on the phenomena being studied, this may be sufficient also when modeling human beings. *Gilbert* [35.52] provides some guidelines whether a more sophisticated cognitive model is necessary or not. He states that the most common reason for ignoring other levels is that the properties of these other levels can be assumed to be constant, and exemplifies this by studies of markets in equilibrium where the preferences of individual actors is assumed to remain constant (note, however, that this may not always be true). Another reason for ignoring other levels, according to Gilbert, is when there are many alternative processes at the lower level that could give rise to the same phenomenon. He exemplifies this by the famous study by *Schelling* [35.14] regarding residential segregation. Although Schelling used a very crude model of the mental state and behavior of the individuals, i. e., ignoring the underlying motivations for household migration, the simulation results were valid (as the underlying motivations were not relevant for the purpose of Schelling's study). On the other hand, there are many situations where a more sophisticated cognitive model is useful, in particular when the mental state or behavior of the individual provides constraints on, or in other ways influences the behavior at the system level. However, as Gilbert concludes, the current research is not sufficiently mature in order to give advice on which cognitive model to use (BDI, Soar, ACT-R, or other). Rather, he suggests that more pragmatic considerations should guide the selection.

The model of the environment is mostly dictated by the system to be simulated, where the modeler has to decide on the granularity of the values of the attributes of the environment. The interaction model is often chosen based on the theory or practical situation that is the basis for the simulation, but sometimes the limitations of the formal framework used restricts the possibilities. Also here the modeler has to decide upon the granularity of the values of the attributes. In general *Edmonds* and *Moss* [35.53] give the advice that a modeler shall not optimize for simplicity of the model, but more for understandability and believability.

#### More Issues in Engineering Agent-Based Simulations

Decision making about the granularity of agent decision is not the only issue when developing an agent-based simulation model for a complex system – yet is the most important one. In the following we will discuss more issues. A more elaborate discussion of issues can be found in [35.54].

**Generative Micro-Macro Link.** A basic reason for attractiveness of agent-based simulation for complex sys-

tem modeling comes from its generative nature [35.36]. The structure and dynamics of the overall system are not directly described, but generated from behavior and interactions of simulated, individual agents. So, there are at least two levels of modeling and observation: the low-level agents and the aggregate system level. *Running* the low level produces the structure and behavior on the aggregate level; in general, a formal a priori analysis before simulating the system is hardly possible, only by running the simulation, the what, where and when of a social phenomenon emerging from the low-level agents, can be fully determined. Formal analyses (or even prediction) of overall simulation outcomes from low-level agent behavior are difficult or impossible.

In many applications, a certain macro level phenomenon in the original system is to be reproduced or optimized. Thus, the micro-level rules determining the behavior have to be adapted in a way that the intended aggregate phenomenon is produced. For agent-based simulation, exploratory, experience-based, less informal methodologies appear to be more appropriate [35.55]. The basic question on how to come up with the appropriate low-level behavior is left to individual creativity and experience. This issue, together with the general level of granularity of the model has also been discussed in the last subsection.

#### Critical Parameter Structures and Calibration.

A simple model is preferable as it contains fewer assumptions and thus less parameters. Parameters may be factors in formulas or thresholds for decision making. Also values for initial values for state variables of all entities are parameters. A model with too many parameters can be tuned to produce anything. That means, a constellation of parameter values can be found, so that the given agent actions and interactions produce any intended overall outcome. So, structural falsification becomes impossible. This limits the analytical value of the model if not accompanied with rigorous processes for quality assurance.

Many parameters also cause practical problems: they need to be set to appropriate values. The necessary effort for calibration becomes an issue in developing agent-based simulations. Hereby, one has to pay attention as the sheer number of parameters may be critical. This can be remedied by putting parameters in relation to each other. Another important problem relates to the nature of the parameters themselves. A single parameter can have an enormous effect on the overall aggregated behavior when shared by many agents or if there are nonlinear feedback loops amplifying its effect. *Izquierdo* and *Polhill* [35.56] denoted decision threshold parameters as *knife-edge parameters*: if the

behavior of the agent changes depending on this parameter. Setting such a parameter homogeneously for all agents can cause chaotic behavior: small changes in the parameter values result in completely different phenomena. This issue can be addressed by allowing individual values for the individual agents or by *smoothing* the effects of a threshold with some stochastic transition. Finally, the test whether the simulation leads to the intended system and individual behavior may not be automatized – especially in abstract models without sufficient underlying empirical data – but human intelligence is needed to identify whether the generated pattern of the complex system is the searched one.

**Size and Scalability.** There is a variety of complex system models with respect to the number of agents, ranging from one-agent systems capable of complex interaction behavior to large-scale simulations with several millions of agents. For many complex system models, a minimum agent number is necessary – for example the effect of pheromone-based ant recruitment cannot be shown by only a small number of simulated ants, but the number of agents has to be synchronized with the environmental configuration and the evaporation rate of the pheromone used to establish a pheromone trail. Scalability with respect to agent numbers is only half of the story: scalability depends on the complexity of the agent behavior and architecture as discussed above. Complex system models contain agents that are capable of flexible decision making, which is clearly more costly than fully scripted behavior programs. With an appropriate tool, as one of the platforms discussed in Sect. 35.3.2, *More Issues in Engineering Agent-Based Simulations*, at least the simpler scalability issues are addressable.

**Other Technical Issues.** Besides those principled problems, there one can identify engineering issues at technical design and implementation – often supported by tools and platforms. If an analysis of the dynamics of the complex system model is needed, the model must be implemented. This is challenging in a way similar to multi-agent systems. Simulated multi-agent systems are also consisting of distributed intelligent decision makers, each with its own thread of control, its local beliefs and interacting and acting in parallel. In addition to the challenges developing a multi-agent system, one can identify:

- Issues about extended design choices on the environmental model. For facilitating the design of the agents, the environmental model can be augmented: A prominent example is crowd simulations using

floor fields capturing gradient data for path finding. Information is explicitly stored in the environment without any correspondence to the original system, but for making agent implementation more efficient. Again, it is a matter of modelers' experience to know how far one can go with these additions.

- During simulation, virtual time is advanced to express the dynamics of the model. As environment and time are artificial, the modeler needs a way for explicitly handling artificial parallelism of the agent's update. In principle, every agent could run in its own software process, but for simple agents explicitly handling virtual parallelism is more efficient. Depending on used infrastructure, the modeler has to take care about these low-level aspects of simulation implementation.

### Tools for Agent-Based Simulation of Complex Systems

Despite the many available tools, implementation of an agent-based simulation model is still not trivial. The currently most prominent tools suitable for complex systems are Swarm, Repast, MASON and NetLogo. Platforms such as SeSAM support modeling better, yet simulation runs tend to be slow. In the following, we will shortly discuss these tools. More elaborate comparisons can be found in [35.57, 58] or [35.59]

**Swarm.** Swarm [35.60] is one of the earliest tools for implementation of agent-based simulations (ABSs) and complex systems. Practically, it provides libraries (in Objective-C or newly also JAVA) that developers can use when building their simulations. Agents are hierarchically organized in Swarms.

**Repast.** Repast (Recursive Porous Agent Simulation Toolkit [35.61]) is also a Java-based platform. Following the hierarchical structure of Swarm, Repast provides a library of classes for the most common tasks associated with the implementation of an ABS. Besides, since the initial focus of Repast was social science, it includes some tools that are useful in this domain such as network analysis. The Repast Symphony forms a visual modeling extension based on state charts.

**MASON.** MASON (Multi-Agent Simulator Of Neighborhoods [35.62]) forms a library based on Java with the goal to particularly support large-scale simulations.

**NetLogo.** NetLogo [35.63] is currently probably the most used platform. It was particularly designed for complex system modeling and simulation with the end user in mind. A NetLogo model has basically three elements. The first is the actual implementation of model

behavior. The used modeling language resembles StarLogo, which is easy to understand and learn. The second and third element of a NetLogo model is the simulation interface for visualization and parameter settings and a third explicit element is a structured documentation.

NetLogo is becoming increasingly popular due to its extensive documentation, the existence of good tutorials, and a large library of preexisting models. Introductory books such as [35.64] are based on NetLogo.

**SeSAM.** The Shell for Simulated Agent Systems [35.65] provides a fully visual interface for the model development. A proprietary model representation language forms the basis for visual programming, etc. The kernel of a SeSAM simulation consists of the behavior models of agents and the world, which is represented as a special, global agent that may manage different kinds of maps.

**Other Tools.** In repositories for agent-based simulation platforms many more systems are listed [35.66]

and [35.67]. An overview is practically impossible. Many other tools are specifically designed for particular purposes. For example, MadKit relies upon an organizational model of agents' societies. Therefore its particular strength is in models focusing on intra- and inter-organizational processes. Similarly, CORMAS (Common-pool Resources and Multi-Agent Systems) is a programming environment that targets natural resources management.

In principle, an agent-based simulation platform shall not just support the implementation of agent behavior, but provide basic infrastructure for, for example, integration of input data, handling virtual time, model instrumentation, data collection, and others. Depending on the nature of the tool, the expressiveness of the language for capturing the agent behavior might be limited. Whether it is sufficient or not, is dependent on the actual objective behind simulating the complex system. Nevertheless, a good development platform amends some of the issues discussed above and thus enables the modeler to concentrate on the core aspects of the model.

## 35.4 Summing Up and Future Trends

The ability to understand and manage different types of complex systems is becoming more and more important, both for research, businesses and government. As we have seen, agent-based modeling and simulation seems a promising approach to many problems involving the simulation of complex systems of interacting entities. Although a large number of different methods and tools for agent-based modeling and simulation have been developed, it seems that the full potential of the agent concept often is not realized. In particular, this is the case when modeling complex systems that include human actors. For instance, most models use a very primitive model of agent cognition yet as argued in [35.52] cognitive layers of agent architectures should be intertwined with social layer.

The question of how to balance complexity of the agents' reasoning and transparency and comprehensiveness of the overall system behavior forms one of the many open issues from a methodological point of view. Although agent-based modeling of complex system forms a highly attractive approach for the full variety of possible objectives, there is not yet any established method for developing a model in a sys-

tematic way, comparable to system dynamics. This may be due to the fact that modeling per se often contributes to understanding a complex system. That is, the complex system to be modeled is not fully understood by the stakeholders or even by the modelers themselves before the modeling and simulation endeavor starts – independent of which objective the model is developed for. Thus, model development and model analysis also contain elements of original system exploration that, especially in the case of complex systems, may lead to new questions and insights influencing the ongoing model development process. Even if the specific open issues that we discussed in Sect. 35.3.2, *More Issues in Engineering Agent-Based Simulations*, are addressed by new methodologies to be developed, this will probably remain as a profound issue as long as there are systems that appear to be *complex*. More generally, we argue that the art and practice of engineering agent-based models is an important area of future research; as for handling, predicting and especially for understanding complex systems, modeling and simulation form the centerpiece of any activity.

# 36. Models and Experiments in Robotics

Francesco Amigoni, Viola Schiaffonati

This chapter surveys the practices that are being employed in experimentally assessing the special class of computational models embedded in robots. The assessment of these models is particularly challenging mainly due to the difficulty of accurately estimating and modeling the interactions between the robots and their environments, especially in the case of autonomous robots, which make decisions without continuous human supervision. The field of autonomous robotics has recognized this difficulty and launched a number of initiatives to deal with it. This chapter, after a conceptual premise and a broad introduction to the experimental issues of robotics, critically reviews these initiatives that range from taking inspiration from traditional experimental practices, to simulations, benchmarking, standards, and competitions.

## 36.1 A Conceptual Premise

The issues involved in the experimental assessment of computational models are several and diverse. In this chapter, we focus on a challenging class of computational models that present complex interactions with the real world, namely those of robotics, and in particular of *autonomous robotics* (intended as the discipline aiming at developing robots that operate in unpredictable environments without a continuous human supervision), and on how experiments have recently been conceptualized, discussed, and performed in this field. Taking the perspective that robots are a way to implement models of human-designed processes, these models need to be validated and experiments are usually the way to carry out this validation. This section, therefore, is dedicated to the clarification of the key concepts – robot system, computational model, technical artifact, and experiment – that constitute the starting points of what will be discussed in the rest of the chapter.

In general, a robot system can be conceived as a computational model, provided with a specific ar-

chitecture, capable to interact with the surrounding physical environment by means of sensors and actuators, and to fulfill a function which is the reason why the system has been designed and implemented. By a computational model, we mean a representation that is formulated in terms of computable functions [36.1], where a function  $X()$  is said to be computable if for each argument  $n$  of  $X$ , the corresponding value  $X(n)$  can be obtained by adopting a mechanical calculus (algorithm). In other words, a model is computational if it can be defined in purely mechanical terms: only mechanical procedures of calculus are required to give reason of it. But what is modeled in the case of a robot system, given that the associated model is computational? First, the phenomena or the behavior that the robot system should represent; then, (part of) the environment in which the robot system is inserted and with which it should interact, where the interaction between the system and the environment strongly depends on the way the system itself is modeled.

Let us focus our attention now on the reasons why a robot system is built; these are generally related to responding to some needs, such as to perform some actions in the environment or, more generally, to obtain a desired behavior. The conceptualization of robots as *technical artifacts* [36.2], namely as material objects that have been deliberately produced by humans in order to fulfill a practical function, may help in better clarifying these reasons. The term *artifact* emphasizes the fact that these objects are not naturally occurring, but they are the result of purposeful human actions. More generally, technical artifacts can be characterized as possessing three key features:

- The *technical function* that is related to the question *What is the technical artifact for?* In robotics, the technical function can be defined by referring to the task the robots have to accomplish and to the environment in which the task is performed. Note that a task includes both an activity and a way to quantify a performance in executing this activity.
- The *physical composition* that is related to the question *What does the technical artifact consist of?* In particular, the physical components of robots are selected in order to cope with the intended task and environment. For example, using wheels for locomotion can be afforded only if the environment in which robots are expected to move is rather smooth, planar, and relatively empty. If this is not the case, locomotion needs to be based on legs or crawlers, or the use of aerial robots could be considered. Similarly, equipping a robot with a thermal camera could be useful if the task is to detect victims, while if the task is to assess the topological structure of a building, other sensors could be more appropriate.
- The *instructions for use* that are related to the question *How must the technical artifact be used?* For example, the use of autonomous robots in search and rescue applications is a rather complex job and usually requires the presence of human operators to supervise operations and to actively intervene on the system in case of unexpected problems. Hence, the instructions for using these robots are significantly complex and usually require human operators to undergo some training. Timing in issuing commands and attention in guaranteeing the safety of all involved people (and, to a lesser degree, of all robots) are fundamental and should be part of the training of human operators.

These three features are not independent of each other: to fulfill the technical function that the artifact is for, the artifact itself has to be physically composed in a certain way and the user has to carry out certain actions, specified by the instructions for use. In sum-

mary, a technical artifact can be said to be a “physical object with a technical function and use plan designed and made by human beings” [36.2, p. 7].

Adopting the view that a robot system is a technical artifact embedding a computational model of an intended behavior, its assessment is usually conducted on the field, and experiments are a way to achieve this assessment in a rigorous way. In this context, experiments can be seen as a way to evaluate technical artifacts according to whether and to what amount the function for which they have been built is fulfilled. Apparently, a contradiction seems to arise when considering the necessity of evaluating an artifact, that has been designed and implemented by a human being, and whose complete knowledge, thus, should be under the control of that designer. However, not only these types of artifacts can be so complex that it is difficult to fully manage their knowledge, but also their interaction with the environment is largely unpredictable and, therefore, a rigorous evaluation is needed, which is mainly based on experimentation. Obviously, experimentation can take many forms and to help clarify the kind of experimentation embraced in autonomous robotics, we deem useful to adopt the distinction between epistemic experiments and directly action-guiding experiments recently pointed out by *Hansson* [36.3].

*Epistemic experiments* provide us with information about the workings of the world we live in. The outcome looked for is precisely the one providing such information and does not need to coincide with anything that any person would wish to happen (except as part of the experiment itself). This is the traditional view of experimentation that both historical and philosophical accounts of experimental methods have been almost exclusively devoted to analyze. But if we look at the practice of experimentation in prescientific times, as *Hansson* suggests, we can recognize that there are also so-called *directly action-guiding experiments*, namely experiments that satisfy the following two criteria:

- The outcome looked for should consist in the attainment of some desired goal of human action.
- The interventions studied should be potential candidates for being performed in a nonexperimental setting in order to achieve that goal.

These criteria are satisfied, for example, in a clinical trial of an analgesic, where the outcome looked for is pain reduction, and the intervention is a treatment to be administered to achieve this outcome in ordinary patients. A systematic test on an autonomous robot employed to assist an elderly person in her home is also an example of a directly action-guiding experiment: the outcome looked for is the proper interaction of the robot with the person and the experimental intervention con-

sists in the careful tuning of the abilities that the robot must possess to positively achieve this goal.

The notion of directly action-guiding experiments can be applied to a number of different situations, and indeed to many technological tests performed in the engineering disciplines, including robotics. In the rest of the chapter, we will base our analysis and discussion

referring mostly to this notion of experiment, even if it will be evident that a clear cut distinction between episodic and directly action-guiding experiments is not always possible being the experimental validation of robot systems at the intersection between science and engineering under many respects, as we will try to evidence in the next sections.

## 36.2 Experimental Issues in Robotics

The experimental validation of robots has been playing a decisive role in many areas of robotics, such as in industrial robotics, by addressing both the measures of robot performance and the assessment of their safety. These experiments usually take the form of tests, where standardized procedures have been developed. To assess, for example, the performance of commercialized industrial manipulators (in terms of accuracy, repeatability, and spatial resolution) rigorous testing protocols have been provided (see later). In other areas of robotics research, such as in the field of autonomous robotics for service applications, the term *experiment* has been intended more vaguely and experimental activities are often carried out with lower standards of methodological rigor.

In the last years, however, the autonomous robotics community has experienced a growing interest for the development of good experimental methodologies. This interest can be traced back to different reasons: from a scientific perspective, it concerns the desire of this rather novel community to adopt the same methodological standards of other scientific disciplines; from a more practical and commercial perspective, it deals with the possibility of measuring some parameters in a standard way (e.g., safety of a home assistant robot) or of having objective benchmarks to compare and evaluate different products.

In an effort of improving the quality of experimental activities, some attempts [36.4] have been made to take inspirations from how experiments are performed in traditional sciences, such as physics and biology, by trying to translate in the practice of autonomous robotics the general experimental principles of natural sciences (comparison, repeatability, reproducibility, justification, explanation, . . .). However, from a recent analysis [36.5], it emerges that these principles are not yet full part of the current research practice. Let us consider for example reproducibility, namely the possibility to independently verify the results of a given experiment so that different experimenters should be able to achieve the same results, by starting from the same initial conditions, by using the same type of instruments, and by adopting the same experimental

techniques. Notwithstanding emphasis is put on the importance of reproducibility (usually called replicability in this context) as a way to increase the experimental level of the field, good practices to promote it, such as the availability of shared data and code, are still not very common and few attempts have been made to critically analyze how reproducibility should be attained in experiments with autonomous robots.

