**Springer Handbook  
of Model-Based Science**

---

**Springer Handbooks** provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

## Foreword: Thinking Inside and Outside

Hardly a minute of our lives goes by without reasoning, without “going beyond the information given” (Bruner, 1966). Reasoning happens without our awareness and without our intention. Our visual system rapidly parses light arriving to the retina into figures and ground, into the faces, bodies, objects, scenes, and actions that we recognize in fractions of a second and that enter awareness. The gist stays with us, but the details are not recorded, a process revealed in *change blindness*. Perception is deeply and inherently tied to action, epitomized in mirror neurons, single cells in a monkey cortex that respond both to perceiving an action and to performing it, linking perception and action in a single neuron. The world we see is constantly changing; in order to act, perception is used to predict what happens next, allowing us to catch balls and avoid collisions. Experienced chess and basketball players parse and predict at a more sophisticated level, but the underlying processes seem to be similar, extensive practice in seeing patterns, interpreting them, and selecting appropriate actions. This kind of reasoning is fast thinking (Kahneman, 2011) and the kind of reasoning thoughtfully and thoroughly analyzed in this impressive volume is slow thinking, thinking that is deliberate and reflective and that can unfold over weeks and years and even centuries.

How does deliberative reasoning happen? It happens in a multitude of ways, as is shown insightfully in the many domains analyzed in the chapters that follow. Might there be a way to encompass all of them? Here is one view of thinking, let us call it the *inside-outside* view, a view inspired by theories of Bruner (1966), Piaget (1954), Norman and Rumelhart (1975), Shepard (1984), and Vygotsky (1962), among others, who, however, cannot be held responsible for the present formulation. The inside part is the thinking that happens between the ears; the outside part is the thinking that gets put into the body and the world. This view is iterative, as what gets put in the world can get internalized and then get worked on inside. Inside thinking can be further separated into representations and operations. Representations and operations are useful fictions, ways to think and talk about thinking. Do not expect philosophical precision from them (there is a temperamental difference between and psychologists and philosophers: psychologists live on generalities that ignore sloppy variability, philosophers live

on elegant distinctions) or look for them in the brain. On this view, representations are internalized perceptions. However, representations cannot be copies, they are highly processed. They are interpretations of the content that is the focus of thought. They may select some information from the world and ignore other information, they may rework the information selected, and they may add information, drawing on information already stored in the brain. In this sense, representations are models. On this view, operations are internalized actions, which are analogous to actions in the world. Operations act on representations, transforming them and thereby creating new representations. Examples are in order. We may form a representation of the arrangement of furniture in a room or a corporate structure. We can then draw inferences from the representations by imagining or carrying out actions on the representations, such as comparing parts or tracing paths, for example that the coffee table is too far from the couch or the route from one division to another is too circuitous. You have probably noted that those inferences also depend on functional information stored between the ears. We can then transform the arrangements to create new configurations and act on those to draw further inferences. Seen this way, representations can be created by operations; these processes are iterative and reductive. However, momentarily, representations are regarded as static and transformations as active, changing representations to generate inferences that go beyond the information given to yield new thoughts and discoveries.

The ways that we talk about thinking suggest generality to this view. When we understand, we say that we see something; we have an image or an idea, or a thought or a concept. These are static and they stay still to be acted on. Then we pull ideas together, compare them, turn them inside out, divide them up, reorganize them, or toss them out.

Forming representations, keeping them in mind, and transforming them can quickly overwhelm the mind. When thought overwhelms the mind, the mind puts thought in the body and the world. Counting is a paradigmatic example: actions of the finger or the

**Barbara Tversky**  
Stanford University and  
Columbia Teachers College

hand (or the head or the eye) on an array of objects in the world, pointing to them or moving them, while keeping track of the count with number words. Counting is a sequence of actions on objects linked one-to-one to a sequence of concepts. If representations are internalized perceptions and transformations of thoughts are internalized actions, re-externalizing representations and transformations should promote thought. Moreover, they do, as counting and countless other examples demonstrate. The actions of the body on the objects in the world exemplify the outside kind of thinking and, importantly, they are linked to internal actions, in this case, keeping track of the count.

Putting thought into the world expands the mind. Putting thought into the world allows physical actions to substitute for mental ones. Putting thought in the world makes thought evident to others and to ourselves at other times. Putting thought into the world separates the representing and the transforming and makes them apparent. To be effective, both inside and outside, the representations and the transformations, should be congruent with thought (e.g., Tversky, 2011, 2015). Maps preserve the spatial relations of landmarks and paths. Discrete one-to-one actions help children add and continuous actions help children estimate (Segal, Tversky, and Black, 2014). Gesturing the layout of an environment helps adults remember the spatial relations (Jamalian, Giardino, and Tversky, 2013).

This analysis, representations and operations, inside and outside, is simple, even simplistic. The complexity comes from the interactions between and within inside and outside, in the constructions of the representations, and in the subtleties of the inferences. Representations and operations are intimately interlinked. Representations, internal or external, carry content, but they also have a format, i.e., the way that information is captured and arrayed. The format encourages certain inferences and discourages others. The Arabic number system is friendlier to arithmetic computations than the Roman number system. Maps are friendlier to inferences about routes, distances, and directions than tables of GPS coordinates. Finding the *right* representation, i.e., the one that both captures the information at hand and enables productive inferences, can be hard work; the history of science is filled with such struggles from the structure and workings of the universe to those of the smallest particles. In *The Double Helix* (1968), *Watson* describes the intricate back-and-forth between empirical findings, theory, hypotheses, conversation, photographs, and models that led to the discovery of the model of DNA that succeeded in integrating the biological and chemical structures and phenomena. Typically, there is no single right representation exactly because

different representations capture different information, highlight different relationships, and encourage different inferences. A pilot's map will not serve a hiker or a bicyclist, or a surveyor. Chemists have a multitude of representations of molecules, human biologists of the body, statisticians of a set of data, each designed to simplify, highlight, explain, understand, explore, or discover different aspects of multifaceted, often elusive, phenomena.