It is true that, dealing with technical artifacts, robotics cannot be fully assimilated to a natural science, where experiments are generally conducted for hypotheses testing purposes and with a strong theoretical background. Robotics possess an engineering component that makes it plausible to adopt the notion of directly action-guiding experiment to give reason of its experimental practice: experiments in engineering fields have other objects (technical artifacts rather than natural phenomena) and other purposes (testing rather than understanding) – to put it simple – with respect to experiments in the sciences. Robot systems are human-made artifacts; accordingly, experiments have the goal of demonstrating that a given artifact is working with respect to a reference model (e.g., its requirements or its expected behavior) and, possibly, that it works better than other similar artifacts with respect to some metrics, thus making experiments closer to tests typical of engineering disciplines. At the same time, the most advanced robot systems are extremely complex, and their behavior is hardly predictable, even by their own designers, especially when considering their interactions with the natural world, which are difficult, if not impossible, to model in a fully satisfactory way. In this sense, experiments in autonomous robotics have also the goal of understanding how these complex systems work and interact with the environment and, therefore, are somehow similar to experiments in the natural sciences. We will see how this peculiar position at the intersection between science and engineering is reflected also in the experimental practice characterizing the field.

In the following sections, we attempt to depict the picture of how the topic of experiments in autonomous robotics has been recently addressed. However, as this

debate is still very open, we will not present any systematic and complete survey, but rather a number of issues, results, initiatives – also partially overlapped – able to give back the sense of this intriguing and interdisciplinary research field, devoted not only to the investigation and development of methodological approaches, but also to rethink of the traditional notion of experiment as developed so far. The rest of the chap-

ter, thus, will cover various topics stemming from the attempt to develop good experimental methodologies in autonomous robotics, to simulations, benchmarks, standards, and competitions. Being the field not yet fully systematized, we will present the state of the art intertwined with some considerations in order to offer a more structured, even if still partial, view of this field and its progress.

### 36.3 From Experimental Computer Science to Good Experimental Methodologies in Autonomous Robotics

The reflection on experiments and the application of the experimental method to the broad field of computer science has traversed the history of this discipline from its beginning. Probably one of the first and most famous definitions of computer science as an experimental science goes back to the 1976 paper by *Newell* and *Simon* published in the occasion of their acceptance of the Turing award [36.6, 114]:

“Computer science is an empirical discipline. We would have called it an experimental science, but like astronomy, economics, and geology, some of its unique forms of observation and experience do not fit a narrow stereotype of the experimental method. None the less, they are experiments. Each new machine that is built is an experiment. Actually constructing the machine poses a question to nature; and we listen for the answer by observing the machine in operation and analyzing it by all analytical and measurement means available.”

This conception of machines and programs as experiments has been influential for many years, promoting the idea that the appeal to experience is fundamental in contrast with the view of computer science as a pure mathematical and deductive discipline.

The quest for experiments in computing began to be treated systematically at the beginning of the 1980s, following a crisis in what was then called experimental computer science. In an Association for Computing Machinery (ACM) report published in 1979 [36.7], experimental research in computer science is strongly related to the measurement and testing of computing algorithms and systems. At the same time, a *rejuvenation* of experimental computer science is advocated from very concrete perspectives: for example, by promoting experimental facilities for computer systems research. Experimental computer science is to be rejuvenated also according to *Denning*, who proposed in a short article that the experimental work produced in computer science should be judged by traditional stan-

dards [36.8]. In a way, this approach tries to go beyond the *construct and test* paradigm of Newell and Simon, by proposing that experimental computer science has to deal with the process of supporting and testing hypotheses, thus making computing closer to the standards of rigor and the practice of traditional sciences.

More recently, a trend has once again emerged toward making the experimental scientific method take center stage in computing. These recent efforts have shown a renewed need for an experimental methodology in this discipline [36.9–12]. Experiments are deemed to have an impact on several aspects of computing: their importance is recognized for assessing computing systems’ performance and for triggering new developments. Despite the increasing interest in a more rigorous methodological approach to computing, many lament that the current methodology is inadequate and that, in comparison with other fields (e.g., natural sciences), computer scientists should experiment more [36.13]. Indeed, several articles describe demonstrations rather than real experiments [36.14], and their sections on experimental results present just weak examples to show the superiority of the proposed solution over a limited amount of alternatives [36.15, 16]. Many of these recommendations [36.17–20] present common traits: they stem from the acknowledgment of a crisis in computing that is meant to be overcome with a greater maturity of the discipline, in terms of a more rigorous experimental method and a more scientifically grounded approach to the search for solutions. Taking inspiration from experimental principles adopted in traditional scientific disciplines has become a leitmotif in many analyses, which recognize, for example, the benefits of replicable results [36.21] or the importance of negative results [36.22], two of the cornerstones of experimental scientific method. However, some authors warn about the acritical adoption of principles coming from traditional science [36.23].

The same concerns can be individuated also in the debate about the nature and role of experiments in

autonomous robotics. A seminal paper in this respect is [36.24] that, despite its emphasis on artificial intelligence (AI) and artificial agents, presents an insightful analysis on the topic of experimentation that constitutes the basics of the current debate in autonomous robotics. This paper, in particular, analyzes the possible relationships between controlled experimentation and the rise of benchmarks and testbeds as current research tools. At the same time, it warns against the idea that their use is sufficient to achieve scientific progress. According to the authors, unless generalization and explanation are provided, benchmarks and testbeds, even when appropriately providing metrics for comparing competing systems, do not constitute real scientific progress.

The interest in solidly based experimental research in autonomous robotics has progressively increased in the last 20 years. An interesting example is given by the symposium series on Experimental Robotics, which have been held starting from 1989 on the topics of experimental robotics research [36.25]. However, it is only in the last years that this interest has been coupled with a careful analysis on how the concept of experimentation should be translated in the practice of autonomous robotics, also giving rise to a debate about the status of the discipline itself. To this end both the creation of the EURON Special Interest Group on Good Experimental Methodology in Robotics Research (GEM) and the series of workshops about replicable experiments in robotics [36.26] have been playing a decisive role. The workshop series has contributed to raise several issues and to increase the sensibility of the community on these topics. If we consider the article [36.27] as representative of the kind of approach advocated we can see that, besides the discussion of practical issues, several more theoretical aspects are discussed, ranging from the scientific status of robotics to the definition of a robotics experiment. If, from the one side, much emphasis is put on the definition of a replicable robotic experiment, taking inspiration from the traditional approach of experimental sciences, from the other side, the guidelines proposed within the GEM Special Interest Group represent an attempt to translate in practice the same definition. In particular, the paper [36.26] presents a structured set of questions intended to help reviewers recognize, and authors write, high quality papers reporting of replicable experimental work, addressing questions such as *Are the system assumptions/hypotheses clear? Are the evaluation criteria spelled out explicitly? Is there enough information to reproduce the work? Are the drawn conclusions precise and valid?* The questions are further debated in the special issue on Replicable and Measurable Robotics Research of the IEEE Robotics and Automation Magazine [36.28].

Within the context set by the above efforts, a particular interesting proposal in the direction of promoting rigorous experimental research in robotics is that described in [36.29] in which, besides adopting the standards by which scientific experiments are usually designed, conducted, and presented, particular attention is devoted to the other sciences of the artificial, e.g., human–computer interaction and human–robot interaction, as a way for shaping good experimental research practices in the broader robotics community. It is worth noticing that this work is extremely mature in the acknowledgment and in the analysis of the many open critical issues toward the construction of a science of robotics, putting a right emphasis in particular on two key points: the humility to give oneself the chance to be wrong and the importance of generalizable results that, even if difficult, are not impossible.

In the same direction [36.4] identifies some basic issues of experiments in mobile robot localization and mapping, starting from a representative sample of the current state of the art. These issues, when viewed in the context of some general principles about experiments in science (comparison, reproducibility and repeatability, justification and explanation), permit to derive some insightful considerations on the role of experiments in mobile robotics, ranging from questions about the purpose of experiments to the current publication policies that should be revised accordingly. In particular, the analysis is conducted in the light of some principles that have been proposed for the development of good experimental methodologies in autonomous robotics, and in particular:

- *Comparison*, as the knowledge of what has been already done within a field and the possibility for researchers to accurately compare new results with the old ones.
- *Reproducibility*, as the possibility for independent scientists to verify the results of a given experiment by repeating it with the same initial conditions, instruments, and techniques.
- *Repeatability*, as the property of an experiment that yields the same outcome from a number of trials, possibly performed at different times and in different places.
- *Justification and explanation*, as the capacities to derive well-justified conclusions and to look for an explanation.

Moreover, [36.5] arguably provides one of the few systematic analyses of the current experimental trends in the autonomous robotics papers presented over 11 years at the *International Conference on Autonomous Agents and Multiagent Systems* (AAMAS).

The experimental trends identified from the sample of papers considered for the analysis range from those that fit with the above principles (more experiments in recent years, more use of simulations than real robots, increased use of standard platforms) to those that point out some issues that are still critical at the moment (weakness of experimental comparison of systems, little attention to statistical analysis, low availability of data and code) and show that some of the general experimental principles listed above are currently poorly attained.

It is interesting to observe that, from the general discussions on the ways to promote good experimental methodologies, in the very last years also more concrete proposals have been advanced. From the one side, attempts have been made to practically translate the general guidelines in different specific robotic contexts (see [36.30] for an example of how experimental methodologies and suitable metrics for performance evaluation can be applied to carry out repeatable experiments for unmanned marine vehicles). From the other side, different frameworks to practically promote reproducibility of robot systems experiments have been put at work (see [36.31], for an example of a novel process facilitating the reproduction of robotic experiments by

means of different software tools and [36.32] for a facility for experimenting with robots from remote).

An important issue in evaluation of experimental results in robotics is relative to *ground truth*, namely to the availability of the *optimal behavior* or of the *perfect performance* of a robot in a task. For example, for a robot intended to build the map of an initially unknown building, the ground truth is the blueprint of the building; for a robot intended to estimate its own location within a known environment using the data it perceives, the ground truth is the actual position of the robot (for instance, measured by hand). What sometimes makes the evaluation of robot systems difficult is the impossibility of knowing the ground truth, both before and after the completion of the tasks.

In what follows, we analyze the various concrete forms taken by the debate for the development of good experimental methodologies in autonomous robotics: we start by discussing computer simulations and how they are used as experiments in this field; then we continue with benchmarking as a way to objectively evaluate robots systems and the role played in it by standards, to conclude with an analysis on how competitions and challenges are developing toward a more experimental attitude.

## 36.4 Simulation

Although it is out of the scope of the present section to provide a systematic definition of simulations and to discuss the epistemological problems arising from their growing use in scientific practice (for a complete discussion on these issues see Chap. 34 this handbook), we start with a general terminological clarification to focus later on the way in which computer simulations are used as experiments in the field of autonomous robotics.

The ways a simulation can be defined are different and have been the object of attention of many scholars, particularly in the last 20 years (Chap. 34 this handbook). Without the pretense of taking into account the whole debate, we can say that in general a simulation can be considered a way to reproduce the behavior of a system using another system (in line with [36.33]), by providing a dynamic representation of a portion of reality. Simulations are closely related to dynamic models that include assumptions about the time-evolution of a system, as they are based on models that represent a dynamic portion of reality. However, simulations represent reality in a different way than models do. Without entering the discussion on the various meanings of the term model [36.34], it is sufficient for us to say that a model is a representation, where what is represented

in the model depends on the purposes for which the model has been conceived. Consider for instance a scale physical model of a bridge, which is a representation replicating some features of the real object (the bridge that is going to be built) by abstracting from the full details and concentrating on the aspects relevant for the purpose. For example, if the scale model has been constructed in order to show to its purchasers the final shape of the bridge, then it will not be important its material, color, or dimension. If, instead, the scale model has been constructed to test the resistance of some materials, used in construction, to some atmospheric agents, the sole model is not sufficient, but it has to be put in a (controlled) environment where it can be subjected to the actions of the atmospheric conditions. In this case the model is *executed* in the reality by means of the actions performed by the environment. We call this execution of a model a *simulation*. When the model is computational, namely a formal mechanism able to compute functions (Sect. 36.1) and executed by a computer, we call it a *computer simulation*. Therefore, not every execution of a computational model is a simulation. To call it a simulation, a computational

model must represent a system whose state changes in time.

It is undoubtedly evident that science today has entered what has been called the *age of computer simulation* [36.35]: the massive use of computer simulations in virtually every domain of science has drawn attention to their epistemological justification. Recently the experimental properties of computer simulations have been examined, and philosophers have begun to consider in what sense, if any, computer simulations are experiments (see [36.36] for a detailed analysis of this debate). Positions range from a full acceptance of the identity thesis (computer simulation studies are literally instances of experiments) to its rejection in different degrees. We believe that focusing on autonomous robotics, simulations *can be used* as experiments in the case in which the purposes of simulation and those of experiment coincide. This happens when experiments and simulations are performed for discovering new explanatory hypotheses, for confirming or refusing theories, for choosing among competing hypotheses, and so on. Indeed, besides exploiting similar techniques, experiments and simulations share the ability and necessity of controlling the features under investigation. The set-up of a simulation presents several communalities with that of an experiment: hypotheses to be tested, circumstances to be controlled, and parameters to be set. Moreover, simulations can be used as experiments for a number of practical reasons. They can be used to perform several accelerated experiments, as simulations can be repeated exactly with small efforts, with guarantee of a precision degree not always possible in empirical cases. Simulations can be used to perform experiments that are difficult to make in reality, being free from many of the practical limitations of real experiments, such as the possibility to change boundaries and initial conditions. Simulations can also be used to perform experiments that are impossible to make in reality, such as studying realms of reality which are not physically accessible. However, it is perfectly plausible to have simulations that are made without any experimental purpose in mind (for example, think of simulations adopted for teaching purposes).

The use of computer simulations in science calls for the epistemological justification of their results. Usually the reasons for trusting simulations are two-sided: either the models used in simulations are strongly grounded in well-founded theories or there are experimental data against which simulation results can be checked. This is not always possible when simulations are used as forms of *explorative experiments*, where neither well-founded theories nor experimental data are present, and where the main sources of credibility for such simulations seem to be: the prior successes of the

model-building techniques adopted, the production of outcomes fitting well with previously accepted data, observations, and intuitions, and the capability of making successful predictions and of producing practical accomplishments.

In autonomous robotics, the use of simulations for experimental purposes has grown along the years (see the most recent proceedings of the conference series on *Simulation, Modeling, and Programming for Autonomous Robots* [36.37] for an overview of the different applications). Several papers today present only experiments performed in simulation to validate a proposed robot system. Simulations provide a convenient way to explore different robotic scenarios at lower cost with respect to using real robots. They reduce the effort needed for writing software programs, debugging them, and displaying results. They also often run much faster than their real counterparts. As we have seen, a simulation needs a dynamic model of the system it reproduces. In the case of autonomous mobile robotics, the system that is reproduced is a robot that acts in an environment. The dynamic model must therefore include a representation of the robot and a representation of its interaction with the environment. Let us detail the elements involved in these two representations in the case of mobile robots. Roughly speaking, a mobile robot is modeled by representing its locomotion, sensing, and control subsystems. The interaction of a mobile robot with an environment is a complex issue. For example, it involves a model describing the behavior of the robot in the environment after the control subsystem issued a command. If the command is *go forward* 50 cm, the actual movement of a wheeled robot in a real environment could be more or less than half a meter because of slipping wheels, of rough terrain, of errors in the motors moving the wheels, and of several other reasons. Indeed, it is not always easy to capture this variability in a computational model. Similar problems emerge in modeling the perception of the robot in the environment. Current robotic simulations model in different ways the uncertainties on the effects of actions and on the perceptions. A first approach to uncertainty is usually based on use of physical engines (see below), while a second approach is based on artificially adding uncertainty to the data, according to different probability distributions.

Autonomy makes modeling a robot's interaction with the environment even more complicated, because these interactions are hardly predictable. This is probably one of the reasons for the late adoption of simulations in autonomous robotics. Until few years ago, the models of interaction between robots and the world were not sufficiently accurate and using simulations based on these models was simply not convenient for

the community. If a simulation is based on inaccurate models of the interaction with the world, it is not representative of the behavior of real autonomous robots and, as such, cannot be used to validate the behavior of the simulated robots and to generalize it to real robots. Nowadays, one of the most used *simulator* for autonomous mobile robots, USARSim [36.38], models the interaction of robots with the environment using a software, called Unreal engine, initially developed for a multiplayer combat-oriented first-person shooter computer game, Unreal Tournament 2004. Unreal engine contains a physical engine that accurately simulates the interaction of three-dimensional physical objects and that allows to obtain highly realistic simulations, which have been validated against real data [36.39, 40]. Resorting to components developed in the extremely competitive field of computer games is an interesting way to have state-of-the-art models of the physical interaction between objects.

Another interesting trend that is emerging is the use of publicly available data sets composed of data collected in the real world by some researchers ([36.41, 42] can be considered among the first examples of this tendency). These data sets consist in sensor data collected in real-world experimental tests of robot systems and made available to test other robot systems. From the one hand, we can think of these data sets as models of the interaction between the robots and the real environment. Using these data sets appears very similar to perform a simulation, in which the underlying model is very precise, because it exactly records the interaction of real robots with real world. According to this view, the difficulty of building a model for a simulation of how a robot perceives the environment is addressed by letting the data collected during real operations be the model. From the other hand, using publicly available data sets can be considered as a real (not simulated) experiment, in which activities of collecting and processing real-world data are performed in different places at different times. Another initiative, OpenSLAM [36.43], takes a step further and aims at sharing not only data sets, but also the code of the software systems of robots, in this case relative to the simultaneous localization and mapping problem. What is emerging here is a sort of continuum, ranging from performing completely simulated experiments, to using data sets like to performing real-world experiments.

If we consider the systematic, even if limited, analysis of the trends in using simulations for experimental purposes in autonomous robotics that we have already discussed [36.5], we can observe an increasing use of simulations over the years. Results show that the fraction of papers with experiments that use simulated

robots has increased and, in general, simulation dominates over real robots, which can be explained by the lower costs and the relatively easier operational aspects of simulation (Fig. 36.1).