This very simple view hides enormous complexity. It can be accused of being an oversimplification. If it were all that simple, design, science, and mathematics would be done with, and they are not. Fortunately, the volume at hand corrects that oversimplification. Introducing this volume is a humbling task. So many kinds of reasoning are revealed so perceptively in so many domains. The diverse thoughtful and thought-provoking contributions reveal fascinating intricacies in model-based reasoning, the nuances of finding suitable representations (models), and the complexities of using them to draw inferences. The many insights in each contribution and in the section overviews cannot readily be summarized, they must be savored. They will be a continuing source of inspiration.

## Foreword

Thomas Kuhn considered that a sign of maturity in the development of a scientific field was the acquisition of a paradigm; researchers will no longer need to constantly battle over the foundations of their discipline, could agree on the proper questions to ask and the theories, techniques, and procedures to answer them. However, paradigms, Kuhn thought, can also lead to quite esoteric research and, after periods of extended anomalies and crises, are eventually displaced by sufficiently unprecedented, sufficiently open-ended achievements, which, leaving a number of problems still to solve, open new avenues for research.

Whether or not there are Kuhnian paradigms in model-based science is perhaps less important than the undeniable fact that, as a domain of inquiry, we have here all the significant signs of a mature field. Crucial questions are raised and addressed with innovative approaches, earlier and more traditional issues are revisited with new insights, and a cluster of apparently unrelated problems are addressed from a perspective that has noteworthy unifying traits.

The crucial concept that brings all of this together is one that is perhaps as rich and suggestive as that of a paradigm: the concept of a *model*. Some models are concrete, others are abstract. Certain models are fairly rigid; others are left somewhat unspecified. Some models are fully integrated into larger theories; others, or so the story goes, have a life of their own. Models of experiment, models of data, models in simulations, archeological modeling, diagrammatic reasoning, abductive inferences; it is difficult to imagine an area of scientific investigation, or established strategies of research, in which models are not present in some form or another. However, models are ultimately understood, there is no doubt that they play key roles in multiple areas of the sciences, engineering, and mathematics, just as models are central to our understanding of the practices of these fields, their history and the plethora of philosophical, conceptual, logical, and cognitive issues they raise.

What Lorenzo Magnani and Tommaso Bertolotti, together with their team of subject-area editors, have created is more than a snapshot of a growing, sophisticated, multifaceted field. They have provided a rich map (a model!) of a sprawling, genuinely interdisciplinary, eclectic, and endlessly fascinating nested series of domains of research.

With this Springer *Handbook*, model-based science acquires more than a clear sign of maturity: it has the excitement, energy, and innovation of those sufficiently groundbreaking, sufficiently boundless, achievements that will nurture and inspire generation upon generation to come.

Editor-in-Chief, *Synthese*

## Preface

The debate about models has crossed philosophy along the centuries, ranging from the most speculative to the most pragmatic and cognitive outlooks. Recently, epistemological perspectives and both scientific and cognitive insights sparked new interdisciplinary studies about how models are created and used. The relevance of the discourse about models transcended the boundaries of philosophy of science, as it was immensely boosted by the progress being made in computation since the 1950s, making the discourse on models not only relevant to scientists and philosophers, but also to computer scientists, programmers, and logicians. Another field of study, strictly connected to modeling, was the study of inferential processes that would go beyond traditional logic and yet play a crucial role in the creation and use of models. The most relevant field, in this respect, concerns abduction and studies on hypothetical cognition.

To provide an initial definition, we can agree that a model is something we use in order to gain some benefit in the understanding or explanation of something else, which can be called the target. “A model allows us to infer something about the thing modeled,” as summarized by the late *John Holland* in his 1995 book *Hidden Order*. A model lets us understand the target, and consequently behave in a way that would not be possible without it; different models usually optimize the understanding of different aspects of the target.

This definition of a model should make it easy to appreciate how many situations that we face every day are tackled by making use of models; to deal with other people we make models of their minds and their intentions, to operate machinery we make models of their functioning, in the remote case of trying to escape from wild animals we make models of their hunting strategies and perceptual systems, to explore novel environments we make models of their spatial configurations, to mention only a few. We make use of models in a wide array of circumstances, but what all models actually share is a dimension of non-abstractness; we create them, or make use of models that have already been constructed by other people, and models usually display a distributed nature, since they are either built on external, material supports (i. e., by means of artifacts, paper sheets, sound waves, body gestures) or, in the case of mental models, are encoded in brain wirings by synapses and chemicals (a mental map, for instance, is the mental simulation of the action of draw-

ing a map – a powerful model construction activity – whose embodiment in the brain was made possible by the enhancement of human cognitive capabilities).

In order to grasp to the fullest the rich universe of models, their relevance in model-based science, but also as cognitive architectures, we divided the handbook into nine parts. The first three parts can be seen as the *ABC* of the discourse, providing a cognitive and theoretical alphabet for the understanding of model-based science, while the remaining six parts each deal with precise, and applied, fields of model-based science.

Part A – *Theoretical Issues in Models*, edited by Demetris Portides, sets the foundation for all of the subsequent debates, exploring the relationships between models and core notions such as those of theory, representation, explanation, and simulation; furthermore, the part extensively lays out the contemporary and complex debate about the ontology of models, that is, the different stances concerning their existence and reality, answering questions such as *How real are models?*, *Are they fictitious?*, *Do they exist like an object exists or like an idea exists?*.

In Part B – *Theoretical and Cognitive Issues in Abduction and Scientific Inference*, Editor Woosuk Park selected contributions exploring the fundamental aspects of a key inference in the production of models, both at the cognitive and scientific levels: abduction. This can be defined as the most basic building block of hypothetical reasoning, or the process of inferring certain facts and/or laws and hypotheses that render some sentences plausible, that explain (and also sometimes discover) a certain (eventually new) phenomenon or observation.

Atocha Aliseda edited Part C – *The Logic of Hypothetical Reasoning, Abduction, and Models*, offering a broad perspective on how different kinds of logic can be employed to model modeling itself, and how this sheds light on model-building processes. As a bridge between the more theoretical and the more specific parts, Part D – *Model-Based Reasoning in Science and History of Science*, edited by Nora Alejandrina Schwartz, frames some issues of exemplar theory and cases concerning the use and the understanding of models in the history and philosophy of physics, biology, and social sciences, but is also about the relevant subject of thought experiments.

Albrecht Heeffer edited Part E – *Models in Mathematics*, which illuminates crucial issues such as the

role of diagrams in mathematical reasoning, the importance of models in actual mathematical practice, and the role played by abductive inferences in the emergence of mathematical knowledge.

In Part F – *Model-Based Reasoning in Cognitive Science*, Editor Athanasios Raftopoulos has selected a number of contributions highlighting the strict relationship between model-based science and model-based reasoning (cognitive science being both a model-based science and the science of modeling), namely the model-based processes underpinning vision and diagrammatic reasoning, but also the relevance of deeper cognitive mechanisms such as embodiment and the neural correlates to model-based reasoning.

Francesco Amigoni and Viola Schiaffonati edited the contributions composing Part G – *Modeling and Computational Issues*, concerning the main intersections between computation, engineering, and model-based science, especially with respect to computational rendering and the simulation of model-based reasoning in artificial cognitive processes, up to robotics.

Part H – *Current and Historical Perspectives on the Use of Models in Physics, Chemistry, and Life Sciences*, edited by Mauro Dorato and Matteo Morganti, offers an exemplary outlook on the fundamental aspects concerning models in hard sciences and life sciences, from a perspective that is not chiefly historical (absorbed by Part D), but rather focuses on practical and theoretical issues as they happen in actual scientific practice.

Cameron Shelley edited the final Part I – *Models in Engineering, Architecture, and Economical and Human Sciences*, providing a series of stimulating and innovative contributions focusing on less represented examples of model-based reasoning and science, for instance in archaeology, economics, architecture, design and innovation, but also social policing and moral reasoning. The focus of this closing part also resides in its ability to show that model-based sciences go beyond the tradition of exact and life sciences, as indeed the reliance on models affects nearly all human endeavors.

The brief excursus on the contents does little justice to the richness and the extensive variety of topics reviewed by the Handbook, but it should be enough to convey one of the main ideas of the Handbook: *Models are everywhere*, and the study thereof is crucial in any human science, discipline, or practice. This is why we conceived this book, hoping to make it highly relevant not only for the philosophy, epistemology, cognitive science, logic, and computational science communities, but also for theoretical biologists, physicists, engineers, and other human scientists dealing with models in their daily work.

We like to see the ample theoretical breadth of this Handbook as having a counterpart in its editorial gen-

esis. Indeed, when we were offered the opportunity to be general editors of the Springer Handbook of Model-Based Science, an intense activity of decision-making followed. To be able to make a decision, we had to think about what editing a handbook was like. Otherwise said, in order to decide we had to know better, and in order to know better we had to make ourselves a *model* of handbook editing. This complex model was partly in our heads, partly in sketches and emails. Part of it was deduced from evidence (other handbooks), part of it came out as hypotheses. Once the model was sufficiently stabilized, giving us a good projection of the major criticalities and some (wishful) scheduling, we accepted the challenge, and the model – continuously updating the progression of the work – would guide our behavior step by step.

We undertook the editing of this Handbook because, so far, there is a vast amount of literature on models, on the inferential and logical processes underdetermining them, and on the philosophy of model-based science, but it is dispersed in more or less recent (and variably authoritative) collections and monographs, journal articles, and conference proceedings. The aim of this Handbook is to offer the possibility to access the core and the state-of-the-art of these studies in a unique, reliable source on the topic, authored by a team of renowned experts.

The present Handbook is the exemplary fruit of research and collaboration. As general editors, we were able to rely on the formidable team of editors we mentioned above, who took the reigns of their parts: Atocha Aliseda, Francesco Amigoni, Mauro Dorato, Albrecht Heeffer, Matteo Morganti, Woosuk Park, Demetris Portides, Athanasios Raftopoulos, Viola Schiaffonati, Nora Alejandrina Schwartz, and Cameron Shelley. They are all remarkable and hard-working academics, and we are most grateful to them for taking the time and shouldering the burden to contact authors, inspire and review contributions, whilst keeping in touch with us. In turn, the editors could count on some of the most renowned and promising scholars in each discipline and field; they are too many to mention here, but our undying recognition and gratitude go to them as well. In addition to our recognition, all of the editors and authors certainly have our congratulations and admiration upon the completion of this work.

Many of the editors and contributors were already part of the ever-growing *MBR (model-based reasoning) community*, an enthusiastic group of philosophers, epistemologists, logicians, cognitive scientists, computer scientists, engineers, and other academics working in the different and multidisciplinary facets of what is known as *model-based reasoning*, especially focusing on hypothetical-abductive reasoning and its role in sci-

entific rationality. The outreach of this handbook goes far beyond the theoretical and personal borders of the MBR community, but it can nevertheless be saluted as a celebration of the 17 years of work and exchange since the first MBR conference was held in Pavia, Italy, in 1998. For us, this Handbook is also a recognition of the work and lives of the many beautiful minds who came to join us, or interacted with the MBR community, who are no longer among us but who will be forever remembered and appreciated.

Last but clearly not least, we are most grateful to Springer's editorial and production team for their constant trust, encouragement, and support. In particular, we wish to thank Leontina Di Cecco, Judith Hinterberg, and Holger Schaepe, as their resilient help and collaboration made a difference in achieving this Handbook.

Finally, beyond its tutorial value for our community, it is our hope that the Handbook will serve as a useful source to attract new researchers to model-based science (and model-based reasoning), and inspire decades of vibrant progress in this fascinating interdisciplinary area. The contents of this Handbook admirably present a very useful bringing together of the vast accomplishments that have taken place in the last 50 years. Certainly, the contents of this Handbook will serve as a valuable tool and guide to those who will produce the even more capable and diverse next generations of research on models.

Pavia, Italy  
Lorenzo Magnani  
Tommaso Bertolotti

## About the Editors

**Lorenzo Magnani**, philosopher, epistemologist, and cognitive scientist, is a Professor of Philosophy of Science at the University of Pavia, Italy, and the Director of its Computational Philosophy Laboratory.

He has been a visiting researcher at Carnegie Mellon University, McGill University, the University of Waterloo and Georgia Institute of Technology and a Visiting Professor at Georgia Institute of Technology, City University of New York, and at Sun Yat-sen University, China.

In the event of the 50th anniversary of the re-building of the Philosophy Department of Sun Yat-sen University in 2010, an award was given to him to acknowledge his contributions to the areas of philosophy, philosophy of science, logic, and cognitive science. He was appointed Member of the International Academy for the Philosophy of the Sciences (AIPS) in 2015.