It is interesting to notice that the fraction of papers presenting experiments with real robots is somehow constant over the years. This could be related to the fact that papers addressing some topics, like target tracking, are more frequently presenting experiments with real robots. A common situation is that in which extensive experiments are performed in simulation and simpler demonstrations are performed with real robots. By considering the simulation tools, with a particular focus on standard simulators as opposed to custom ones (where the former ones refer to commercial or publicly available systems, while the latter ones refer to systems that are usually not available outside the laboratory that developed them), the use of standard simulators seems to be increasing over the years, which could be related to the fact that more and more reliable simulation platforms have recently become available (Fig. 36.2).

Looking at the standard simulators used in the last years, it emerges that most of them are used in competitions like RoboCup (Table 36.1).

Despite their increasing use in this community, simulations are often criticized for not being realistic enough, and for producing results that do not transfer easily to the real world, such that until few years ago simulations were considered as *fake robotics* by most researchers. Such problems arise when simulation models are too naive, because they embed insufficient knowledge on the real system, sensors and actuators models are not carefully calibrated, real-world noise is not accounted for, and, most importantly, the correspondence between the simulated performance and that in the real world is not validated. Particularly interesting

Fig. 36.1 Fraction of robotics papers at AAMAS that use simulated and real robots in experiments (after [36.5])

for this discussion, as it is representative of many open issues, is a post about simulations as a research tool in robotics recently appeared on *Winfield's* blog [36.44]. Besides the provocative opening (“If you write papers with results based on simulation and submit them for peer-review, then be warned: if I should review your

paper then I will probably recommend it is rejected.”), a list of insightful criticisms is discussed. It is claimed that papers presenting results based on simulation have the following problems, not always related to the very nature of simulations but sometimes to the presentation of results: the lack of details on the simulation tools used, the lack of validation in the case of custom built simulators, the fact that the robots used to test the algorithms are not specified (real robots or abstractions of robots?), the lack of information on how the robot is modeled in the simulator, the lack of a serious analysis of the limits of these simulation tools (the so-called reality gap), the necessity to provide access to all of code in order to make others repeat the same results. The post concludes by equating an engineering simulation to any scientific instrument [36.45] and with the invitation to treat it accordingly, namely to fit for purpose, to be set-up and calibrated for the task at hand, and to be understood – especially in its limitations. These discussions, far from providing definite answers, show how the simulation topic is under attention today and give the feeling of the evolution not only of the tools, but also of the methodological analysis required to use them in an appropriate way.

## 36.5 Benchmarking and Standards

Devising rigorous evaluation procedures to assess the capabilities, reliability, dependability, and performance of robot systems in precisely defined settings is often referred to as *benchmarking*. Objective evaluation of robot systems is a need for their scientific and technical evolution, for their industrial employment, and for their market positioning. Not surprisingly, benchmarking is strictly related to the development of *standards* for robot systems. This section surveys the efforts in these two areas, keeping the discussion at a general level without attempting to cover all the details of the several benchmarking and standard activities relative to specific areas of robotics.

As already discussed, an early attempt to set up a methodological framework that accounts for the relationships between controlled experiments and benchmarks for artificial agents (of which robots constitute

a significant class) is reported in [36.24]. In this framework, benchmarks are intended to involve “precisely defined, standard tasks” [36.24, p. 17] and, ideally, “problems that are both amenable to precise analysis and representative of a more complex and sophisticated reality” [36.24, p. 19] and that “cannot depend on any system-specific details, nor can the scoring system” [36.24, p. 19]. The goal of benchmarks is then to tell “us something we want to know about the behavior” [36.24, p. 18] of an agent, for which a model of the task is required, especially “when we design benchmarks to be failed, but in this case, we need a model of the factors that make the benchmark difficult” [36.24, p. 19]. On the other hand, controlled experimentation is seen as a different activity, in which [36.24, p. 17] “a researcher varies the features of a system or the environment in which it is embedded and measures the effects of these

variations on aspects of system performance” arguably resulting in more generalizable significant results with respect to benchmarks.

From 1999, significant efforts to promote benchmarks in robotics have been put in place within the EU-funded European Robotics Network (EURON). EURON has performed a number of actions with the goal not only to define specific benchmarks, but also to propose and encourage the acceptance of benchmarks in the community, which culminated in the First European Workshop on Benchmarks in Robotics Research and in the IROS Workshop on Benchmarks in Robotics Research, both held in 2006 [36.46]. Starting from these seminal events, a series of similar workshops have blossomed with the organization and supervision of the EURON GEM Special Interest Group [36.26]. The activities performed in EURON include the proposal of a list of features that a benchmark should have [36.47]: it has to be defined for a *task* valuable in the real world, it has to be *standard* and *precisely defined*, it has to be associated to some *performance metrics*, it has to be *repeatable*, *independent*, and *unambiguous*, and it has to be widely *accepted*. Another contribution from EURON is the advancement of the idea that competitions could serve as benchmarks for “comparing the performance of competing systems by means of very well-defined rules and metrics” [36.46, p. 4]. *del Po-bil* [36.46] also presents an exhaustive survey of the state of the art of the efforts in comparative research, including competitions, benchmarks, challenges, and relevant conferences.

Along the direction traced by EURON, some other projects have been funded by the European Union and have aimed at defining benchmarks for specific robotics domains. For example, EUROP (EUropean RObotic Platform) supported activities on standards, RoSta [36.48] defined a standard benchmark for mobile service robots, and Rawseeds [36.42] produced and made publicly available high-quality data sets collected by robots in real environments, corresponding ground truth data, and benchmark problems on which different algorithms for robot self-localization and mapping can be compared.

In the United States, the National Institute of Standards and Technology (NIST) has actively promoted competitions and field exercises as “two different yet effective ways of systematically evaluating the performance of robotic systems” [36.49, p. 2]. For example, NIST has worked toward the development of performance metrics and standards for robots employed in urban search and rescue applications, taking care “not to explicitly test for particular technological solutions; rather, the tests measure how effectively or efficiently a robot can complete certain tasks, without assuming

a particular approach” [36.49, p. 3]. In this way, robot capabilities can be evaluated without inhibiting innovations of robot developers. Such standard test methods [36.50] include detailed specifications of tasks that users expect the robot to perform reliably, of scripts for the test administrator and the robot operator to follow, and of quantitative ways to measure the performance of the robot (Fig. 36.3). In parallel to the definition of such standard benchmarking procedures, the PerMIS (Performance Metrics for Intelligent Systems) workshop series has been established as one of the main venues for discussing and disseminating the definition of methodologies to measure the performance of robots in different settings, from industrial to military applications [36.51].

As a matter of fact, practical use of benchmarks (developed by independent organizations) is still limited for most robot applications, notwithstanding several proposals have been advanced for benchmarking robot-specific capabilities, for instance path planning [36.52], navigation [36.53], simultaneous localization and mapping [36.54], and object manipulation [36.55].

Benchmarks have also been proposed to comparatively evaluate robotics software and architectures, as for example in [36.56]. How to move from benchmarking basic robot capabilities to benchmarking more complex cognitive activities is not yet well understood paralleling, in a sense, the difficulty in choosing human intelligence benchmarks. A possibility [36.57] seems to be evaluating a whole robot system (as opposite to evaluating some of its components) while executing a task

Fig. 36.3 NIST Robot Test Facility (photo by NIST)

which is intended to be difficult and to require the integration of different components (e.g., foraging and survival require navigation, image processing, learning, ...). Other two proposals for developing benchmarks for cognitive abilities of robots consist in a collection of individual tasks that, although individually limited in breadth, collectively cover a broad spectrum [36.58] and in setting up a Total Turing Test in which a human interrogator should distinguish the performance of an autonomous robot from that of a tele-operated robot in performing a given task [36.59]. In this context, tasks intended to test the cognitive abilities of robots are sometimes embedded in competitions (as discussed later).

Some negative effects of benchmarks have been reported in other technology domains. For example, to overcome some limitations of computer processors early benchmarks, designed to measure millions of instructions per second (MIPS) and millions of floating point operations per second (MFLOPS), benchmarks evaluating performance of processors using real-world applications were later introduced, but producers then developed specific optimizations in the attempt to perform well on benchmarks [36.52]. Knowing these shortcomings and building on experiences from other domains [36.60] should be considered to avoid the same errors in developing robot benchmarks.

Standardization activities have been performed with the aim of defining methods for the quantitative measurement of the performance of robot systems in order to keep a global quality culture, to set minimum require-

ment levels, to reduce confusion of consumers when developing innovative robots for specific domains (like manufacturing, floor cleaning, ...), and to help scientific research. Unsurprisingly, standard activities have been mostly related to *security* of industrial robots. For example, ISO (International Organization for Standardization) and IEC (International Electrotechnical Commission) have issued standards for safety of industrial and personal care robots ([36.61] for a survey of these and other standard activities within ISO). Other safety standards have been promoted by RIA (Robotic Industries Association) and ANSI (American National Standards Institute). Another focus for standards is the vocabulary. For example, IEEE (Institute of Electrical and Electronics Engineers) has developed a formal reference vocabulary for communicating knowledge about robotics and automation both among robots and between robots and humans [36.62]. Finally, standards for interoperability in robot software development [36.63] and in robot operations, like navigation [36.62], have been proposed.

Overall, benchmarking and standardizing complex systems like robots pose a number of problems [36.49]. For example, developing standards for robot capabilities (like navigation and self-localization) appear to be of a different, and more difficult, nature than developing standards for other devices and technologies (like the Ethernet and other network technologies). Moreover, standards that regulate the interaction between different subsystems usually result in being too *thick*, becoming hard to apply.

## 36.6 Competitions and Challenges

Robot competitions and challenges have flourished since the 1970s, now counting dozens of events per year. From the beginning, it has been recognized that competitions can play several roles in robotics, for example to promote education and research, to push the field forward, to entertain general audience, and to build community [36.64–67]. These roles are often conflicting and balancing them in devising a robot competition has been proven difficult [36.68]. After some early recommendations about being “careful not to confuse a competition with research” [36.69, p. 39], a more recent trend advocates for recasting robotics challenges and competitions as experiments, recognizing that [36.70, p. 10]:

“[c]hallenge and competition events in robotics provide an excellent vehicle for advancing the state of the art and evaluating new algorithms and tech-

niques in the context of a common problem domain.”

Along the same line, it has also been proposed to use competitions as benchmarks, since they provide standardized test beds that are largely independent of the settings roboticists usually experience in their laboratories and allow for direct comparison of approaches for solving a task [36.71]. However, in defining good benchmarks, designers of competitions should avoid to encourage ad hoc solutions instead of more adaptable and flexible approaches [36.68]. This section discusses in some depth the advancements and the results obtained adopting the perspective that views competitions as sort of experiments.

From a broad perspective, competitions and challenges share some similarities with experiments. Robots usually compete in precisely definite settings

and are scored according to precise performance measures, which parallel, at least to some degree, the controlled conditions and measures of experiments. However, competitions and challenges often evaluate whole robot systems, while experiments presented in the literature mainly evaluate a single robot ability or subsystem. Moreover, some challenges are intended to be performed just once, while experiments aims at being reproducible (Table 36.2). More generally, robotics competitions and challenges usually evaluate general abilities of robot systems and push to development of solutions, while experiments evaluate specific hypotheses, explore phenomena, and share result.

A robotics competition (challenge) usually involves some robots, a dynamic, but rather controlled, environment, a clear measure of success, and rules for calculating scores [36.72–74]. Without attempting at providing any exhaustive survey and detailed account of how specific events are organized and run, in the following we discuss some robotics challenges and competitions in order to trying to assess their potential role as experiments.

One of the best known examples is RoboCup [36.75], which is taking place since 1996 and aims at providing “a standard problem so that various theories, algorithms, and architectures can be evaluated. Computer chess is a typical example of such a standard problem.” RoboCup features robotic soccer (Fig. 36.4), rescue, and home competitions, in which robots compete in dynamic unpredictable environments with real-time constraints. Competitions take place both in the real world and in simulation. The environments are precisely defined and can be easily reproduced in different places. However, this is not true for other elements that characterize the competition, like the opponent team and the light and noise conditions. In the soccer competitions, the measures and the criteria according to which two robot systems (teams) are compared are clearly defined only for the purposes of the game. For example, it is difficult to draw any conclusion about the general behavior of robots and their components from the fact that one team won, say, 2 : 0 against another team. In other leagues, like in RoboCup@Home, some attempts have been recently made toward more solid procedures to benchmark and track the progress of robots in per-

**Fig. 36.4** Humanoid Kid Size League match at RoboCup 2011 (photo by Viktor Orekhov, <http://www.robocup2013.org/press/>)

forming tasks (that are possibly changed over time to keep the competitions challenging) [36.76].

The DARPA Robotic Challenge (DRC) [36.77] consists of tasks related to human assistance in responding to disasters, “[i]t was designed to be extremely difficult.” Tasks are related to the development of autonomous humanoid-like robots able to operate in hazardous settings. During the DRC trials, in December 2013 (Fig. 36.5), the main scoring mechanism has been task completion (e.g., number of open valves), while time has not been a factor (taking 30 s and 30 min to complete a task is worth the same amount of points), but is used as tiebreaker. The goal of the DRC trials, beyond selecting teams that will advance to the finals, has been to set up “a baseline on the current state of robotics.” In the DRC finals, that took place in June 2015, speed weighted more in the score.

The interest in designing competitions as experiments has also resulted in two projects funded by the European Union under the FP7 Challenge 2 *Cognitive Systems and Robotics*. euRathlon [36.78] is an outdoor competition for robots involved in emergency-response scenarios. In the words of their organizers:

“euRathlon aims to be an important milestone for robotics research. Not only will it provide opportunities to put the latest robotics technologies to test under realistic disaster scenario conditions, we also recognise that there is currently an urgent need to develop useful benchmarks that will advance the field of robotics.”

The 2013 competition has been for ground robots, the 2014 competition for underwater robots (Fig. 36.6), and the 2015 competition required a “team of terrestrial, marine, and aerial robots to work collaboratively to survey the scene, collect environmental data and identify

**Table 36.2** Competitions versus experiments

Competitions	Experiments	
Precisely defined settings	Controlled conditions	✓
Performance measure	Measures	✓
Involve whole robot systems	Evaluate single robot abilities	✗
Sometimes performed just one time	Tend to be reproducible	✗

**Fig. 36.5** A test trial of the DARPA Robotic Challenge (DARPA)

critical hazards.” The settings in which the competitions take place are precisely defined to represent mock emergency-response scenarios, including conditions like limited visibility and salty water. Scores of the competitions have been a mix of measured quantities and subjective judgments given by a human Judging Team. Data sets recorded during the competition are made publicly available to the community as “a valuable pool for benchmarking, testing and comparison”.

The other EU-funded project is RoCKIn [36.79] that addresses domestic (RoCKIn@Home) and industrial (RoCKIn@Work) environments, focusing on autonomous service and industrial robots, respectively

**Fig. 36.6** euRathlon 2014 competition (<http://www.eurathlon.eu/>)

(Fig. 36.7). Explicit emphasis is put on “assess, compare, and evaluate competing approaches” exploiting “benchmarking procedures and good experimental methods” making the “integration of benchmarking technology with the competition concept [...] one of the main objectives of RoCKIn.” In both @Home and @Work competitions, rules precisely define the settings for the competitions. One of the distinctive features of RoCKIn is in its scoring system, which is based on the presence of two classes of benchmarks, called task benchmarks and functionality benchmarks, somehow following the approaches proposed in [36.47] and in [36.80]. The first ones are devoted to evaluating the performance of integrated robot systems, while the second ones focus on the performance of specific subsystems (like object recognition and localization). A *task benchmark* deals with complete robot systems, implying that a large set of interacting robot elements are examined together at the same time. *Functionality benchmarks* define a precise setup in which a single robot functionality can be evaluated. Such evaluation is performed according to well-specified quantitative measures and criteria, specific for the functionality under test. Also RoCKIn makes data collected during competitions available to the community.

From the above picture, it emerges that the question whether robotics competitions and challenges are

**Fig. 36.7a,b** RoCKIn@Home (a) and RoCKIn@Work (b) competitions (copyright by RoCKIn project)

experiments is far from being satisfactorily answered. However, an interesting attempt to provide a partial answer could come from considering different competitions and challenges as different forms of experimentation, for example starting from the taxonomies of experiments performed in computing and in AI as presented in [36.81] and [36.80]. For instance, referring to the classification of [36.81], RoboCup soccer competitions seem to be between *feasibility experiments*, that are basically a form of empirical demonstration, intended as an existence of proof of the ability to build a tool or a system, and *trial experiments*, which take a step further and evaluate various aspects of systems using some predefined variables which are often measured in laboratories, but can occur also in real contexts of use (with some limitations). The DARPA Robotics Challenge and euRathlon support the idea of *field ex-*

*periments*, which are similar to trial experiments, but take place outside the laboratory in complex sociotechnical contexts of use. Finally, the RoCKIn competitions seem to aim at moving toward *comparison experiments*, which refer to comparing different solutions in some setup and based on some precisely defined measures and criteria to assess the performance. Overall, no current competition fulfills the requirements for the *controlled experiments*, namely the golden standard of experimentation in the natural sciences that refers to the original idea of experiment as controlled experience, where the activity of rigorously controlling (by implementing experimental principles such as reproducibility or repeatability) the factors that are under investigation is central, while eliminating the confounding factors, and allowing for generalization and prediction.

## 36.7 Conclusions

In this chapter, we have discussed the issues involved in the experimental assessment of computational models embedded in autonomous robots. These are particularly challenging because of their interaction with the real world. The current debate on the development of good experimental methodologies in this field has been our starting point, together with the acknowledgment that robotics, at least from a methodological point of view, lies in between science and engineering. This is also the reason why, besides the traditional notion of epistemic experiment, also that of directly action-guiding experiment, as recently conceptualized in the philosophy of science and technology [36.3], is relevant. This field is still very open and, thus, it is impossible to present a coherent and systematic view. For this reason, we have chosen to present a number of topics and initiatives that are currently under discus-

sion and various and profitable interconnections among them. In doing so, we have tried to give an overview of the main trends, but at the same time we have pointed out many criticalities and some promising directions.

Besides the undeniable role for the development of the disciplinary status of autonomous robotics and its methodological maturity, we believe that this debate has the potential to constitute a possible starting point to revise and enlarge traditional model-based science [36.82], intended as a way to representing and understanding the world, toward model-based engineering, where specific scientific and technological practices are taken into account and where modeling practices are justified mostly from a pragmatic point of view in a methodological context that privileges contexts and purposes over representations [36.83].