Amongst his various publications, his book *Abduction, Reason, and Science* has become a well-respected work in the field of human cognition. The book *Morality in a Technological World* develops a philosophical and cognitive theory of the relationships between ethics and technology in a naturalistic perspective. The book *Abductive Cognition. The Epistemological and Eco-Cognitive Dimensions of Hypothetical Reasoning* and the last monograph *Understanding Violence. The Intertwining of Morality, Religion, and Violence: A Philosophical Stance* have been more recently published by Springer, in 2009 and 2011.

Since 1998, initially in collaboration with Nancy J. Nersessian and Paul Thagard, he has created and promoted the MBR Conferences on Model-Based Reasoning. Since 2011 he is the editor of the book series *Studies in Applied Philosophy, Epistemology and Rational Ethics (SAPERE)* by Springer.

**Tommaso Bertolotti** is a Postdoctoral Fellow in Philosophy of Science and Adjunct Professor of Cognitive Philosophy in the Department of Humanities – Philosophy Section, University of Pavia. His research interests include philosophy of science, niche construction theories, cognitive science of religion, social epistemology, and philosophy of technology. He was recently invited to several expert workshops and conferences concerning cyberbullying and internet safety in general, organized by the European Commission together with other institutions and major IT companies. Among his latest publications are *Contemporary finance as a critical cognitive niche* (2015), *An epistemological analysis of gossip and gossip-based knowledge* (2014), *Camouflaging truth: A biological, argumentative and epistemological outlook* (2014), *Generative and Demonstrative Experiments* (2013), *From mindless modeling to scientific models: The case of emerging models* (2012), and the book *Patterns of Rationality. Recurring Inferences in Science, Social Cognition and Religious Thinking* (Springer 2015).

## About the Part Editors

### Demetris Portides

University of Cyprus  
Dept. of Classics and Philosophy  
1678 Nicosia, Cyprus  
[portides@ucy.ac.cy](mailto:portides@ucy.ac.cy)

### Part A

Demetris Portides received his PhD from the University of London (LSE) in 2000. He teaches in the Department of Classics and Philosophy at the University of Cyprus. His research interests include topics in philosophy of science, particularly idealization and abstraction, scientific models, and scientific representation. He is currently working on the ways by which idealization and abstraction are employed in the construction of scientific models.

---

### Woosuk Park

Korea Advanced Institute of Science and Technology (KAIST)  
School of Humanities and Social Science  
Daejeon, 34141, Korea  
[woosukpark@kaist.ac.kr](mailto:woosukpark@kaist.ac.kr)

### Part B

Woosuk Park is currently Full Professor of Philosophy at Korea Advanced Institute of Science and Technology (KAIST). He received his PhD degree from the State University of New York at Buffalo with his dissertation on Duns Scotus' haecceity theory of individuation. He was interested in the issues on the border between logic and ontology. He has expanded the scope of research primarily by his historical approach. His research area now includes the history of logic and axiomatic methods and the history of medieval science and philosophy. Recently, he has become the most interested in abductive cognition. In a series of papers, he has dealt with Lorenzo Magnani's innovative ideas such as animal abduction or visual abduction, thereby examining to what extent Magnani goes with and beyond Peirce. He has published articles in international journals, including *Journal of Applied Logic*, *Erkenntnis*, *Foundations of Science*, *Review of Metaphysics*, and *The Modern Schoolman*.

---

### Atocha Aliseda

Universidad Nacional Autónoma de México (UNAM)  
Instituto de Investigaciones Filosóficas  
04510 Ciudad de México, Mexico  
[atocha@filosoficas.unam.mx](mailto:atocha@filosoficas.unam.mx)

### Part C

Atocha Aliseda received her PhD from Stanford University in Philosophy and Symbolic Systems (1997) and later held a postdoctoral position at Groningen University (2000–2002). She is Full Professor at the Institute for Philosophical Research at the National Autonomous University of México (UNAM). She has published and edited a number of books and articles on logic and the philosophy of science and specializes on abduction and the logics of scientific discovery. She is currently working on clinical reasoning.

### Nora Alejandrina Schwartz

Universidad de Buenos Aires  
Faculty of Economics  
Buenos Aires, Argentina  
[nora\\_schwartz@yahoo.com.ar](mailto:nora_schwartz@yahoo.com.ar)

### Part D

Nora A. Schwartz received her Professor degree in Philosophy from the Universidad de Buenos Aires, Argentina, where she has been teaching since 1997. Professor Schwartz is a member of Asociación de Filosofía de la República Argentina and Sociedad Argentina de Análisis Filosófico. Her research focuses on physical models implicated in creative scientific reasoning leading to conceptual innovation. She takes the cognitive-historical approach developed by Nancy Nersessian in a critical way, emphasizing the cultural dimension of physical models with which scientists reason. She also analyzes the features that satisfactory scientific models should have in order to draw inferences about the reality modeled by them. Currently, she is investigating Luigi Galvani's "discovery of animal electricity". In particular, she is interested in his selection of different three-dimensional objects as model candidates to reason about human neuromuscular system and in the improvement that this historical research case may make to the understanding of analogy.

**Albrecht Heeffer**

Part E

Ghent University  
Centre for Logic and Philosophy of Science  
9000 Ghent, Belgium  
[albrecht.heeffer@ugent.be](mailto:albrecht.heeffer@ugent.be)

Albrecht Heeffer holds a degree in Engineering and a PhD in Philosophy. He publishes on the history of optics, the history of mathematics, and the philosophy of mathematical practice. He is a Research Fellow at Ghent University, Belgium. Albrecht has been a Visiting Fellow at Kobe University (2008), the Sydney Center for the Foundations of Science (Sydney University, 2011), and The Max Planck Institute for History of Science (Berlin, 2014).

**Athanasios Raftopoulos**

Part F

University of Cyprus  
Department of Psychology  
1678 Nicosia, Cyprus  
[raftop@ucy.ac.cy](mailto:raftop@ucy.ac.cy)

Athanasios Raftopoulos received his PhD from the Johns Hopkins University in 1993. He teaches in the Department of Psychology at the University of Cyprus. His research interests include philosophy of science, philosophy of perception, epistemology, philosophy of the mind, and cognitive science. He is currently working on the relation between cognition and perception.