# Biorobotics

## 37. Biorobotics

Edoardo Datteri

Starting from a reflection on the various roles played by simulations in scientific research, this chapter provides an overview of the biorobotic strategy for testing mechanistic explanations of animal behavior. After briefly summarizing the history and state of the art of biorobotics, it also addresses some key epistemological and methodological issues that need to be taken into serious consideration when setting up and performing biorobotic experiments. These issues mainly concern the relationship between the biorobot and the theoretical model under investigation, the choice of criteria for comparing animal and robotic behaviors, and the pros and cons of computer versus robotic simulations.

### 37.1 Robots as Models of Living Systems

#### 37.1.1 Data-Oriented and Model-Oriented Simulations

Computing devices are used in contemporary biological and psychological research not only as *number-crunching* tools for the analysis of experimental data, but also to simulate theoretical models of biological and cognitive systems. Two broad classes of computer simulation studies are found in the current scientific literature. A typical example of the first class is biomolecular simulation of the behavior of ion channels [37.1]. Ion channels are proteins arranged to form pores in the membrane of cells. Under particular chemical and physiological conditions, they undergo conformational changes that permit or block the movement of particular substances across the membrane. A detailed reconstruction of these changes is difficult to obtain via current molecular imaging technologies [37.1, p. 430]:

“A variety of experimental techniques can provide information about the dynamics of proteins and other biomolecules, but they are generally limited

in their spatial and temporal resolution, and most report ensemble average properties rather than the motion of individual molecules.”

Computer simulations may be used to overcome these difficulties. The detailed molecular structure of a particular class of ion channels may be represented by a program and the system may be allowed to compute the conformational changes that these channels would undergo under various chemical conditions, according to the physical laws governing atomic interactions. Simulations of this kind therefore [37.1, p. 429]:

“serve as a computational microscope, revealing biomolecular mechanisms at spatial and temporal scales that are difficult to observe experimentally.”

Biomolecular simulations exemplify one of the roles played by computer simulations in scientific research, namely the role of *generating data* about the behavior of a system. This is the use made of computer simulations in what we will here refer to as *data-ori-*

ented simulation studies. As illustrated by the proposed example, data-oriented simulations may be particularly useful when the required data are difficult or impossible to obtain by means of conventional observational or measurement techniques: in these cases, “simulations [...] replace experiments and observations as sources of data about the world” [37.2].

Simulations are not always used for this purpose, however. In many cases, they are used to *test a theoretical model* of the target system, rather than to obtain data about it. This is a *model-oriented* use of simulations (Fig. 37.1). A distinction between these two classes of simulation studies has also been proposed by *Guala* [37.3], who defined it in the following terms:

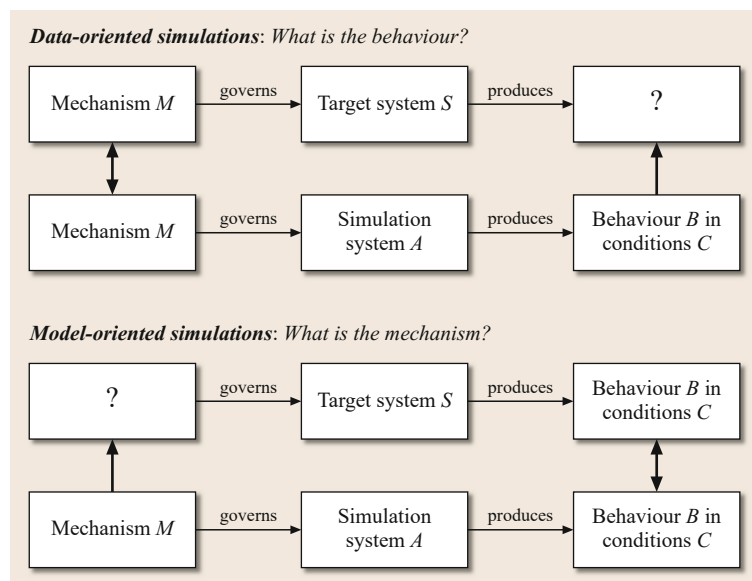

“Typically, simulations are used in one of two different ways: either (1) to bootstrap from the fact that a given effect (which we have observed in system *A*) can be produced by means of simulation *B*, to the fact that the relations governing the behavior of *B* also govern the behavior of *A*. Or (2) to argue that a certain effect observed by simulating with *B* will also be observed in the case of *A* because the two are governed by similar relations.”

Cases 1 and 2 correspond to model-oriented and data-oriented simulation studies, respectively.

In cognitive science and neuroscience, robots are often used as model-oriented simulations. For example, in so-called *biorobotic* studies, which are the main focus of this chapter, robots are used to test theoretical models of human and animal behavior. Interestingly, biorobotic, model-oriented simulation studies predate the creation of the first digital computer. What is per-

haps the first example of biorobotic simulation dates to 1913, when engineers John Hammond Jr. and Benjamin Miessner built a robot, known as the *electric dog*, which was able to track light sources by means of a simple sensory-motor mechanism. Notably, the mechanism implemented was similar in many respects to that which physiologist *Jacques Loeb* [37.4] had suggested was used by moths to seek light sources [37.5]. The fact that *by virtue of this mechanism* the robot was able to generate a light-seeking behavior – thus replicating the behavior of moths to some extent – was taken by Loeb himself as corroborating his claim that the hypothesized mechanism could also account for the light-seeking abilities of moths. The behavior of the *electric dog* robot was thus taken as a basis on which to test (and ultimately in this case, to accept) a theoretical model of insect behavior.

Since that first pioneering instance, robots have been used to test a variety of models of animal behavior: a history and a concise summary of the state of the art are provided in Sect. 37.2. One purpose of this chapter is to outline the structure of robotic model-oriented simulation experiments. It is worth noting that the expression *simulation experiments* is used here to refer to scientific experiments involving (robotic) simulation systems. It is not meant to imply that simulations are experiments in any significant sense of the term. Rather, it is here assumed that simulation systems are something that can be experimented on, given that one can assess their behavior under various experimental conditions and in response to interventions of various kinds. Moreover, it is assumed that simulation systems may be actively used as experimental tools at some step

**Fig. 37.1** Diagram illustrating the distinction between data-oriented and model-oriented simulations. As explained in the text, data-oriented simulation systems implement the mechanism governing the target system *S* (as illustrated by the *double arrow*) to find out what behavior *S* would display under conditions *C*. In model-oriented simulation experiments, matches or mismatches between the behaviors of *S* and *A* under conditions *C* are taken as a basis for testing whether the mechanism implemented in *S* coincides with the mechanism *M* implemented in *A* or not

in a procedure aimed at gathering data on, or testing a model of, a biological system (see Chap. 34 by *Imbert* in this volume and [37.6], for an analysis of whether simulations can be *literally* regarded as experiments).

Another purpose of this chapter is to raise some interesting methodological and epistemological issues biorobotics experiments give rise to, including the issue of understanding under what conditions one is justified in taking robotic behaviors as a basis for accepting or rejecting a biological or cognitive theoretical model (for other epistemological and methodological analyses of biorobotic methodology that address many of the issues discussed here, see [37.7–10]). These issues point to the existence of a gap between being able to *reproduce* a given behavior in a robotic or computer system and being able to *explain* it. Before going on to address them, and to examine the structure of biorobotic methodology in detail, it may be useful to provide a preliminary analysis of the notions of theory and explanation in cognitive science and neuroscience.

### 37.1.2 The Structure of Biorobotic Methodology

#### Behavioral Explananda

Explaining human and animal behavior is one of the primary goals of the cognitive sciences and neurosciences. The phenomena to be explained in these areas – whose linguistic formulation is often referred to as explanandum (plural explananda) in philosophical analyses of the concept of explanation – typically consist of *behavioral regularities*, that is to say, regular connections between a set of environmental conditions *C* and a behavior *B* (for the sake of brevity, in this chapter the term explanandum refers both to the statement describing the phenomenon to be explained and to the phenomenon itself). The term *C* refers to a more or less large set of environmental conditions (such as the presence of a light source, a minimum external temperature of 20°C, the absence of electromagnetic fields), while *B* stands for a more or less abstract description of the motor behavior of the target system (such as percentage success rate in hitting the light source over a given period of time, or the trajectory followed by the animal while approaching the light source). For example, Loeb's explanandum, which consists of a regular connection between the presence of a light source (*C*) and the generation of motor trajectories leading to the light (*B*), may be formulated in this way.

Cognitive and neuroscientific research often seeks to explain human and animal *capacities*, such as the ability to control arm movements in order to reach a target specified within a given sensory frame of reference (see for example [37.11]). Capacities may be reformu-

lated as behavioral regularities [37.12]: for example, the ability to reach a target with one's hand may be reformulated as a regular connection between the presence of a target (possibly plus other conditions of environmental normalcy) and the generation of movements bringing the arm endpoint into proximity of this target. Higher-level cognitive capacities may be formulated as behavioral regularities too. Contemporary research on spatial memory capacities in rats [37.13] seeks to explain, for example, why rats regularly make fewer and fewer errors in locating a reward in a maze on each successive trial, and why they make errors of a particular sort when some aspects of the environment are selectively changed. Many cognitive studies attempt to explain why humans regularly manage to solve particular classes of problems or why they show regular reactions to certain complex stimuli (for example, why it systematically takes a longer time to say the color of the word *red* written in green than to say the color of the word *green* written in green, the so-called Stroop effect, [37.14]). This is not to say that the explanation of *singular* behaviors – *why did system S display behavior B in experimental trial number 312?* – is never pursued. Indeed, that question would first be addressed by identifying the conditions *C* holding in trial number 312 and supposedly responsible for that singular (or exceptional) behavior. From that point on, the explanandum would then take the form: *why does S regularly produce B under conditions C?*

#### Behavioral Mechanisms

Explanations in the cognitive sciences and neurosciences typically include a description of a *mechanism M* supposedly responsible for a behavioral regularity *R* (for the sake of brevity, the term *M* will be used in this text to refer both to the description of a mechanism and to the mechanism itself, depending on the context). Detailed analyses of the structure of neuroscientific and cognitive mechanism descriptions are provided in [37.15–18]. For the purposes of the present discussion, it is sufficient to note that explanatory mechanism descriptions specify a number of components, characterize the behavior of each component in a more or less precise way, and define how these components interact with one other. For example, *Wolpert et al.* [37.11] explained motor control abilities in humans by describing a mechanism made up of various components (notably including an *inverse model* of the controlled object) and the mutual connections among these components (for example, by stating that some parameters of the *inverse model* component vary as a function of output from a *feedback controller* component). The behavior of each component is typically formulated as a regularity (which takes the form of an input-output regularity

in cognitive models). For example, the behavior of the *inverse model* component in [37.11] is characterized as a mapping from desired trajectories to motor commands.

Here a fundamental difference emerges between explanations in neuroscience and in cognitive science. Neuroscientific explanations use the theoretical vocabulary of the neurosciences to describe explanatory mechanisms: they define mechanisms in terms of the electrical or chemical behavior of neurons and neural areas. Cognitive science explanations describe explanatory mechanisms in terms of representations and information processing modules: the components of cognitive science mechanisms typically perform input-output mappings among representations possessed by the system (see [37.19] for a more specific analysis of the relationship between cognitive and neuroscientific mechanism descriptions).

Note that the term *theory* is often used in these fields to denote explanatory mechanism descriptions. For example, the theory on rodent navigation described in [37.20], and tested by means of computer model-based simulations, coincides with the description of a mechanism that supposedly enables rats to effect a number of spatial behaviors. The term *explanation* on the other hand is typically used to denote a structure composed of an explanandum and an explanatory mechanism description.

### Abstraction

To set the stage for the ensuing discussion of the methodological issues arising in biorobotics, it is worth reflecting on the *abstract* character of mechanistic explanations of behavior. Such explanations may be said to be abstract for at least two reasons. To introduce the first of these reasons, let us once more focus on Loeb's *explanandum*: when moths are in the proximity of a light source, they regularly generate movements leading to it. As it stands, this is a literally *false* assertion. Any generalization (i. e., a statement expressing a regularity) is strictly speaking false when it has exceptions, and moths do not *always* reach light sources. They will be unable to do that, for example, if their light receptors are damaged, if some other internal drive prevails over the light-seeking one, or if transparent glass is interposed between them and the light source. For analogous reasons, rats do not always improve their goal-seeking abilities in mazes on successive trials: the explananda addressed by contemporary studies on spatial memory in rats consist of, strictly speaking, literally false (exception-ridden) generalizations. They would be true only in the absence of a number of possibly perturbing factors, which typically are not, or only partially, specified in *C*. How then may we interpret

the claim that *S* regularly produces *B* under conditions *C*? Should one end up conceding that neuroscientists and cognitive scientists work with literally false (i. e., exception-ridden) explananda?

To adopt a more reasonable position, in line with the so-called semantic conception of scientific theories [37.21], we may say that neuroscientific and cognitive explananda state the behavior of *ideal* systems. According to this interpretation, claiming that system *S* regularly produces behavior *B* under conditions *C* amounts to making a counterfactual claim about an ideal system placed under ideal conditions: were *S* subjected *only* to conditions *C* – in other words, were *C* a correct and complete description of the conditions under which *S* stands – it would regularly display behavior *B*. Mechanism descriptions are abstract too. They clearly do not describe *all* the mechanisms found in the target system *S*, but only the mechanism *M* that is supposed to produce the behavior to be explained; and it is assumed that *M* will produce that behavior only if no perturbing condition intervenes. In other terms, claiming that system *S* exhibits *R* by virtue of mechanism *M* amounts to making a counterfactual assertion to the effect that, were *M* the *only* mechanism at work in *S*, it would produce *R*.

In sum, cognitive and neuroscientific theories are formulated to explain ideal behavioral regularities. They pursue this goal by modeling the behavior of an ideal system governed by the postulated mechanism *M* and by nothing else: hence, they are *abstract* explanations. This view is well expressed by *Frederick Suppe* [37.21, pp. 82–83]:

“The theory does not attempt to characterize the phenomena in all their complexity, but only attempts to do so in terms of a few parameters abstracted from the phenomena. For example, classical particle mechanics attempts to characterize mechanical phenomena *as if* they depended only on the abstracted position and momentum parameters. In point of fact, however, other unselected parameters usually do influence the phenomena; so the theory does not characterize the actual phenomena, but rather characterizes the contribution of the selected parameters to the actual phenomena, describing what the phenomena *would have been had* the abstracted parameters been the only parameters influencing them.”

Note that some contemporary philosophers of science forcefully claim, contrary to what I argue here, that neuroscientists and cognitive scientists address exception-ridden explananda (for example [37.15]). The *prima facie* plausibility of this hypothesis is given by the apparently exception-ridden character of most

neuroscientific *explananda* (the examples on moth locomotion and rat navigation being cases in point). The view proposed here – i. e., that neuroscientists seek to explain the behavior of ideal systems – is preferred, insofar as it is more consonant with scientific practice (see [37.22], for a discussion) and fully in line with the semantic view of scientific theories, whose virtues with respect to the so-called *received view* have been extensively emphasized in the philosophical literature. Whether the methodological analysis of biorobotic experiments proposed here may also fit with a different conception of scientific theories is a question that goes beyond the scope of the current chapter, whose aim is to provide (at the least) a plausible account of how, and under what conditions, biorobotic experiments can assist in the discovery of, and theorization on, biological and cognitive mechanisms.

### Explanation

Having analyzed the nature of biorobotic explananda and theories, it is worth focusing on the notion of *explanation*. Explaining *S*'s behavior *B* under *C* by reference to *M* amounts to making two closely related, but conceptually distinct claims. The first is that:

- 1 All systems governed only by *M* produce behavior *B* when only conditions *C* hold.

This assertion concerns what, in *Suppe*'s semantic analysis of scientific theories [37.21], is labeled the class of *theory-induced systems*, that is to say, the class of the ideal systems defined by the theory under investigation. Explaining *S*'s behavior by reference to *M*, however, implies also asserting the existence of a close relationship between *S* and the class of the theory-induced systems defined by *M*, a relationship that we express here as follows (see [37.21] for a more detailed analysis of the relationship between theory-induced systems and the systems whose behavior is to be explained):

- 2 *S* implements mechanism *M*.

This amounts to asserting that *S* has a number of components behaving and organized as specified in *M*. Of course in reality *S* will have other components and will be affected by boundary conditions not included in the ideal theory-induced systems (here we assume that the ideal theory-induced systems are *impoverished* versions of the concrete systems under investigation, obtained by abstracting out components and features that are deemed to be irrelevant for the present explanatory purposes; however, some theory-induced systems have features that are incompatible with the theory itself; see *Suppe*'s analysis of *idealization* as distinct from *abstraction* in [37.21]).

Claims 1 and 2 are conceptually independent of one another. It may be the case that *M* exhibits behavior *B* under *C* (as asserted by Claim 1), and that, at the same time, *S* does *not* implement *M* even though it displays behavior *B* under *C*: in that case, one concludes that *S* displays *B* under *C* by virtue of a different mechanism to *M*. It may also be the case that *S* actually implements *M*, but that *M* does not produce *B* under *C*: *M* will then be responsible for *other* behaviors exhibited by *S*, and will be irrelevant to explaining why *S* produces *B* under *C*. In both cases, by rejecting either Claim 1 or 2, one rejects the explanation stating that *S* produces *B* under *C* by virtue of *M*.

Distinguishing between these two claims enables us to understand how robots may be used to test cognitive and neuroscientific explanations. Indeed, to evaluate whether *S*'s behavior *B* under *C* may be explained by reference to *M*, one must have good reason to argue that *M* is implemented in *S* (Claim 2) and that *M* alone is responsible for *B* under *C* (Claim 1). As we shall see in the next section, biorobots can be especially useful for testing the latter claim. Before addressing this point, it should be noted that *dysfunctional* behaviors are typically explained mechanistically in cognitive and neuroscience. A dysfunctional behavior is one that differs, to some extent, from the behavior normally produced under particular conditions *C* by individuals belonging to a particular reference class. Explanation of these behaviors proceeds by identifying the mechanism *M* responsible for the *normal* behavior, and by finding out how *M* would need to be *damaged* to produce the dysfunctional behavior. For a thorough epistemological and methodological discussion on the explanation of dysfunctional behaviors in cognitive neuroscience, see [37.23].