**Francesco Amigoni**

e Bioingegneria  
20133 Milano, Italy  
[viola.schiaffonati@polimi.it](mailto:viola.schiaffonati@polimi.it)

Viola Schiaffonati has Laurea (Milano, 1999) and PhD (Genova, 2004) degrees. She is Associate Professor of Logic and Philosophy of Science at the Dipartimento di Elettronica, Informazione e Bioingegneria of Politecnico di Milano. Her main research interests include the philosophical foundations of artificial intelligence and robotics and the philosophy of computing sciences and information, with particular attention on the philosophical issues of computational science and the epistemology of experiments.

**Mauro Dorato**

Part H

University of Rome  
Dipartimento di Filosofia, Comunicazione  
e Spettacolo  
00144 Rome, Italy  
[mauro.dorato@uniroma3.it](mailto:mauro.dorato@uniroma3.it)

Mauro Dorato earned his PhD in Philosophy from the Johns Hopkins University (1992). He is Full Professor for Philosophy of Science at the University of Rome 'Tre'. He has been Director of the PhD Program in Philosophy since 2013. His research focuses on the philosophy of physics, philosophy of time and the nature of scientific laws. Currently he is Co-Editor of the *European Journal for Philosophy of Science*.

**Matteo Morganti**

Part H

University of Rome  
Dipartimento di Filosofia, Comunicazione  
e Spettacolo  
00144 Rome, Italy  
[matteo.morganti@uniroma3.it](mailto:matteo.morganti@uniroma3.it)

Matteo Morganti is Associate Professor at the University of Rome 'Tre'. He works in the field of philosophy of science and is particularly interested in the interplay between science and analytic metaphysics and in the issue of scientific realism versus antirealism and the interpretation of contemporary physical theories. He earned his PhD at the London School of Economics and has worked at IHPST in Paris and the University of Konstanz.

**Cameron Shelley**

Part I

University of Waterloo  
Centre for Society, Technology & Values  
Waterloo, N2L 3G1, Canada  
[cam\\_shelley@yahoo.ca](mailto:cam_shelley@yahoo.ca)

Cameron Shelley received his PhD in Philosophy from the University of Waterloo in 1999. He is currently a Lecturer at the Centre for Society, Technology & Values in the Department of Systems Design Engineering at the University of Waterloo. His research focuses on model-based reasoning and philosophical issues in technology, such as the involvement of ideology and fairness in technological design.

## Contents

<b>List of Abbreviations</b> .....	XXXVII
------------------------------------	--------

### Part A Theoretical Issues in Models

<b>1 The Ontology of Models</b>	
<i>Axel Gelfert</i> .....	5
1.1 Kinds of Models: Examples from Scientific Practice .....	6
1.2 The Nature and Function of Models .....	8
1.3 Models as Analogies and Metaphors .....	10
1.4 Models Versus the Received View: Sentences and Structures .....	12
1.5 The Folk Ontology of Models .....	16
1.6 Models and Fiction .....	18
1.7 Mixed Ontologies: Models as Mediators and Epistemic Artifacts ....	20
1.8 Summary .....	21
<b>References</b> .....	22
<b>2 Models and Theories</b>	
<i>Demetris Portides</i> .....	25
2.1 The Received View of Scientific Theories .....	26
2.2 The Semantic View of Scientific Theories .....	36
<b>References</b> .....	47
<b>3 Models and Representation</b>	
<i>Roman Frigg, James Nguyen</i> .....	49
3.1 Problems Concerning Model-Representation .....	51
3.2 General Griceanism and Stipulative Fiat .....	55
3.3 The Similarity Conception .....	57
3.4 The Structuralist Conception .....	66
3.5 The Inferential Conception .....	76
3.6 The Fiction View of Models .....	83
3.7 Representation-as .....	91
3.8 Envoi .....	96
<b>References</b> .....	96
<b>4 Models and Explanation</b>	
<i>Alisa Bokulich</i> .....	103
4.1 The Explanatory Function of Models .....	104
4.2 Explanatory Fictions: Can Falsehoods Explain? .....	108
4.3 Explanatory Models and Noncausal Explanations .....	112
4.4 How-Possibly versus How-Actually Model Explanations .....	114
4.5 Tradeoffs in Modeling: Explanation versus Other Functions for Models .....	115
4.6 Conclusion .....	116
<b>References</b> .....	117

<b>5 Models and Simulations</b>	
<i>Nancy J. Nersessian, Miles MacLeod</i> .....	119
5.1 Theory-Based Simulation .....	119
5.2 Simulation not Driven by Theory .....	121
5.3 What is Philosophically Novel About Simulation? .....	124
5.4 Computational Simulation and Human Cognition .....	127
<b>References</b> .....	130
<b>Part B Theoretical and Cognitive Issues on Abduction and Scientific Inference</b>	
<b>6 Reorienting the Logic of Abduction</b>	
<i>John Woods</i> .....	137
6.1 Abduction .....	138
6.2 Knowledge .....	141
6.3 Logic .....	148
<b>References</b> .....	149
<b>7 Patterns of Abductive Inference</b>	
<i>Gerhard Schurz</i> .....	151
7.1 General Characterization of Abductive Reasoning and Ibe .....	152
7.2 Three Dimensions for Classifying Patterns of Abduction .....	154
7.3 Factual Abduction .....	155
7.4 Law Abduction .....	158
7.5 Theoretical-Model Abduction .....	159
7.6 Second-Order Existential Abduction .....	161
7.7 Hypothetical (Common) Cause Abduction Continued .....	162
7.8 Further Applications of Abductive Inference .....	169
<b>References</b> .....	171
<b>8 Forms of Abduction and an Inferential Taxonomy</b>	
<i>Gerhard Minnameier</i> .....	175
8.1 Abduction in the Overall Inferential Context .....	177
8.2 The Logicity of Abduction, Deduction, and Induction .....	183
8.3 Inverse Inferences .....	185
8.4 Discussion of Two Important Distinctions Between Types of Abduction .....	189
8.5 Conclusion .....	193
<b>References</b> .....	193
<b>9 Magnani's Manipulative Abduction</b>	
<i>Woosuk Park</i> .....	197
9.1 Magnani's Distinction Between Theoretical and Manipulative Abduction .....	197
9.2 Manipulative Abduction in Diagrammatic Reasoning .....	198
9.3 When Does Manipulative Abduction Take Place? .....	203
9.4 Manipulative Abduction as a Form of Practical Reasoning .....	204
9.5 The Ubiquity of Manipulative Abduction .....	206
9.6 Concluding Remarks .....	212
<b>References</b> .....	212

## Part C The Logic of Hypothetical Reasoning, Abduction, and Models

<b>10 The Logic of Abduction: An Introduction</b>	
<i>Atocha Aliseda</i> .....	219
10.1 Some History .....	219
10.2 Logical Abduction .....	222
10.3 Three Characterizations .....	225
10.4 Conclusions .....	228
<b>References</b> .....	229
<b>11 Qualitative Inductive Generalization and Confirmation</b>	
<i>Mathieu Beirlaen</i> .....	231
11.1 Adaptive Logics for Inductive Generalization .....	231
11.2 A First Logic for Inductive Generalization .....	232
11.3 More Adaptive Logics for Inductive Generalization .....	237
11.4 Qualitative Inductive Generalization and Confirmation .....	240
11.5 Conclusions .....	245
11.A Appendix: Blocking the Raven Paradox? .....	246
<b>References</b> .....	247
<b>12 Modeling Hypothetical Reasoning by Formal Logics</b>	
<i>Tjerk Gauderis</i> .....	249
12.1 The Feasibility of the Project .....	249
12.2 Advantages and Drawbacks .....	251
12.3 Four Patterns of Hypothetical Reasoning .....	252
12.4 Abductive Reasoning and Adaptive Logics .....	255
12.5 The Problem of Multiple Explanatory Hypotheses .....	256
12.6 The Standard Format of Adaptive Logics .....	256
12.7 $LA_s^r$ : A Logic for Practical Singular Fact Abduction .....	258
12.8 $MLA_s^s$ : A Logic for Theoretical Singular Fact Abduction .....	261
12.9 Conclusions .....	265
12.A Appendix: Formal Presentations of the Logics $LA_s^r$ and $MLA_s^s$ .....	265
<b>References</b> .....	267
<b>13 Abductive Reasoning in Dynamic Epistemic Logic</b>	
<i>Angel Nepomuceno-Fernández, Fernando Soler-Toscano,</i> <i>Fernando R. Velázquez-Quesada</i> .....	269
13.1 Classical Abduction .....	270
13.2 A Dynamic Epistemic Perspective .....	272
13.3 Representing Knowledge and Beliefs .....	275
13.4 Abductive Problem and Solution .....	278
13.5 Selecting the Best Explanation .....	281
13.6 Integrating the Best Solution .....	284
13.7 Working with the Explanations .....	287
13.8 A Brief Exploration to Nonideal Agents .....	289
13.9 Conclusions .....	290
<b>References</b> .....	292
<b>14 Argumentation and Abduction in Dialogical Logic</b>	
<i>Cristina Barés Gómez, Matthieu Fontaine</i> .....	295
14.1 Reasoning as a Human Activity .....	295

14.2	Logic and Argumentation: The Divorce .....	297
14.3	Logic and Argumentation: A Reconciliation .....	299
14.4	Beyond Deductive Inference: Abduction .....	303
14.5	Abduction in Dialogical Logic.....	306
14.6	Hypothesis: What Kind of Speech Act?.....	310
14.7	Conclusions .....	312

## List of Abbreviations

1-D	one-dimensional
2-D	two-dimensional
2.5-D	two-and-a-half-dimensional
3-D	three-dimensional
3M	mechanism-model-mapping constraint
4-D	four-dimensional
5-D	five-dimensional

### A

AAMAS	autonomous agents and multiagent systems
AB	abnormal behavior
ABC	amoeba-based computing
ABM	agent-based model
ABS	agent-based simulation
ACT-R	Adaptive Control of Thought-Rational
AEC	architecture, engineering and construction
AGM	Alchourrón, Gärdenfors and Makinson
AI	artificial intelligence
AKM	Aliseda–Kakas/Kowalski–Magnani/Meheus
AL	adaptive logic
ALP	abductive logic programming
AM	Automated Mathematician
AmI	ambient intelligence
ANN	artificial neural network
ART	adaptive resonance theory

### B

bd	basic property of determinedness
BDI	belief, desire, intention
BIM	building information model
BMN	braided monoidal categories
BN	Bayesian network
BOID	beliefs, obligations, intentions and desires
BPTT	backpropagation through time

### C

CA	cellular automata
CAD	computer-aided design
CAESAR	cellular automaton evolutionary slope and river
CAPM	capital asset pricing model
CBR	case-based reasoning
CC	causal connection
CCG	clock-controlled genes
CDS	complex dynamic systems
CERN	European Organization for Nuclear Research
CG	causal graph

CHILD	channel-hillslope integrated landscape development
CI	cognitively impenetrable
CIF	cash inflow
CL	classical logic
CMIP	coupled model intercomparison project
CMR	computational matrix representation
COF	cash outflow
COR	chains of reasoning connections
CORMAS	common-pool resources and multi-agent systems
CP	cognitive penetrability
CPL	classical propositional logic
CPM	classical particle mechanic
CPU	central processing unit
CR	causal response
CRTM	computational and representational theory of mind

### D

DAT	derivability adjustment theorem
DC	demarcation criterion
DCF	disjunctive conceptual fault
DDI	denotation, demonstration, interpretation
DEKI	denotation, exemplification, keying-up and imputation
DEL	dynamic epistemic logic
DEVS	Discrete Event System Specification
DIAMOND	diagrammatic reasoning and deduction
DJ	data jacket
DL	description logics
DN	deductive-nomological
DNA	deoxyribonucleic acid
DoF	degree of freedom
DRNN	dual recurrent neural network
DSL	domain specific language
DSM	discrete state machine

### E

E.O.L.	ease of learning
EELD	evidence extraction and link discovery
EL	epistemic logic
ENIAC	electronic numerical integrator and computer
EPR	Einstein–Podolsky–Rosen
ER	epistemic representation
ERH	external reality hypothesis
ERP	event-related potentials
ESM	Earth system model
ESS	evolutionary stable strategy
EU	expected utility
EUT	expected utility theory