### Biorobotics and the Study of Ideal Mechanisms

In the previous section, it is argued that two claims are made in asserting that *S*'s behavior *B* under *C* may be explained by reference to *M*. The first states that a system governed only by mechanism *M*, in the ideal setting in which only conditions *C* hold, would produce behavior *B* (or more concisely, that *M* can produce *B* under *C*). Testing a claim in this form only by reasoning about the structure of *M* and the contents of *C* is likely to be very difficult, even when *M* is relatively *simple*. In [37.24], a basic mechanism is proposed to explain lobsters' ability to reach the source of chemical streams in water (a behavior known as *chemotaxis*). The proposed mechanism is structurally similar to that of one of the first Braitenberg vehicles [37.25] and, incidentally, to the mechanism proposed by Loeb to explain the light-seeking abilities of moths. According to the proposed mechanism, the system has two chemical sensors

(chemoreceptors) located at the two sides of the animal. The higher the chemical concentration perceived by one receptor, the greater the movement on the opposite side of the animal: high concentration on the right side will induce rapid movement of the left motor organs, and vice versa. At first sight, this mechanism seems to be able to guarantee efficient chemotaxis. Suppose, for example, that the source of the chemical stream is located to the right of the animal, at a certain distance from it. In this circumstance, chemical concentration will probably be higher on the animal's right side. According to the proposed mechanism, the left motor organs will be moved faster than the right ones, making the system veer to the right, and thus towards the chemical source.

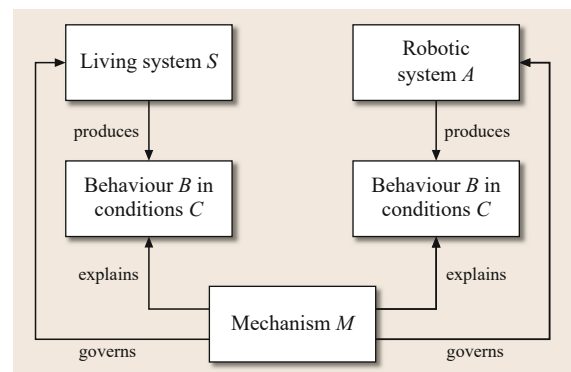

Is this argument sufficient to conclude that the proposed mechanism guarantees efficient chemotaxis? The answer largely depends on whether higher chemical concentration on the right (or left) reliably signals that the source is located on the right (or left) of the animal, a question that in turn depends on the shape of the chemical plume. If the plume is concave and highly irregular, a higher concentration will not always be a good indicator of the true position of the source. Without accurate information about the structure of the environment and the exact distribution of the relevant sensory stimuli one cannot easily predict the behavior of the system, even if the mechanism is relatively *simple*. This lesson, extensively illustrated by [37.25], has been also offered in the cybernetic era by the pioneer of electroencephalography William Grey Walter. This scientist famously built simple light-seeking devices whose sensory-motor mechanism was not very different from the mechanism later formulated by [37.24]. Yet the behavior of the devices in domestic environments turned out to be extremely difficult to predict: according to their creator, they even displayed forms of “uncertainty, randomness, free will” [37.26, p. 44]. *Herbert Simon* similarly pointed out that very simple mechanisms – whatever *simple* may mean in this context – can exhibit behaviors that are difficult to predict, if the environment is rich with unpredictable stimuli [37.27].

To sum up, whether a system governed by the mechanism described above can in fact replicate efficient chemotaxis in a realistic underwater environment is difficult to assess only by reasoning about the structure of the mechanism itself. Here biorobotic, model-oriented simulations may help. In the previous section, we claimed that mechanism descriptions in cognitive science and neuroscience may be said to be abstract for two reasons, of which so far we have discussed only one (i. e., abstraction from the numerous boundary conditions and concurrent mechanisms at work in *real* systems). The second reason concerns the *material substrate* of the target system. A fundamental assumption

of mechanistic theorizing in cognitive science and neuroscience is that whether a system governed only by  $M$  can exhibit  $R$  or not is a question that does not depend on the material the system is made of. Nothing prevents  $M$  from being implemented in both biological systems and artificial systems. Equivalently, there is no reason to deny *a priori* that any given living system and any given robotic or computer device can implement the *same* mechanism. Biorobotic methodology consists precisely of building a system  $A$  governed by  $M$  (i. e., a *robotic simulation* of  $M$ , see Fig. 37.2), and assessing – by means of an appropriately conducted *biorobotic experiment* – whether  $A$  produces behavior  $B$  under conditions  $C$ , that is to say, whether it replicates the behavior whose manifestation by  $S$  (see the left side of Fig. 37.2) is to be explained. If it does, one may be induced to conclude that the hypothesis that systems governed by  $M$  exhibit  $B$  under  $C$  is corroborated, thus providing partial support for the claim that the living system  $S$  produces  $B$  under  $C$ ; otherwise, one may be induced to reject this hypothesis.

One of the fundamental epistemological issues arising in biorobotic experimentation is easily identified. In this methodology, one draws conclusions regarding the behavior of an *ideal* theory-induced system (i. e., a system governed only by  $M$  in the ideal setting in which only conditions  $C$  hold) by analyzing the behavior of a *real* man-made system. In Sect. 37.3.1 we will reason about whether this inference may be justified, pointing out that – quite paradoxically – biorobotic experiments conducted with the aim of explaining biological behaviors must rely on the explanation of robotic behaviors, which is not always (as vividly illustrated by Braitenberg) as straightforward as it may seem.

Biorobots are thus used as *epistemic tools* to acquire information about the behavior that a system governed

**Fig. 37.2** Diagram showing the functional relationships holding among the mechanism  $M$  under investigation, the living system  $S$ , the robotic system  $A$ , and the behavior to be explained, in biorobotic studies on animal behavior

by  $M$  would exhibit under the ideal conditions  $C$ , that is to say, to explore the behavioral implications of  $M$ . Such a tool may be useful when it is difficult to arrive at these implications only by considering the structure of  $M$ , as illustrated by the study on lobster navigation. Indeed, in that study, the robotic simulation of the mechanistic hypothesis formulated by the authors turned out not to be able to perform efficient chemotaxis. After a number of control experiments aimed at excluding a particular class of artifacts due to the structure of the robot (discussed in Sect. 37.3.1), the authors concluded that the proposed mechanism *could not* account for the chemotaxis behavior, therefore rejecting Claim 1. The authors' diagnosis was that, as discussed above, higher chemical concentrations are not reliable indicators of the direction of the chemical source, due to the turbulence of the water and to the consequently irregular shape of the chemical stream.

This example helps to draw out even further the distinction between data-oriented and model-oriented simulations made in Sect. 37.1.1. In biorobotics, the robotic simulation  $A$  is used to ascertain the behavioral implications of the mechanism  $M$  supposedly implemented in  $S$  under conditions  $C$ . This is also true of the data-oriented biochemical simulations mentioned above: they are used to acquire information about the behavior that ion channels would display in some circumstances *according to* a hypothesis about their structure and to the best available theories on atomic interactions. The output of data-oriented simulations is therefore an implication of these theories. However, the theories underpinning the biomolecular simulation have *already* been accepted as the best current theories on the matter, and it is for this reason that their implications – outputted by the simulation – are interpreted as the behavior that the target system would display in the simulated circumstances. In biorobotic model-oriented studies, on the contrary, the underlying mechanistic models are *not* accepted at first, and their implications – analyzed against the data available about the target system – are taken as a basis for evaluating their plausibility. Mismatches between the behavior of the target system and of the simulation are undesired in data-oriented simulation studies. In model-oriented simulation studies, on the contrary, they constitute a valuable experimental result, as they may be taken as good reason to reject the mechanism under assessment.

#### Internal Comparisons and Lesion Studies

The overt motor behavior of the robot is not the only aspect of the robot that may be compared with  $S$ 's behavior. While the robotic simulation is running, its internal components continuously change state, and in some cases it may be interesting to make comparisons

with the state of the corresponding components in the nervous system of the target system, if suitable data are available. In [37.28, p. 199], for example, a simulation of a neural network mechanism supposedly underlying spatial memory in rats was described. The behavior of the artificial neurons, identified during the functioning of the robot, was compared with the behavior of given hippocampal neurons in the rat nervous system, which were thought to correspond to the artificial ones, and the two were found to match to some extent [37.28, p. 199]:

“The responses of simulated neuronal units in the hippocampal areas during its exploratory behavior are comparable to those of neurons in the rodent hippocampus.”

Detection of such *internal* matches may be taken as further evidence corroborating the simulated theoretical model.

It is also to be noted that biorobotic studies may involve experiments in which *artificial lesions* are created in given components of the robot and the resulting behavior assessed. Such experiments may be useful for testing mechanistic explanations of dysfunctional behaviors. As discussed earlier, dysfunctional behavior  $B^*$  under  $C$  is explained mechanistically as the result of a specific impairment of the mechanism  $M$  responsible for the corresponding *normal* behavior  $B$  under  $C$ . The explanatory mechanism, in these cases, consists of an impaired version  $M^*$  of  $M$ . To test whether  $M^*$  can produce  $B^*$ , one may build a robotic implementation of  $M$ , *injure* it so that it may be considered an implementation of  $M^*$ , and assess whether it exhibits behavior  $B^*$ . An example of a (nonrobotic) model-oriented lesion study is described in [37.29]. Experiments involving changes to particular aspects of a biorobot may also be useful for arguing that the same mechanism  $M$ , with minor modifications, can account for a variety of different phenomena. Suppose that mechanism  $M$ , simulated in a robot  $A$ , turns out to be able to exhibit behavior  $R$ ; and suppose that, by changing some parameters of it – without modifying the overall structure of the mechanism –  $A$  displays behavior  $R^*$  different from  $R$ . One may take this result as a basis on which to conclude that  $M$  has some potential for *unification*, according to the analysis of scientific unification provided by philosopher Philip Kitcher [37.30] (it is worth noting, however, that possessing a high unification potential is not, according to some authors, either necessary nor sufficient to provide a *good* explanation – see for example [37.31]; as far as necessity is concerned, in particular, it is not clear whether a mechanism description that can explain behavior  $R_1$  should depend on whether it can explain a different behavior  $R_2$ ). Finally, as discussed later in

Sect. 37.1.2, artificial lesion experiments may also help to test whether the robot accurately implements the theoretical model under scrutiny.

### Biorobotics and the Study of Neural Implementation

Showing that  $M$  can produce  $R$  (Claim 1), as discussed in the previous section, is necessary in order to claim that  $S$ 's behavior  $R$  may be explained by reference to  $M$ . But it is not sufficient, as it does not exclude that  $S$  exhibits  $R$  by virtue of a mechanism that is different from  $M$  but equally efficient (as mentioned earlier, there is a gap between being able to *reproduce*  $R$  in a machine and being able to *explain*  $R$ ). One must therefore also show that  $M$  is implemented in  $S$ , that is to say, that  $S$  has components that are organized and behave as prescribed by  $M$ : this is the second claim introduced in Sect. 37.1.2, *Explanation*. A variety of experimental techniques may be used for this purpose, depending on whether  $M$  is expressed using cognitive (representational) or neuroscientific theoretical vocabulary. Can biorobotic experimentation help in this case too?

It follows from the previous discussion that, if robot  $A$  implementing  $M$  displays behavior  $R$ , one cannot conclude that  $M$  is implemented in  $S$  too. Similarly, if  $A$  does not display  $R$ , one is not authorized to conclude that  $M$  is not implemented in  $S$ . It may be the case that  $M$  is implemented in  $S$  without producing  $R$ . In the biorobotic experiments on lobster chemotaxis discussed earlier, the robot consistently failed to reach the source of the chemical stream. Based on these results, the authors concluded that the simulated mechanism  $M$  did not guarantee efficient chemotaxis. This theoretical conclusion does not imply that  $M$  is not implemented in lobsters, however. Indeed, as the authors suggest at a certain point of their discussion,  $M$  could be regarded as *too simple* rather than completely *wrong*. Indeed, there are good reasons to believe that it might be an effective chemotaxis mechanism in the presence of *homogeneous chemical plumes*. But the plumes that *real* lobsters are able to track are irregular and filamentous. Therefore, one might conclude that lobsters' chemotaxis mechanism is totally different from  $M$ ; or, alternatively, one might well conclude that lobsters use  $M$  supplemented with other components that enable the system to locate the right track when the plume is too scattered. In the latter case,  $M$  would be implemented in  $S$  (although *not only*  $M$ ) while, at the same time,  $M$  as it stands would be irrelevant to explaining lobsters' chemotaxis. To generalize, a target system  $S$  might implement  $M$  even though  $M$  is not the mechanism responsible for the behavior to be explained.

### Constraining and Revising the Space of Possible Mechanisms

For the reasons illustrated in the previous section, one cannot obtain from a biorobotic experiment *per se* any strong reason to decide whether  $S$  implements  $M$  or not. However, weak reasons may be obtained in some cases. Suppose that, based on a number of biorobotic experiments, one concludes that  $M$  is the *only* mechanism producing  $R$  out of several alternative mechanisms, and that no more adequate mechanistic hypothesis can be conceived. This result would increase one's confidence that  $M$  is *the* mechanism producing  $R$  in  $S$ , that is to say, that  $M$  is implemented in  $S$ , although it may still not be viewed as providing strong evidence to support this claim.

To take another example, suppose that  $M$  is known to be *partially* implemented in  $S$ , i. e., that some components of  $M$  can be found in  $S$ , while other components of  $M$  are only fictional (i. e., no information is available as to whether they are in  $S$  or not). In this case, success in robotically replicating  $R$  may be taken as at least a weak reason for predicting that the fictional components will also be found in  $S$ . This case is exemplified by the biorobotic inquiry into mechanisms of spatial memory in rats reported in [37.32]. These authors' mechanistic hypothesis mentioned a number of neural structures that are known to exist in the nervous system of rats, notably including a population of so-called *place* cells, which fire selectively whenever the rat crosses a particular point of the environment [37.13, 33]. To obtain an efficient goal-seeking mechanism, the authors also postulated the existence of so-called *goal* cells, whose function is to signal proximity to goal locations; these cells were argued by the authors to be essential to goal-seeking behavior, even though no information on their existence in the rat nervous system was available at the time of publication of the study. In the biorobotic experiments, the robot implementing place and goal cells was found to be able to generate efficient goal-seeking behavior. This result provided at least a weak reason to believe that goal cells are not only fictional entities, but that they must be really implemented in the rat brain. In this case too, successful biorobotic replication of  $R$  may induce one to expect that some fictional components of  $M$  are to be found in the target system  $S$ . It is worth noting that the construction of a biorobot may also guide the localization of fictional components of  $M$  within the target system. As discussed earlier, the state of  $A$ 's components while the system is running may be monitored and compared with the internal state of  $S$  as established using an appropriate experimental technique. Thus, for example, one might record the activity of artificial goal cells during experiments, and search for neurons displaying compa-

rable activity in the rat brain in order to identify the neural counterparts of the fictional goal cells in the target system.

In sum, although the primary role of robotic model-oriented simulation experiments is to support reasoning on the relationship between  $M$  and the behavioral regu-

larity  $R$  to be explained, they may also assist indirectly in the analysis of the relationship between  $M$  and the target system  $S$ . The roles played by biorobotics in the explanation of human and animal behaviors will be further exemplified in the brief summary of the state of the art in biorobotics provided in the next section.

## 37.2 A Short History of Biorobotics

### 37.2.1 Cybernetic and Artificial Intelligence

As mentioned above, the history of biorobotics stretches back to the first decades of the twentieth century: the idea of building electric or electromechanic simulations of living system behaviors to discover the mechanisms producing them was pursued by many physiologists and psychologists even before the birth of the digital computer. An example, in addition to the *electric dog* described in Sect. 37.1, is the learning device built by engineer *Bent Russell* [37.34], which featured hydraulic mechanisms loosely inspired by the learning theories of Spencer and Thorndike (Russell's machine and many other model-oriented simulation studies carried out in the twentieth century are discussed at length by philosopher and historian of science *Roberto Cordeschi* in [37.5]). Other examples of simulations carried out before the age of the digital computer include various circuits built by psychologist *Clark Hull* and collaborators. An electronic device built by *Hull* and the electrotechnical engineer *Robert G. Krueger* proved able to replicate various forms of Pavlovian conditioning [37.35]. A nonelectronic simulation of learning was built by *Hull* and chemist *H.D. Baernstein* [37.36]. Baernstein's device inspired electrochemist *Thomas Ross* to build a robot able to memorize the structure of mazes on the basis of a sort of *mechanical* memory (reports on the device and its memory abilities appeared in the journal *Psychological Review*, [37.37, 38]). Some years later, cybernetics pioneer *Norbert Wiener* et al. extensively discussed the role of machines in the study of animal behavior in two articles published in the journal *Philosophy of Science* between 1943 and 1945 [37.39, 40], and *William Grey Walter* built the earlier-mentioned *turtles*, which were able to navigate, and react to light stimuli in, domestic environments [37.26].

The use of model-oriented *computer* simulations characterizes the information-processing approach to psychology pursued by Herbert Simon and Allen Newell in the artificial intelligence (AI) era. Their famous *logic theorist* and *general problem solver* programs were presented not only as machines displaying

remarkable problem-solving abilities, but also as simulations of theoretical models of intelligent *human* behavior couched in information-processing theoretical vocabulary [37.41, 42]. They proposed computer simulations as tools “both for constructing theories and for testing them” [37.43, p. 2011]. A similar model-oriented simulation approach was also pursued by *Nathaniel Rochester* et al. to test models of brain functioning [37.44]. More recent model-oriented computer simulations deployed to test neuroscientific models of animal behavior include the LIMAX system, used to theorize on the *logic* of learning in the *limax* slug [37.45], and the computer simulation built by *Hawkins* to test a model of learning in *Aplysia* [37.46].

Information-processing theories of intelligent behavior developed during the artificial intelligence era offered good bases for explaining and simulating various human-level problem-solving abilities exhibited in well-structured environments. However, they turned out to be inadequate for modeling sensory-motor behaviors produced by living systems in partially structured or chaotic environments, and under strict time constraints. AI robots were extremely slow and unable to produce timely reactions to environmental changes, not only due to the speed limitations of the computers available in the 1960s and 1970s, but also due to the structure of the algorithms used to process sensory data and plan motor behaviors (a paradigmatic example of an AI robot is Shakey, described in [37.47]). In the mid-1980s robots were built that exhibited efficient sensory-motor behavioral capacities in partially structured environments based on a parallel and distributed architecture dubbed *behavior-based architecture* [37.48]. Behavior-based algorithms had many aspects in common with the control architectures devised and implemented in the cybernetic era and later described by *Valentino Braitenberg* [37.25]. Their formulation, and the sensory-motor efficiency of the first behavior-based robots, renewed the interest of the robotics community in the construction of robotic systems able to reproduce aspects of animal behavior and in the robotic simulation of neural and psychological mechanisms.

## 37.2.2 Contemporary Invertebrate and Vertebrate Simulation Studies

Many model-oriented biorobotic studies have been conducted, especially from the 1990s onwards. Some of these concern invertebrate sensory-motor capacities. In [37.49, 50] a series of biorobotic studies aimed at explaining how female crickets find possible mates by following their calling song were described. Other notable examples include biorobotic inquiries into the mechanisms underlying the remarkable navigation abilities of the desert ant *Cataglyphis* [37.51], the navigation mechanisms of flying insects [37.52, 53], moths' ability to track chemical streams [37.54], and locust visuomotor coordination [37.55]. As mentioned earlier, biorobots have been used to study the mechanisms of visuomotor coordination in lobsters too [37.24, 56]. Biorobotic simulations have also been deployed to study sensory-motor behaviors in vertebrates. Examples include studies on locomotion in lampreys [37.57, 58] and salamanders [37.59], and on the mechanisms underlying general aspects of locomotion exhibited by a variety of animal species [37.60–63]. The mechanisms underlying spatial memory and navigation in rats have been investigated using biorobots in [37.20, 28,

32, 64, 65]. Sense of touch in animals has been explored by means of whisker-controlled robots in [37.66, 67]. Visuomotor coordination in the barn owl has been studied by [37.68]. There have also been biorobotic inquiries into primate behavior, notably including studies on postural control [37.69] and on cerebellar mechanisms of motor control in humans [37.70]. See [37.71] for a detailed discussion on the role of biorobotics in the study of primate behavior.

Model-oriented simulative approaches have additionally been used to advance understanding of the *development* of behavior (see for example the biorobotic study on the development of visuomotor coordination in cats described in [37.72]). Detailed reviews of biorobotic investigations on the *evolution* of behavior are offered by [37.73] and [37.74]. It is worth mentioning here the possibility of building *hybrid* simulations of mechanism descriptions, i.e., simulation systems in which some components of the target mechanism consist of biological tissues appropriately connected with other components that are artificial. Systems of this kind have been used to study the mechanisms of lamprey sensory-motor behavior [37.75–77]; see [37.78] for a methodological analysis.

## 37.3 Methodological Issues

### 37.3.1 The Epistemic Requirements of Good Biorobots

#### Biological Mimicry

In the previous section, we reviewed studies illustrating the role played by biorobotics in the explanation of human and animal behavior. In all of these studies, the behavior of a robotic system  $A$  is taken as a basis for assessing whether a system governed by  $M$  only would produce behavior  $B$  under  $C$  (as discussed in Sect. 37.1.2, *Explanation and Biorobotics and the Study of Ideal Mechanisms*). This assessment is essential, though not sufficient, in order to conclude that  $M$  is the mechanism enabling  $S$  to exhibit  $B$  under  $C$ . In the current section we ask under what conditions – if any – one is really *justified* in bringing robotic behaviors to bear on the mechanism  $M$  under scrutiny. More precisely, let us assume that  $A$ , in a sufficient set of experimental trials, has actually exhibited behavior  $R$ , thus reproducing the behavior of the target system (an assumption that is discussed in Sect. 37.2). What auxiliary assumptions are needed to justifiably take this result as a basis for concluding that  $M$  can generate  $B$  under  $C$ ? This key epistemological question has been addressed

in other methodological analyses of biorobotics [37.8, 9]. Awareness of these auxiliary assumptions may help to carry out methodologically sensible biorobotic experiments and to evaluate the soundness of studies reported in the literature.

Some of these assumptions follow quite directly from the discussion carried out so far. In order to take  $A$ 's behavior as bearing on whether a system governed only by  $M$  would display  $B$  in a setting in which only conditions  $C$  hold, one must ensure that (a)  $A$  is governed only by  $M$  and (b) only conditions  $C$  hold in the experimental setting. Let us focus on assumption (a) and postpone discussion of assumption (b) until Sect. 37.3.3. Assumption (a) places a constraint on the structure of robot  $A$ , a constraint that may seem quite hard to satisfy – not least, because robots are complex devices: to work properly any given robot is likely to need many peripheral components not mentioned in the mechanism description under scrutiny, as we will discuss in the following subsection. It is worth noting, however, that other authors seem to place even stronger constraints on the structure of *good* biorobots.

*Krichmar* et al. [37.28], for example, proposed a list of principles that should guide the design and building

of *good* biorobots, which notably includes the following one: “The device must be controlled by a simulated nervous system having a design that reflects the brain’s architecture and dynamics” [37.28, p. 198]. This principle, similarly to assumption (a), places a constraint on the mechanism governing the device. However, this constraint is defined in terms of the mechanisms at work in the target system (the brain). Reformulated using our terminology, it prescribes that *A* be governed by a mechanism *M* which is known to be (at least partially) implemented in the target system *S*. A similar constraint is formulated by [37.71, p. R910, emphasis added], who claim that “robots incorporating the biomechanics of the animal system under study become physical models to test hypotheses”. Let us generalize by distinguishing the following two constraints:

1. The robot *A* must be governed only by *M*.
2. *M* must be implemented in the target system *S*.

Let us label the combination of Constraints 1 and 2 *biological mimicry*. It goes without saying that biological mimicry is a much stronger constraint than the mere prescription that *A* must be governed by *M*. Note that the terms *validation* and *verification* are often used in the literature in reference to the evaluation of these two requirements [37.2]. Validation refers to the evaluation of the *goodness* of the theoretical model (Requirement 2), while verification is the process of checking whether the theoretical model has been accurately simulated (Requirement 1).

Is biological mimicry, as defined above, required to justify the use of *A* to test whether *M* can produce *B* under *C* or not? Arguably not. More precisely, Constraint 1 above is surely required: if *A* is not governed only by *M*, it is not clear why one should interpret *A*’s behaviors as implied by *M*. On the contrary, Constraint 2 is not required for *A* to be a *good* biorobot. Remember that *A*’s role in biorobotics is to provide evidence of the behavioral implications of *M* under *C* (Sect. 37.1.2, *Biorobotics and the Study of Ideal Mechanisms*). There is no reason to claim that *A*’s behaviors may be interpreted as implied by *M* only if *M* is implemented in *S*: a robot could well be used to explore the behavioral implications of purely notional mechanisms that are impossible to implement biologically. This brings to light a substantial methodological difference between data-oriented and model-oriented simulation studies. In order to use *A* to generate data about the target system *S*, *A* must be a *good* model of *S* – otherwise there are no good reasons to interpret *A*’s behavior as the behavior that *S* would exhibit under the same conditions. This constraint is concisely stated by Wendy Parker in the following terms [37.79]; see also [37.80, 81]:

“scientists typically select a simulating system on the basis of its being hoped or believed to be similar to the target system in ways deemed relevant, given the goals of the simulation study.”

On the contrary, similarity between the mechanism governing the machine and the mechanism at work in the target system is not required to authorize the experimental use of the machine in a model-oriented study.

Note that so far we have reasoned about the conditions under which one is justified in interpreting *A*’s behaviors as implications of *M*. We have argued that Constraint 2 is not required in order to make this use of *A*. This is not to say that simulation of a mechanism that is already known to be (at least partially) realized in *S* is not to be praised for *other* reasons not related to the justification of using *A*. One may well agree with [37.65, p. 1527, emphasis added], who assert that:

“a close fidelity to the known properties of the nervous system is *likely to be* a main ingredient of success in modeling studies aimed at reaching an understanding of higher brain function.”

They complain that, so far [37.65, p. 1501]:

“very little has been done to incorporate detailed models of cellular and synaptic properties into large scale simulations of interconnected networks in multilevel systems.”

Darwin robots, on the contrary, “are based on physiological and anatomical data” [37.65, p. 1498]. Indeed, (robotic) simulations of mechanisms that “reflect the brain’s architecture and dynamics” may offer interesting experimental opportunities to cognitive and neuroscience research. It could be that detailed information is available about the neural structures and morphological features of a given species, but explanations of how they are organized to produce behavior are lacking. In this particular case, one might propose a particular organization of those components (i.e., formulate a mechanism description *M* that includes them), simulate it using a robot, and verify whether the robotic system can produce the behavior under investigation. This case emphasizes the role that biorobotics may play in systematizing anatomical and physiological observations into potentially explanatory mechanisms.

It is for these reasons that many authors actually *aim* to build robotic systems, which at least partially meet Constraint 2. Pyk et al. [37.54, p. 197], for example:

“report on a project that aims at constructing [...] a system based on [their] understanding of the pheromone communication system of the moth.”

Lambrinos et al. [37.51, p. 40], in commenting on their biorobotic inquiry into the mechanisms underlying the navigation strategies of the desert ant *Cataglyphis*, pointed out that:

“the goal of this approach is to develop an understanding of natural systems by building a robot that mimics some aspects of their sensory and nervous system and their behavior.”

In a biorobotic study on forearm posture maintenance in humans, Chou and Hannaford [37.69] claimed that their goal was:

“to apply knowledge of human neuro-musculoskeletal motion control to a biomechanically designed, neural controlled, ‘anthroform’ robotic arm system”

Blanchard et al. [37.55] implemented a mechanistic model of obstacle avoidance in locusts that was “based closely on the anatomy and physiology”.

It follows from the present discussion that artificial device *A* need *not* replicate the behavior of the target living system *S* to be used to test a model *M* of *S*’s behavior: what is required is that *A* be governed by *M*, independently of whether it replicates *S*’s behavior or not. Behavioral match between *S* and *A* is one of the possible *outcomes* of the experiments, but it is not among the *epistemic requirements* needed to use *A* to test *M*. However, an electronic device accurately reproducing the behavior of the corresponding living system may be used as a component of a larger simulation system in a model-oriented study. The robotic device described in [37.82] is a case in point. As reported by the authors, it was able to replicate accurately the output of mammalian muscle spindles (sensors able to detect changes in the length of muscles) based on a detailed theoretical model of them. This device was not used to discover theoretical models of muscle spindle behavior as in model-oriented simulations (good models were already available), but was nevertheless intended to play a useful role in scientific research. To make this clearer, let us suppose that *M* is a neural model of motor control that has muscle spindles among its components. Building a robotic model-oriented simulation of *M* clearly requires the inclusion of a robotic component that accurately reproduces the behavior of muscle spindles. The device described in [37.82] may be useful for this purpose (rather than for the narrower purpose of testing the plausibility of a model of the muscle spindle itself, which is already available). Similar considerations apply to other attempts to build biologically accurate sensors, see for example [37.83, 84].

To sum up, what is needed to license the use of robot *A* as an experimental platform for investigating the im-

plications of mechanism description *M* is that *M* be the only mechanism governing *A*. *Good* biorobots need not feature mechanisms closely based on the physiological or psychological structure of the target system (although biological mimicry may yield valuable findings for cognitive and neuroscientific research). To be sure, biorobotic simulations can be particularly useful when no information is available on the biological implementation of *M* (thus, when Constraint 2 above is false): they may assist in evaluating whether *M* can generate in principle the behavior under investigation, thus whether a biological or psychological implementation of *M* is worth searching for. Let us now focus on Constraint 1: under what conditions, if any, may robot *A* be said to be governed only by the mechanism under scrutiny?

### Simulation Accuracy

The very aim of building a robot governed by a neuroscientific or cognitive mechanism seems puzzling at first sight: how can an artificial, *inorganic* system be governed by the same mechanism at work in a *biological* system? Cognitive and neuroscientific mechanisms are made up of neural and psychological components, and for this reason it may seem more appropriate to say that robots can at most realize *artificial translations* of them, but not exactly *them*. We earlier dispelled this doubt in Sect. 37.1.2, *Biorobotics and the Study of Ideal Mechanisms*. There is no *a priori* reason to deny that an artificial system may be governed by *the same* mechanism governing the behavior of a biological or psychological system, despite the fundamental difference in the matter of which the two systems are made. Indeed, as discussed earlier, a basic tenet of the mechanistic approach to scientific explanation pursued in cognitive science and neuroscience is that whether a system governed only by *M* can exhibit *R* or not is a question that does not depend on the material that the system is made of, but rather on the way that material is organized (i. e., on whether that system is organized as prescribed in *M*). For example, that one may explain spatial memory behaviors in rats by reference to hippocampal *place cells* depends on the fact that these cells fire *regularly* in correspondence with certain points in the environment, rather than on the fact that they are cells made of organic molecules. Appropriately replacing living place cells in the hippocampus of a rat with electronic circuits displaying the same regularities would not alter the animal’s overall spatial memory mechanism (replacements of this kind are made in bionic model-based simulations of sensory-motor behaviors, of which an example is the aforementioned study described in [37.77]).

In principle, then, there is no reason to deny that a robotic system *A* may be governed by the same

mechanism  $M$  supposedly governing biological or psychological system  $S$ , even though  $A$  and  $S$  are made of completely different materials. What matters, for  $A$  to be governed by  $M$ , is whether  $A$  has components behaving as specified in  $M$  (e.g., components correctly reproducing the regularity associated with place cells) and organized accordingly. What seems to be more difficult to establish is whether  $A$  is governed *only* by  $M$ , an essential requirement in order to interpret  $A$ 's behavior as the behavior that a system governed only by  $M$  would display under conditions  $C$  (as discussed in Sect. 37.1.2, *Explanation*). Indeed, neuroscientific and cognitive mechanism descriptions are typically much *simpler* than the mechanisms actually implemented in their robotic simulations. In these cases, the behavior that a system governed only by  $M$  would have under conditions  $C$  must be *inferred* from  $A$ 's behaviors under  $C$ . What auxiliary assumptions are needed to draw such an inference?

Let us try to address this question by making a provisional distinction between the mechanism *implemented* in  $A$  (MI) and the mechanism *governing*  $A$  (MG) in particular circumstances. This distinction may be informally stated as follows. The mechanism description MI implemented in  $A$  is a full description of the components making up the system, at some (e.g., electronic or software) level of description. It describes the intended behavior of the components and their organization in normal conditions, and it may be thought of as the best blueprint used by the builders of the robot during the course of implementation. The mechanism MG governing  $A$  under a particular set of circumstances  $C$  is the mechanism actually responsible for  $A$ 's behavior under  $C$ . The two mechanism descriptions need not always be identical.

First, if some components implemented in  $A$  are silent, or exert a negligible influence on  $A$ 's behavior under conditions  $C$ , they cannot be said to be responsible for  $A$ 's behavior, and should be therefore excluded from the mechanism governing  $A$  under  $C$ . In this case, the mechanism MG governing  $A$  under  $C$  is a restriction of the mechanism MI implemented in  $A$  (MG may be obtained from MI by ignoring all the ineffective components). Suppose, for example, that  $A$  implements a mechanism establishing a relationship between left light sensors and right motors and vice versa (as in [37.24]), plus (a) a wireless communication module for exchanging data with an external computer and (b) a circuit that produces a *wandering* behavior when environmental light is too low. All these components figure in the description MI of the mechanism implemented in the robot. However, the wireless communication module will probably never have an impact

on  $A$ 's motor behavior. On the contrary, component (b) may influence  $A$ 's behavior in some circumstances, for example, in the dark. When there is sufficient environmental light, however, this component will be silent and will not be effectively responsible for  $A$ 's behavior: turn it off, or extract it from the system, and  $A$ 's behavior will not change under those conditions. Therefore, *when there is sufficient environmental light*, MG does not include (b).

Second, in some cases the behavior of certain components implemented in the machine may violate the behavior specified in the blueprint. Suppose that MI prescribes that a transistor is placed between each light sensor and the motor on the opposite side, to amplify smaller sensory signals. Suppose, however, that under particular conditions (for example, excessive heat) the transistor displays an utterly anomalous behavior (for example, its pins get short-circuited). In such cases, the mechanism MG actually governing the robot is different from the mechanism MI specifying the *normal* behavior of the components.

It follows from these remarks that the same robot may be reasonably said to be governed by *different* mechanisms in different conditions, even though there is a sense in which it *implements only one* mechanism. Let us now link this claim with the epistemic requirements of *good* biorobots. We have argued that to inform about the behavior a system governed only by  $M$  would display under conditions  $C$ ,  $A$  must be governed *only* by  $M$ . And we have illustrated that robots possessing a rich mechanistic structure may be said to be governed by *simpler* mechanisms in some circumstances. What is essential for a *good* biorobot, in other words, is that  $M$  exactly coincides with the mechanism *responsible* for  $A$ 's behavior in circumstances  $C$  independently of the other components implemented in it. How may we establish whether this essential requirement is satisfied by  $A$  – in other words, how does one go about identifying *the* mechanism actually governing  $A$  under conditions  $C$ ? By nothing other than a process of *explanation*, totally analogous to the process leading to the identification of the mechanism governing the behavior of any system. The mechanism description MG governing  $A$  under  $C$ , according to the proposed analysis of the term *governing*, is a *mechanistic theory* of  $A$ , resulting from an explanation of  $A$ 's behavior under  $C$ . Any explanation will mention only the relevant factors making the difference in the behavior to be explained [37.85, 86]. Thus the *wandering* component is not likely to figure in an explanation of the behavior *in the light* of the phototaxis robot described above; nor the wireless communication module, if the behavior to be explained is restricted to the movements of the robot.

### Explaining Robotic Behaviors

These remarks illustrate a quite startling aspect of biorobotic methodology: the use of robotic simulation to test a mechanistic explanation of a biological behavior rests on *explanations of the behavior of the robot*, aimed at determining whether the robot is actually governed by the mechanism under scrutiny. Such explanation processes are essential to deciding whether  $M$  is to be accepted or rejected as a basis for explaining the target behavior. And the explanation of robotic behaviors is not always straightforward, even for those who have built the system: the behavior of man-made systems may be as hard to understand as the behavior of any physical system. The technical blueprint  $MI$  helps, but in some cases it may be not enough. Often even the builder, who knows the internal structure of the system better than anyone else, will have to revisit it, formulate hypotheses as to why the robot produced peculiar behaviors in certain circumstances, and carry out experiments to test these hypotheses. It is by a process of explanation that one identifies a fault in a transistor or the unexpected activation of a component that was presumed to be silent in particular experimental settings. Detailed reports of robotic explanation processes can be found in the biorobotic literature; see for example [37.24] and [37.49].

It is worth noting, however, that further auxiliary assumptions may be needed to interpret  $A$ 's behaviors as the behavior that a system governed only by  $M$  would produce under conditions  $C$ . Indeed,  $A$  may fail to be governed by  $M$  for reasons not discussed so far. Current technology might not permit the construction of components behaving exactly as prescribed by  $M$ , obliging the researcher to design components that at best exhibit an adapted version of the required behavior. Alternatively, the formulation of  $M$  might be too vague to enable one to judge whether  $A$  is governed by  $M$  or not. Consider that many cognitive and neuroscientific models have unfixed parameters, describe the behavior of components only qualitatively, and display gaps, such as missing components (these are referred to as *mechanism sketches* in [37.15]). All these underspecified aspects must be fixed in the course of implementation. Given that a vague mechanism description  $M$  may be fully specified in a variety of ways, thus obtaining various mechanism descriptions  $M_1, \dots, M_n$ , which potentially differ greatly from each other in terms of behavioral output, one may legitimately ask whether the particular  $M_i$  governing  $A$  faithfully reflects the vague theory  $M$  under scrutiny. And in some cases it may be far from clear whether  $A$ 's behavior should be brought to bear on a vague  $M$ . Suppose, for example, that  $A$  fails to exhibit the target biological behavior  $R$ . This result may be taken as a good reason to reject  $M_i$ , that is, to

conclude that the particular parameters chosen to derive  $M_i$  from the vague  $M$  cannot produce  $R$ . But it may not be sufficient to also reject  $M$ , insofar as *other* different parameters might well work.