## Part A Theoretical Issues in Models

Ed. by Demetris Portides

**1 The Ontology of Models**

Axel Gelfert, Singapore, Singapore

**2 Models and Theories**

Demetris Portides, Nicosia, Cyprus

**3 Models and Representation**

Roman Frigg, London, UK  
James Nguyen, London, UK

**4 Models and Explanation**

Alisa Bokulich, Boston, USA

**5 Models and Simulations**

Nancy J. Nersessian, Cambridge, USA  
Miles MacLeod, Enschede,  
The Netherlands

It is not hard to notice the lack of attention paid to scientific models in mid-twentieth century philosophy of science. Models were, for instance, absent from philosophical theories of scientific explanation; they were also absent from attempts to understand how theoretical concepts relate to experimental results. In the last few decades, however, this has changed, and philosophers of science are increasingly turning their attention to scientific models. Models and their relation to other parts of the scientific apparatus are now under philosophical scrutiny; at the same time, they are instrumental parts of approaches that aim to address certain philosophical questions.

After recognizing the significance of models in scientific inquiry and in particular the significance of models in linking theoretical concepts to experimental reports, philosophers have begun to explore a number of questions about the nature and function of models. There are several philosophically interesting questions that could fit very well into the theme of this set of chapters. For example, *what is the function of models?* and *what is the role of idealization and abstraction in modeling?* It is, however, not the objective of this set of chapters to address every detail about models that has gained philosophical interest over time. In this part of the book five model-related philosophical questions are isolated from others and are explored in separate chapters:

1. What is a scientific model?
2. How do models and theories relate?
3. How do models represent phenomena?
4. How do models function in scientific explanation?
5. How do models and other modes of scientific theorizing, such as simulations, relate?

Of course, the authors of these chapters are all aware that isolating these questions is only done in order to reach an intelligible exposition of the explored problems concerning models, and not because different questions have been kept systematically apart in the philosophical literature that preceded this work. In fact, the very nature of some of these questions dictates an interrelation with others and attempts to address one leads to overlaps with attempts to address others. For example, how one addresses the question *what sort of entities are models?* or how one conceives the theory–model relation affects the understanding of their scientific representation and scientific explanation, and vice versa. Although this point becomes evident in the subsequent chapters, a conscious attempt was made by each author to focus on the one question of concern of their chapter and to attempt to extrapolate and explicate the different proposed philosophical accounts that

have been offered in the quest to answer that particular question. We hope that the final outcome is helpful and illuminating to the reader.

*Axel Gelfert* in his contribution, **Chap. 1: *The Ontology of Models***, explicates the different ways in which philosophers have addressed the issue of what a scientific model is. For historical reasons, he begins by examining the view that was foremost almost a century ago, which held that models could be understood as analogies. He then quickly turns his attention to a debate that took place in the second half of the twentieth century between advocates of logical positivism, who held that models are interpretations of a formal calculus, and advocates of the semantic view, which maintained that models are directly defined mathematical structures. He continues by examining the more recent view, which identifies models with fictional entities. He closes his chapter with an explication of what he calls the more pragmatic accounts, which hold that models can best be understood with the use of a mixed ontology.

In **Chap. 2: *Models and Theories***, *Demetris Portides* explicates the two main conceptions of the structure of scientific theories (and subsequently the two main conceptions of the theory–model relation) in the history of the philosophy of science, the received and the semantic views. He takes the reader through the main arguments that led to the collapse of the received view and gives the reader a lens by which to distinguish the different versions of the semantic view. He finally presents the main arguments against the semantic view and in doing so he explicates a more recent philosophical trend that conceives the theory–model relation as too complex to sufficiently capture with formal tools.

*Roman Frigg* and *James Nguyen*, in **Chap. 3: *Models and Representation*** begin by analyzing the concept of representation and clarifying its main characteristics and the conditions of adequacy any theory of representation should meet. They then proceed to explain the main theories of representation that have been proposed in the literature and explain with reference to their proposed set of characteristics and conditions of adequacy where each theory is found wanting. The similarity, the structuralist, the inferential, the fictionalist, and the denotational accounts of representation are all thoroughly explained and critically assessed. By doing this the authors expose and explicate many of the weaknesses of the different accounts of representation.

In **Chap. 4: *Models and Explanation***, *Alisa Bokulich* explains that by recognizing the extensive use of models in science and by realizing that models are more often than not highly idealized and incomplete

---

descriptions of phenomena that frequently incorporate fictional elements, philosophers have been led to revise previous philosophical accounts of scientific explanation. By scrutinizing different model-based accounts of scientific explanation offered in the literature and exposing the problems involved, she highlights the difficulties involved in resolving the issue of whether or not the falsehoods present in models are operative in scientific explanation.

Finally, *Nancy Nersessian* and *Miles McLeod*, in **Chap. 5: *Models and Simulations***, explicate a more recent issue that is increasingly gaining the interest of philosophers: how scientific models, i.e., the mathematical entities that scientists traditionally use to represent phenomena, relate to simulations, particularly computational simulations. They give a flavor of the character-

istics of computational simulations both in the context of well-developed overarching theories and in the context where an overarching theory is absent. The authors also highlight the epistemological significance of simulations for all such contexts by elaborating on how simulations introduce novel problems that should concern philosophers. Finally, they elaborate on the relation between simulations and other constructs of human cognition such as thought experiments.

In most cases, in all chapters the technical aspects of the philosophical arguments have been kept to a minimum in order to make them accessible even to readers working outside the sphere of the philosophy of science. Suppressing the technical aspects has not, however, introduced misrepresentation or distortion to philosophical arguments.