In sum, to sensibly interpret  $A$ 's behavior as the behavior that a system governed only by  $M$  would display under conditions  $C$ , one must first explain  $A$ 's behavior and identify the mechanism that actually governs  $A$  under  $C$  (which does not always coincide with the best technical blueprint of the robot available). A *mechanistic theory* on the robot is crucially needed to infer theoretical conclusions about  $M$  based on  $A$ 's behavior. But in many cases other auxiliary premises are implicitly introduced, whose nature has yet to be precisely identified. For in some cases the best one can do is to build an *inaccurate* simulation of  $M$ . This may be due to limitations in current technology or to the fact that  $M$  is formulated in excessively vague terms. Or it may be also due to the fact that, in the experiments, some perturbing condition has actually interfered with the behavior of the robot, some component has unexpectedly broken down, or a module that was expected to be silent has interfered with  $A$ 's behavior. In some cases, such artifacts are simply unavoidable. Should one therefore discard the entire experimental setting? What auxiliary assumptions are needed to justify theoretical conclusions on  $M$  based on an inaccurate robotic simulation of it? These are interesting questions for epistemological research, which may lead to a deeper understanding of the methodological structure and epistemological requirements of *good* biorobotic studies.

### 37.3.2 On the Meaning of Behavior

Biorobotic experiments typically involve comparisons between the behavior of  $A$  and the behavior of the target system  $S$ . Matches or mismatches between the two (under the auxiliary assumptions discussed in the previous section) are taken as a basis for claiming that the mechanism description under scrutiny has been corroborated or disproved. To make sense of what is really done in biorobotic experiments, however, it is worth reflecting on what the *living system behavior* that is compared with robotic behaviors amounts to.

First, typically only *some aspects* of the behavior of the target system are compared with *some aspects* of the behavior of the robot. For example, in the aforementioned biorobotic studies on cricket phonotaxis [37.49] and on lobster chemotaxis [37.24] various aspects of the behavior of the robot were measured with great care in the experiments. However, theoretical conclusions on the target model  $M$  were drawn in both cases only by reasoning on the ability of the robot to reach the source of the stimulus, irrespectively for example of any match

or mismatch between the *trajectories* followed by *A* and *S* (as a matter of fact, in some cases it is impossible to make fine-grained comparisons between *A*'s and *S*'s behaviors due to the unavailability of data on *S*). Thus acceptance or rejection of *M* was based on analysis of only *some* aspects of *A*'s behavior.

This does not count as a methodological limitation of these studies: there is no reason to claim that, in a good biorobotic experiment, one must perform fine-grained behavioral comparisons of the behavior of the two systems. The aspects of *S*'s behavior that are actually taken into account in the comparison define the explanandum of the biorobotic study, thus shaping the class of the theoretical conclusions that can be legitimately drawn from the experiments. If, for example, one takes into account only the robot's ability to find the stimulus source, irrespective of the trajectory leading to it, one will at most draw theoretical conclusions on the ability of the underlying mechanism *M* to find the source of the stimulus. Any theoretical conclusion on *M* will be limited to whether it can explain *that particular aspect* of the behavior of *S*. A finer-grained comparison between the trajectories taken by the two systems will be needed only if the trajectories taken by *S* are part of the explanandum. The choice of the criteria for comparison crucially depends on what one wants to explain (see [37.87] for a detailed reflection on the metrics enabling one to compare animal and robotic behaviors based on a case study on the mechanisms of rat navigation).

These remarks invite us to reflect on the meaning of the term *behavior* as it is used in biorobotics. The behavior of the target system in a general sense is one thing, while the behavior of the target system contained in the explanandum of the study is another. Biorobotic explananda always select some aspects of target system behavior, and thus indirectly constrain the choice of the criteria to be used for assessing whether the robotic simulation replicates the target system's behavior or not. Note that, however, biorobotic explananda do not only consist of a *filtered* description of the behavior of the target system – that is to say, a description that only takes some aspects of that behavior into account. Recall that the behavior to be explained consists of the behavior *B* regularly produced by the target system *under conditions C* (and if *C* occur rarely, the behavioral regularity *R* to be explained will be rarely instantiated). Real moths do not always go towards a light source, and female crickets find the source of male crickets' calling songs only under particular conditions. Consider also that, as pointed out in Sect. 37.1.2, *Explanation*, biorobotic *explananda* are highly idealized: they state behaviors that are produced in the ideal case in which *only conditions C* hold. This is not to say that this ideal

case can never occur. The behavior to be explained may be obtained in highly controlled experimental settings, in which one tries to exclude or neutralize any boundary condition that is not included under *C*. The list of the conditions defined under *C* must be taken into account in the setting up of the biorobotic experiments, whose purpose is to assess whether systems governed only by *M* produce behavior *B* when only conditions *C* hold. Therefore, ideally, the robot *A* should be observed under experimental conditions that are as close as possible to the ideal conditions in which only *C* hold. The explanandum thus crucially defines the conditions under which the behavior of the robot is to be observed, in addition to the criteria to be used for analyzing it. As it will be stressed in the next section, the real conditions under which the behavior of the robot is observed are often far from ideal.

It is worth noting that the formulation of the behavioral regularity under investigation involves various acts of observation and measurement. However, it also involves careful selection of the environmental conditions under which these observations and measurements are carried out. This selection is definitely theory-laden: possibly perturbing conditions are excluded or neutralized in the experimental setup in light of theoretical considerations – possibly supported by previous experiments on the target system – that classify those conditions as *perturbing*. The choice of environmental conditions also depends on the researcher's particular interests: some conditions may be excluded because they have behavioral effects that the researcher wants to exclude from the explanandum to be explored. Contrary to the popular assumption that science starts from the observation of something to be explained, the formulation of an explanandum is typically a constructive process involving progressive refinements of the conditions under which the experimental acts of observation are carried out, a process that is strongly driven by theoretical and pragmatic considerations.

It should also be noted that biorobotic studies do not always start from the analysis of behavioral regularities displayed by particular living species. They often aim at theorizing on the mechanisms underlying very *general* behaviors, which cannot easily be identified with the behavior of particular living systems under particular conditions. For example, Voegtlin and Verschure [37.88] described a number of simulation experiments aimed at exploring mechanisms that produce a variety of learning-related behavioral phenomena. The behavioral task that these robotic and computer simulations were expected to perform was a foraging task, in which the agent was required to avoid collisions with obstacles while locating targets dispersed in the environment. Many living systems are

able to perform this task, human beings included, and the simulation study reported did not focus on any one of them in particular. In such cases, the target behavior does not coincide with the behavior of a single living species: it unifies the behavior of many living systems, which may differ from each other in other respects.

Other simulation studies follow the so-called *animat* approach defined by Webb [37.89] as:

“the invention and study of an artificial creature that does not correspond to any specific real animal, but is (nevertheless) intended to provide some insight into real issues in biological or cognitive science.”

It is worth stressing that there is a sense in which every biorobotic explanandum is *invented*. As discussed above, biorobotic explanations address behaviors exhibited by living systems in highly artificial and controlled conditions, which may even be totally different from the real conditions in which the organism lives. The behavior to be explained is carefully *carved out* of the behavior exhibited by the system in ordinary conditions based on theoretical and pragmatic considerations. The *animat* approach, as defined above, brings this constructive process of invention to an extreme. It authorizes investigations on the mechanisms underlying the behavior of imaginary systems, or the behavior that existing systems might display under conditions that can be never attained. Whether this approach can really contribute to cognitive science or neuroscience is a question that depends on the relationship between the *animat* explananda and the questions addressed in those research disciplines. As discussed above, studies on animal behaviors often investigate highly idealized or general explananda, whose relevance to cognitive or neuroscientific research is typically justified by showing how the behavior of particular biological species may be considered as an instance of such general or idealized behaviors. As argued by Webb [37.89], such a justification must be provided by *animat* researchers too, if they wish to effectively contribute to the study of the behavior of existing living systems: they must show that their explananda may be considered idealized or general versions of specific neuroscientific or cognitive explananda (on the basis of given criteria or rules for idealizing and de-idealizing living system behaviors).

### 37.3.3 Robots and Their Environment: Robotic versus Computer Simulations

It is a basic tenet of contemporary cognitive and neuroscience that a full understanding of the mechanisms governing human and animal behavior cannot be attained without carefully studying the structure of the

environment in which the target behavior emerges. This tenet is closely related to the idea, discussed above (Sect. 37.1.2, *Biorobotics and the Study of Ideal Mechanisms*), that *simple* mechanisms can display *complex* behaviors in *complex* environments. Thus, when observing the behavior of a living system, one should first carefully explore the environmental conditions in which it is produced by *S*. This remark, once again, ultimately concerns the selection of the proper explanandum to be addressed. One must carefully select the conditions *C* that define the behavioral regularity to be explained, by including those that really make a difference to the behavior of the target system and excluding those that are irrelevant. The formulation of a sufficiently inclusive explanandum may contribute to simplifying the explanation. Note that scientific *discoveries*, in biorobotics, may consist both of the formulation of *good* explanatory mechanism descriptions and in the refinement of previous explananda – in the latter case, one discovers that environmental factors that had previously been overlooked affect the behavior of the target system and for this reason are to be included in the explanandum.

Another basic tenet of contemporary neuroscientific and cognitive research is that the morphology of the target system must be carefully analyzed and taken into account in the explanation of behavior, given that *simple* sensory-motor mechanisms may exploit particular features of the system’s body to achieve *complex* behaviors [37.90]; see biorobotic examples in [37.49] and [37.91]. Note that this tenet is perfectly consistent with the abstract character of scientific explanations discussed in Sect. 37.1.2, *Biorobotics and the Study of Ideal Mechanisms*. There we argued that whether mechanism *M* can explain behavior *R* or not is a question that does not depend on the nature of the material the system is made of, but on the way it is organized (i. e., on whether it is organized as prescribed by *M*). However, it is one thing to deny that the explanatory adequacy of *M* depends on the material *S* is made of, and another to deny that it depends on the *body* of *S*. Indeed, morphology describes the physical *organization* of a system, and therefore a morphological description is *abstract* – with respect to the matter the system is made of – just as a neural or cognitive mechanism description is. Suppose, for example, that *S* is found to produce efficient locomotion by exploiting particular passive elastic properties of its legs via a relatively simple control mechanism. Still, the nature of the material of which the legs are made of does not affect the adequacy of this explanation (although whether or not the legs possess the required elastic properties may make a difference). Similarly to the example provided in Sect. 37.1.2, *Biorobotics and the Study of Ideal Mechanisms*, if *S*’s legs are replaced with legs

made of a completely different material, but possessing the same elastic properties, the explanation will not change.

We have argued that, to test whether  $M$  can explain  $R$ , one must assess whether a system whose components behave according to the regularities prescribed by  $M$ , and are organized as specified in  $M$ , exhibits  $R$  or not. It is often claimed that if  $M$  is based on the morphology of a system and  $C$  defines a nontrivial set of real-world conditions, a *robotic* simulation should be built: robots have a body and their behavior may be observed under real-world conditions. However, as is occasionally acknowledged in the biorobotic literature [37.88], there is no reason to deny, at least in principle, that an adequate test may also be effected by creating a purely computer-based simulation of a system *with the selected morphological properties* and observing its behavior under a *simulation of the real-world conditions* included under  $C$ .

One reason often put forward for preferring a robotic simulation over a purely computer one in biorobotic studies is that the physical properties of  $S$ 's body and the various conditions  $C$  defined in the explanandum may be technically difficult to simulate in a sufficiently realistic way (this is the case of the chemical plumes tracked by lobsters in water [37.24]). Furthermore, a detailed description of conditions  $C$  is often not available for simulation. Building an artificial body and immersing it in a real-world environment allows one to sidestep these difficulties. Note, however, that the use of a robotic simulation introduces distinctive methodological issues that are not raised by computer simulation experiments. As discussed earlier, in order to justifiably draw theoretical conclusions about  $M$  on the basis of robot behaviors, one must ensure that the robot really *has* the morphological properties mentioned in  $M$ , and that other properties of the

system do not exert a significant impact on its behavior during the experiments. In addition, the experimental setting must be similar enough to the ideal case in which *only* conditions  $C$  hold – otherwise, one cannot bring robotic behaviors to bear on the hypothesis that systems governed by  $M$  generate behavior  $B$  *under*  $C$ . In particular, it must be verified that no perturbing factor significantly affected robotic behavior during the experiments (consider that the class of factor that may perturb the *normal* functioning of the robot is likely to be very different from that perturbing the behavior of the target living system). This in turn requires, as discussed above, explaining the behavior of the robot.

Computer simulations are on a par with biorobots in this respect, as the need to explain what has happened during the experiments – whether virtual or otherwise – emerges in both cases. However, computer simulations enable one to finely control all the conditions holding in the simulated environment and, more importantly, to create a virtual environment in which one is sure that *only* conditions  $C$  hold. This considerably simplifies the process of explanation. Inquiring into the behavior of a robot, in contrast, may give rise to difficulties of the same order of magnitude of those involved in explaining the behavior of any concrete system – including those related to the discovery and detection of possible perturbing factors. In sum, the emphasis on the morphological and environmental factors responsible for the behavior under investigation is not a good reason, in principle, to prefer robotic simulations over computer simulations. The pros and cons of the former or the latter solution are to be evaluated on a case-by-case basis, taking into account the technical complexities involved in creating accurate simulations of the environment and of the body of the system, and the methodological complexities involved in explaining the behavior of the simulation (see also [37.92]).

## 37.4 Conclusions

In this chapter we have outlined the structure of biorobotic methodology for the study of the mechanisms underlying animal behavior, presented a brief summary of the state of the art in biorobotic research, and discussed some of the epistemological and methodological issues arising, which notably concern the relationship between the mechanistic theory to be tested and the robot, the choice of criteria for comparing the behavior of the robot with the behavior of the target system, and the pros and cons of robotic versus computer simulations. It is important to note that these issues should not be taken as reasons for being skeptical about

the potential of the methodology, which (as pointed out in the previous sections) has made many valuable contributions to the study of animal behavior. Indeed, many studies reported in the literature display a rigorous approach to justifying their theoretical conclusions by carefully reasoning about the relationship between the model to be tested, the experimental settings, and the structure of the robot used. Discussing these issues from an epistemological and methodological point of view may contribute to identifying criteria for setting-up and carrying out *good* biorobotic experiments and, more generally, to placing biorobotics as a strategy for

the study of animal behavior on firmer methodological grounds.

The issues addressed here point to the existence of a profound gap between being able to reproduce a given behavior in a robot and being able to explain it. This gap is not only due to the fact that, as discussed in this chapter, successful simulations do not offer strong evidential grounds for assessing whether the implemented mechanism is implemented in the living system or not (and we have argued that this question must be answered in order to properly explain why the behavior under investigation is produced *by the living system*). It is also due to the fact that reproducing the target behavior is not the same as understanding *how* – i. e., by virtue of what mechanism – that behavior has been produced *by the robotic system*. And, as discussed in Sect. 37.3.1, *Simulation Accuracy*, developing a *theory* on the biorobot is an essential prerequisite for accepting or rejecting a theoretical model on the basis of biorobotic experiments: merely reproducing the behavior is not enough. Consider also, in this regard, that computer and robotic devices enable researchers to progress from “toy models” of behavior [37.93] to the fine-grained simulation of complex theoretical models of the nervous system (the Blue Brain Project of the École Polytechnique Fédérale de Lausanne (EPFL) in Lausanne, aimed at building a large-scale, neuron-level simulation of the brain, is a case in point [37.94]). Still, it is an open question whether large-scale, extremely complex theoretical models – too large and detailed to be grasped by the human mind without external memory and computational

aids – really provide a basis for *understanding* the behavior they are able to produce in simulation. Progress in the computer and robotic replication of living system behaviors does not always go hand in hand with progress in the explanation of them.

We have identified some auxiliary assumptions that are needed to justifiably infer theoretical conclusions about the target mechanism description from the analysis of robotic behaviors. Some of these assumptions concern the choice of a *good* biorobot, of a *good* environmental setting, and of a *good* set of criteria for comparing animal and robotic behaviors. However, alternative auxiliary assumptions may be needed in many cases. For instance, for theoretical and practical reasons it may not be possible to build a perfectly accurate robot, to reproduce the right environmental settings, and to apply the proper criteria for comparisons. In these cases, the auxiliary assumptions identified here turn out to be false. But their falsity needs not neatly imply the impossibility of justifying any theoretical conclusion flowing from the experiments. Other assumptions may be involved in the rational acceptance or refusal of the target mechanism description based on experimental protocols that do not meet the constraints discussed here. Identifying the nature of these rational assumptions, possibly based on a close analysis of case studies, may significantly contribute to extending the regulative framework presented here and, ultimately, to further reinforcing the status of biorobotics as a methodologically sensible strategy for the modeling of animal mechanisms.

This part of the Handbook is devoted to the issue of the use of models in physics, chemistry and the life sciences. As is well known, the question of the role of scientific models and representations has been thoroughly explored, and the available literature is rather extensive. The novelty of the chapters collected in this part of the Handbook is constituted by their focus on domains of scientific inquiry that so far have not received particular attention (if they have received any attention at all). Indeed, in the past authors dealing with scientific models almost exclusively focused on the role of models in physics. The other sciences have been left in the background, perhaps under the implicit, but unjustified, assumption that, once the main philosophical questions of models in physics had been clarified, the results could be straightforwardly extended to the other domains, and in particular to geology, biology, chemistry, and the other natural sciences in general. This physicalistic *sciovinism* is an undeniable but not very beneficial heritage of twentieth century philosophy of science: given the fact that the major scientific revolutions in the first part of this century happened in the domain of physics, philosophers of science tried to solve questions about explanation, realism, evidence, laws, and models by just looking at physics and its mathematical models. However, the scientific enterprise has proven to be much more multifaceted and polychromic than the unified picture handed over to us by the former generations of philosophers has made us believe. Of course, there were significant exceptions also in the last century, but a full awareness of the internal complexity of science and scientific theorizing is probably yet to be achieved. To provide just one example, the widespread conviction that biology has no laws because it is an historical science essentially characterized by contingent factors – as well as the fact that mathematics allegedly lacks a relevant role in biology – has led many philosophers to ignore biology altogether in their reflections on science.

One of the main merits of this section of the Handbook therefore lies in its pluralistic perspective. Chemistry, biology, geology – while regarded as importantly connected to physics on several counts – are all considered on their own merits and treated in depth. The role played by models in these disciplines, that is, is evaluated by the contributors in the specific terms that are appropriate in the relevant domains and theories. And the same holds for the chapters focusing on cognitive science and the social sciences. Despite – and perhaps in virtue of – the fact that each of them presupposes a well-focused, specific perspective, the chapters that follow also give new important insights on the topic of models *in general*. The upshot is that the best way to

understand how models are constructed and applied to the natural world consists in trying to achieve a synthetic or – to put it in Plato's terms – a *synoptic* grasp of the different issues involved in the various disciplines, thereby looking at specific domains and case studies while, at the same time, not losing sight of the forest in favor of the various trees that constitute it.

The chapters contained in this part of the Handbook are all clear, remarkably comprehensive, full of new arguments, and enriched by a wealth of images, graphs, and other forms of visual support. We are sure that readers will find the careful look at new themes and the in-depth analysis of particular aspects of model building and model application particularly stimulating. Before closing this introduction, however, let us briefly summarize each of the chapters that constitute the present part of the Handbook.

In *Chap. 38*, *Giuseppe Longo* and *Maël Montevil* explain how computer simulations brought important novelties in the domain of knowledge construction. In their chapter, they distinguish between mathematical modeling, computer implementations of these models, and purely computational approaches. In all three cases, they suggest that the questions that may be posed concerning the processes under investigation receive different answers. These differences are explored by looking at the various theoretical symmetries that are at work in each framework.

In *Chap. 39*, *Susan Sterrett* carries out a very detailed examination of the role of analogue models in experimentation. Analogue models are actual physical setups used to model something else, useful when what one wishes to investigate is difficult to observe or experiment upon, due to size or distance in space or time. Sterrett describes and discusses several experiments involving analogue models, and the tools for constructing them and interpreting their results.

In *Chap. 40*, *William Goodwin* aims to identify the most significant philosophical insights that have emerged out of the increased interest in scientific models, and to reflect on these insights in the context of chemistry, a discipline that has been relatively neglected in the philosophical literature. Goodwin argues that in chemistry the centrality and significance of models to the scientific enterprise is manifest, and that chemistry is a clear, useful, and interesting context in which to consider general philosophical questions about the nature and role of models in science.

In *Chap. 41*, *Alisa Bokulich* and *Naomi Oreskes* discuss models in geomorphology and the earth sciences, very probably introducing many readers to this

topic for the first time. Their contribution sheds light on the nature of modeling and idealization in sciences that have been as unduly neglected by the philosophical community at large. The geosciences, in particular, deal with issues related to environment, climate and, more generally, a number of complex features determined by physical, chemical, and biological processes that operate at the surface of the earth. As such, they are obviously of the utmost relevance, if only because they promise to provide understanding, and perhaps better control, of the very milieu in which we live.

In [Chap. 42](#), *Elisabeth Lloyd* looks at models in the biological sciences. In particular, starting from the insight that much of evolutionary theory today relies on mathematical models, Lloyd discusses in detail various ways to describe the models that make up evolutionary theory. Special focus is put on the representation of genetic states and changes in a population, which is a crucial part of population genetics theory.

In [Chap. 43](#), *Massimo Marraffa* and *Alfredo Paternoster* study the role of models and mechanisms in cognitive science. The authors give a very well-informed presentation and discussion of the use of models in the cognitive sciences, with special focus on computational models. Their suggestion is that – in

spite of undeniable difficulties in their integration with dynamical aspects – computational models are still to be regarded as fundamental for the study of the mind, in particular in virtue of their clear explanatory significance.

Finally, in [Chap. 44](#), *Federica Russo* discusses the role of model-based reasoning in the social sciences. This chapter provides an overview of various forms of model-based reasoning in social research and discusses the use of experiments and simulations in the study of social contexts. Russo also investigates the links between model-based reasoning and other key philosophical notions, such as explanation, causality, truth, and validity.

While this brief overview cannot do justice to the wealth of novel ideas that are to be found in this part, we hope that it suffices to signal to the readers the extreme importance of taking into account the role of models in those sciences that may supervene on physics, but are not straightforwardly reducible to it. Thus, in expressing our gratitude to the authors for accepting our invitation and for their hard work on their chapters, we close this introduction here and leave the rest of this part of the *Springer Handbook of Model-Based Science* to our readers.

## 38. Comparing Symmetries in Models and Simulations

Giuseppe Longo, Maël Montévil

Computer simulations brought remarkable novelties to knowledge construction. In this chapter, we first distinguish between mathematical modeling, computer implementations of these models and purely computational approaches. In all three cases, different answers are provided to the questions the observer may have concerning the processes under investigation. These differences will be highlighted by looking at the different theoretical symmetries of each frame. In the latter case, the peculiarities of agent-based or object oriented languages allow to discuss the role of phase spaces in mathematical analyses of physical versus biological dynamics. Symmetry breaking and randomness are finally correlated in the various contexts where they may be observed.

Mathematical and computational modeling has become crucial in the natural sciences, as well as in architecture, economics, humanities and more. Sometimes the two modeling techniques are conflated into, or identified with natural processes, typically over continuous or discrete structures, by considering nature either intrinsically continuous or discrete, according to the preferences of the modeler.

Here, we analyze the major differences that exist between continuous (mostly equational) and computational (mostly discrete and algorithmic) modeling, often referred to as computer simulations. We claim that these different approaches to modeling propose different insights into the intended processes: they actually organize nature (or the object of study) in deeply different ways. This may be understood by an analysis of symmetries and symmetry breakings, which are often implicit but strongly enforced by the use of mathematical structures.

We organize the world by symmetries. They constitute a fundamental *principle of (conceptual) construction* [38.1], from Greek geometry to twentieth century physics and mathematics. All axioms by Euclid may

be understood as “maximizing the symmetries of the construction” [38.2]. Euclid’s definitions and proofs proceed by rotations and translations, which are symmetries of space.

Symmetries govern the search for invariants and their preserving transformations that shaped mathematics from Descartes spaces to Grothendieck toposes and all twentieth century mathematics [38.3]. Theoretical physics has been constructed by sharing with mathematics the same principle of (conceptual) construction. Amongst them are symmetries, which describe invariance, and order, which is needed for optimality. Symmetries and order play a key role in theoretical physics, from Galileo’s inertia to the geodetic principle and to Noether’s theorems [38.4–6]. The fundamental passage from Galileo’s symmetry group, which describes the transformation from an inertial frame to another while preserving the theoretical invariants, to Lorentz–Poincaré group characterizes the move from classical to relativistic physics. The geodetic principle is an extremizing principle and a consequence of conservation principles, that is, of symmetries in equations (Noether).

Well beyond mathematics and modern physics, the choice of symmetries as organizing principle is rooted in our search for invariants of action, in space and time, as moving and adaptive animals. We adjust to changing environments by trying to detect stabilities or by forcing them into the environment. Our bilateral symmetry is an example of this evolutionary adjustment between our biological structure and movement: its symmetry plane is given by the vertical axis of gravitation and the horizontal one of movement. The Burgess fauna, some 520 million years ago [38.7] seems to present many cases

of *asymmetric* beasts among these early multicellular organisms, later negatively selected. In this perspective, the role we give to symmetries in mathematics and physics is grounded in prehuman relations to the physical world, well before becoming a fundamental component of our scientific knowledge construction.

By this, we claim that an analysis in theorizing and modeling of the intended symmetries and symmetry breakings is an essential part of an investigation of their reasonable effectiveness and at the core of any comparative analysis.

## 38.1 Approximation

Before getting into our main theme, let's first clarify an *obvious* issue that is not so obvious to many: discrete mathematical structures are not an approximation of continuous ones. They simply provide different insights. Thus, in no way will we stress the superiority of one technique over the other. We will just try to understand continuous versus discrete frames in terms of different symmetries.

It should be clear that, on the one hand, we do not share the view of many, beautifully expressed by René Thom, on the intrinsically continuous nature of the World, where the discrete is just given by singularities in continua. On the other hand, many mythical descriptions of a computational world, or just of the perfection of computational modeling, seem to ignore the limits of discrete approximation as well as some more basic facts in numerical analysis (the first author's first teaching job), which have always been well known. When the mathematical description yields some sensitivity to initial or border conditions, there is no way to approximate that are long enough continuous nonlinear dynamics by an algorithm on discrete data types. Given any digital approximation, the discrete and the continuous trajectories quickly diverge by the combination of the round-off and the sensitivity. However, in some cases (some hyperbolic dynamics), the *discrete trajectory may be indefinitely approximated by a continuous one*, but not conversely. The result is proved by difficult "shadowing theorems" [38.8]. Note that this is the opposite of the *discrete approximating the continuum*, which is taken for granted by many.

Here, we are hinting at a comparison between mathematical techniques that provably differ. These techniques say nothing about the actual physical process, as these are not continuous nor discrete, per se, in our mathematical sense, they are what they are. Yet, it is very easy to check an algorithmic description of a double pendulum against the actual physical device (on sale

for 50 euros on the web): very soon the computational imitation has nothing to do with the actual dynamics. The point is that there is no way to have a physical double pendulum to iterate exactly on the *same* initial conditions (i. e., when started on the same interval of the best possible measurement), as this device is sensitive to minor fluctuations (thermal, for example), well below the unavoidable interval of measurement. By principle and *in practice*, instead, discrete data types allow exact iteration of the computational dynamics starting on exactly the same initial data. Again, this is a difference in symmetries and their breaking.

In conclusion a mathematical analysis of the equations allows to display sensitivity properties, from *mixing*, a weak form of chaos, to high dependence on minor variations of the initial conditions. These are mathematical properties of deterministic chaos. We stress by this that deterministic chaos and its various degrees are a property of the *mathematical model*: by a reasonable abuse one may then say that the modeled physical process is chaotic, if one believes that the mathematical model is a *good/faithful/correct* representation of the intended process. But this is an abuse: the dice or a double pendulum knows very well where it will go: along a unique physical geodesics, extremizing a Lagrangian action, according to the Hamilton principle. It is our problem if we are not able to predict it due to the nonlinearity of the model, which *amplifies fluctuations*, and due to our approximated measurements.

As it happens, the interval of measurement (the unavoidable approximated interface between us and the world) is better understood by continua than over discrete data types (we will go back to this) and, thus, physicists usually deal with equations within continuous frames.

However, the power of discrete computations allows to compute, even forever. By this, an implemented computation gives fantastic images of deterministic chaos.

As a matter of fact, this was mathematically described and perfectly understood by Poincaré in 1892, yet it came to the limelight only after Lorentz's computational discovery of "strange attractors" (and Ruelle's work [38.9]). As deterministic chaos is an asymptotic notion, there is no frame where one can better see chaotic dynamics, strange attractor, or alike than on a computer. Yet, just push the restart button and the most chaotic dynamics will iterate exactly, as we observe and further argue below, far away from any actual physical possibility. And this is not a minor point: it

is *correctness of programs*, a major scientific issue in computer science. Of course, one can artificially break the symmetry, by asking a friend to change the 16th decimal in the initial condition. Then, the chaotic dynamics will follow a very different trajectory on the screen, an interesting information, per se. However, our analysis here is centered on symmetry breaking intrinsic to a theory, that is, on changes which have a physical meaning. This control, which is available in computer simulations, is thus an artifact from a physical perspective.

## 38.2 What Do Equations and Computations Do?

### 38.2.1 Equations

In physics, equations depend on symmetries, either in equilibrium systems, where equations are mostly derived from conservation properties (which are symmetry properties), or in far from equilibrium systems, where equations describe flows, at least in the stationary cases – very little is known in nonstationary cases. This is the physical meaning of most equational descriptions.

One *computes* from equations and, in principle, derives knowledge on physical processes. This is possible by obtaining and discussing solutions – or the lack of solutions: a proof of nonanalyticity such as Poincaré's Three Body Theorem for example, may be very informative. But these derivations are not just formal: they are mostly based on proofs of relevant theorems. The job of mathematical deductions, in physics in particular, is to develop the consequences of *meaningful* writings. Mathematics is not a formal game of signs, but a construction grounded on meaning and handled both by formal "principles of proofs" and by semantically rich "principles of constructions" [38.1]. Typically, arguments are given by *symmetry reasons* or are based on order properties (including well-ordering). Moreover, a mathematical proof may use the genericity of the intended mathematical object or generalized forms of induction that logicians analyze by very large cardinals, an extension of the order of integer numbers obtained by alternating limits and successor operations [38.10]. Once more, theoretical symmetries and meaning step in while proving theorems and solving/discussing equations; also the progress from Laplace's predictability of deterministic process to Poincaré's proof of deterministic though unpredictable processes is a breaking of the observable symmetries (see below for more).

As a matter of fact, we invented very original mathematical structures, from Galois' groups to differential geometry, in order to solve equations or discuss their

solvability. The use of enriched construction principles that are often based on or yielding new mathematical meaning has constantly been stimulated by the analysis of equations. This is part of the common practice of mathematical reasoning. However, well beyond the extraordinary diagonal trick by Gödel, it is very hard to *prove* that *meaningful* procedures are unavoidable in actual proofs, that is to show that meaning is essential to proofs. An analysis of a recent *concrete* incompleteness result is in [38.11]: this means that geometric meaning inevitably steps in proofs even of combinatorial theorems (of arithmetic!), where meaning takes the form of well-ordering which is a geometric judgement. Or very large infinite cardinals may be shown to be essential to proofs [38.12]. In this precise sense, formal deductions as computations, with their finitistic principles of proof, are provably incomplete.

In particular, physicomathematical deductions, used to discuss and solve equations, are *not* just formal computations, i. e., meaningless manipulations of signs. They transfer symmetries in equations to further symmetries, or prove symmetry changes or breaking (non-analyticity, typically). In category theory, equations are analyzed by drawing diagrams and inspecting their symmetries.

### 38.2.2 From Equations to Computations

The mathematical frame of modern computers was proposed within an analysis of formal deductions. In fact Gödel, Kleene, Church, Turing . . . invented computable functions in the 1930s in order to disprove the largely believed completeness hypothesis of formal/axiomatic systems and their formally provable consistency. It is not by chance that an immense mathematical physicist, *H. Weyl*, was one of the few who claimed that the formalist/computational project was trivializing mathematics and conjectured incompleteness, already in

1918 [38.13] (see also [38.1]). Turing, in particular, imagined the logical computing machine imitating a man in the least action of sign manipulation according to formal instructions (write or erase 0 and 1, move left or right of one square in a *child's notebook*), and invented by this the modern split between software and hardware. He then wrote an equation that easily defines an incomputable arithmetic function. Turing's remarkable work for this negative result produced the modern notion of program and digital computer, a discrete state machine working on discrete data types. As we said, computing machinery was invented as an implementation of formal proofs and is provably incomplete even in an arithmetic, let alone proper extension of it, based on principles richer than arithmetic induction (well-ordering, symmetries, infinite ordinals . . .).

Thus, beyond the limits set by the impossibility of approximation mentioned above, there is also a conceptual gap between proving over equations and computing solutions by algorithms on discrete data. The first deals with the physical *meaning* of equations and their symmetries and their breaking, it transfers this meaning to consequences by human reasoning grounded on *gestures* (such as drawing a diagram) and common understanding. It is based on the invention, if needed, of new mathematical structures, possibly infinitary ones from Galois' groups to Hilbert spaces to the modern fine analysis of infinitary proofs [38.14]. These may even be proved to be unavoidable in some cases, such as for well-ordering or the large infinite cardinals mentioned above, well beyond computations and formalisms (see the reference above). Do algorithms transfer "physical meaning" along the computation? Do they preserve symmetries? Are those broken in the same way we understand they are in the natural process under scrutiny?

Our claim is that algorithmic approaches (with the notable exception of interactive automated formal calculus, within its limits) involve a modification of the theoretical symmetries used to describe and understand phenomena in physics, in particular by continua. This means that algorithmic approaches usually convey less or a different physical meaning than the original equation approaches. In other words, the modification of the equations needed for a completely finitary and discrete approach to the determination of a phenomenon leads to losses of meaningful aspects of the mathematization and to the introduction of arbitrary or new features.

As far as losses are concerned, the most preeminent ones probably stem from the departure from the continuum, an invention resulting from measurement from Pythagoras' theorem to the role of intervals in physical measurement. As we already hinted, deterministic unpredictability does not make sense in the computing

world. A program determines and computes on exact data: when those are known, exactly (which is always possible), the program iterates exactly, thus allowing a perfect prediction as the program itself yields the prediction. The point is that deterministic unpredictability is due to the nonlinearity, typically, of the *determination* (the equations) and triggered by nonobservable fluctuations or perturbations *below* the (best) interval of measurement. Now, approximation in mathematics is handled by topologies of open intervals over continua, the so-called *natural topology* over the real numbers.

With regards to this, note that a key assumption bridging mathematics of continua and classical physics is that any sequence of measurements of increasing, arbitrary precision converge to a well-defined state. This is mathematically a Cauchy condition of completeness, which implies that the rational numbers are not sufficient to understand the situation. Cantor's real numbers have been invented exactly to handle these kinds of problems (among other reasons, such as the need to mathematize rigorously the phenomenal continuum in its broadest sense, say the continuum of movement).

Also, the fundamental relation between symmetries and conservation properties exhibited by Noether's theorems depend on the continuum (e.g., continuous time translations), so these results can no longer be derived on a discretized background. In short, these theorems rely on the theoretical ability to transform states continuously along continuous symmetries in equations (of movement, for example) since the intended conserved quantity cannot change during such a transformation. With a discrete transformation the observed quantities can be altered (usually the case in simulations) because there is no continuity to enforce their conservation.

Reciprocally, the changes due to the discretization introduce features that are arbitrary from a physical perspective. For example, a basic discretization of time introduces an arbitrary fundamental time-scale. In numerical analysis, the methodology is to have the (differential) equations as the locus of objectivity and to design algorithms that can be shown to asymptotically converge (in a pertinent mathematical sense, and hopefully rapidly in practice) towards the mathematical solutions of the physically meaningful equations. In these frames, the theoretical meaning of the numerical (or algorithmic) approaches is entirely derivative: such numerical approaches are sound only with respect to, and inasmuch as there are mathematical results showing a proximity with the original equations and the trajectories determined by them. The mathematical results (convergence theorems) define the nature of this proximity and are usually limited to specific cases so that entire research communities develop around the topic of the simulation of a specific family of equations

(Navier–Stokes or alike for turbulence, Schrödinger in quantum physics, ...). As a result, the methods to approach different (nonlinear) equations by computing rely on specific discretizations and their close, often ad hoc, analysis.