# The Ontology of Models

Axel Gelfert

The term *scientific model* picks out a great many things, including scale models, physical models, sets of mathematical equations, theoretical models, toy models, and so forth. This raises the question of whether a general answer to the question *What is a model?* is even possible. This chapter surveys a number of philosophical approaches that bear on the question of what, in general, a scientific model is. While some approaches aim for a unitary account that would apply to models in general, regardless of their specific features, others take as their basic starting point the manifest heterogeneity of models in scientific practice. This chapter first motivates the ontological question of what models are by reflecting on the diversity of different kinds of models and arguing that models are best understood as *functional entities*. It then provides some historical background regarding the use of analogy in science as a precursor to contemporary notions of *scientific model*. This is followed by a contrast between the syntactic and the semantic views of theories and models and their different stances toward the question of what a model is. Scientists, too, typically operate with tacit assumptions about the ontological status of models: this gives rise to what has been called the *folk ontology* of models, according to which models may be thought of as descriptions of missing (i. e., uninstantiated) systems. There is a close affinity between this view and recent philosophical positions (to be discussed in the

penultimate section) according to which models are fictions. This chapter concludes by considering various pragmatic conceptions of models, which are typically associated with what may be called *mixed ontologies*, that is, with the view that any quest for a unitary account of the nature of models is bound to be fruitless.

The philosophical discussion about models has emerged from a cluster of concerns, which span a range of theoretical, formal, and practical questions across disciplines ranging from logic and mathematics to aesthetics and artistic representations. In what follows, the term *models* will normally be taken as synonymous to *scientific models*, and any departure from this usage – for example, when discussing the use of models in non-scientific settings – will either be indicated explicitly or will be clear from context. Focusing on scientific models helps to clarify matters, but still leaves a wide

range of competing philosophical approaches for discussion. This chapter will summarize and critically discuss a number of such approaches, especially those that shed light on the question *what is a model?*; these will range from views that, by now, are of largely historical interest to recent proposals at the cutting edge of the philosophy of science. While the emphasis throughout will be on the ontology of models, it will often be necessary to also reflect on their function, use, and construction. This is not meant to duplicate the discussion provided in other chapters of this handbook; rather, it is the natu-

ral result of scientific models having traditionally been defined either in terms of their function (e.g., to provide representations of target systems) or via their relation to other (purportedly) better understood entities, such as scientific theories.

The rest of this chapter is organized as follows: Sect. 1.1 will set the scene by introducing a number of examples of scientific models, thereby raising the question of what degree of unity any philosophical account of scientific models can reasonably aspire to. Section 1.2 will characterize models as functional entities and will provide a general taxonomy for how to classify various possible philosophical approaches. A first important class of specific accounts, going back to nineteenth-century scientists and philosophers, will be discussed in Sect. 1.3, which focuses on models as analogies. Section 1.4 is devoted to formal approaches

that dominated much of twentieth-century discussion of scientific models. In particular, it will survey the syntactic view of theories and models and its main competitor, the semantic view, along with recent formal approaches (such as the partial structures approach) which aim to address the shortcomings of their predecessors. Section 1.5 provides a sketch of what has been called the *folk ontology* of models – that is, a commonly shared set of assumptions that inform the views of scientific practitioners. On this view, models are place-holders for *imaginary concrete systems* and as such are not unlike fictions. The implications of fictionalism about models are discussed in Sect. 1.6. Finally, in Sect. 1.7, recent pragmatic accounts are discussed, which give rise to what may be called a *mixed ontology*, according to which models are best conceived of as a heterogeneous mixture of elements.

## 1.1 Kinds of Models: Examples from Scientific Practice

Models can be found across a wide range of scientific contexts and disciplines. Examples include the Bohr model of the atom (still used today in the context of science education), the billiard ball model of gases, the DNA double helix model, scale models in engineering, the Lotka–Volterra model of predator–prey dynamics in population biology, agent-based models in economics, the Mississippi River Basin model (which is a 200 acres hydraulic model of the waterways in the entire Mississippi River Basin), and general circulation models (GCMs), which allow scientists to run simulations of Earth’s climate system. The list could be continued indefinitely, with the number of models across the natural and social sciences growing day by day.

In philosophical discussions of scientific models, the situation is hardly any different. The *Stanford Encyclopedia of Philosophy* gives the following list of model types that have been discussed by philosophers of science [1.1]:

“Probing models, phenomenological models, computational models, developmental models, explanatory models, impoverished models, testing models, idealized models, theoretical models, scale models, heuristic models, caricature models, didactic models, fantasy models, toy models, imaginary models, mathematical models, substitute models, iconic models, formal models, analogue models and instrumental models.”

The proliferation of models and model types, in the sciences as well as in the philosophical literature, led Goodman to lament in his 1968 *Languages of Art* [1.2, p. 171]: “Few terms are used in popular and scientific

discourse more promiscuously than *model*.” If this was true of science and popular discourse in the late 1960s, it is all the more true of the twenty-first century philosophy of science.

As an example of a physics-based model, consider the *Ising model*, proposed in 1925 by the German physicist Ernst Ising as a model of ferromagnetism in certain metals. The model starts from the idea that a macroscopic magnet can be thought of as a collection of elementary magnets, whose orientation determines the overall magnetization. If all the elementary magnets are aligned along the same axis, then the system will be perfectly ordered and will display a maximum value of the magnetization. In the simplest one-dimensional (1-D) case, such a state can be visualized as a chain of *elementary magnets*, all pointing the same way

... ↑↑↑↑↑↑↑↑↑↑↑↑↑↑ ...

The alignment of elementary magnets can be brought about either by a sufficiently strong external magnetic field or it can occur spontaneously, as will happen below a critical temperature, when certain substances (such as iron and nickel) undergo a ferromagnetic phase transition. Whether or not a system will undergo a phase transition, according to thermodynamics, depends on its energy function, which in turn is determined by the interactions between the component parts of the system. For example, if neighboring *elementary magnets* interact in such a way as to favor alignment, there is a good chance that a spontaneous phase transition may occur below a certain temperature. The energy function, then, is crucial to the model and, in the case of the Ising

model, is defined as

$$E = - \sum_{i,j} J_{ij} S_i S_j ,$$

with the variable  $S_i$  representing the orientation (+1 or -1) of an elementary magnet at site  $i$  in the crystal lattice and  $J_{ij}$  representing the strength of interaction between two such elementary magnets at different lattice sites  $i$  and  $j$ .

Contrast this with *model organisms* in biology, the most famous example of which is the fruit fly *Drosophila melanogaster*. Model organisms are real organisms – actual plants and animals that are alive and can reproduce – yet they are used as representations either of another organism (e.g., when rats are used in place of humans in medical research) or of a biological phenomenon that is more universal (e.g., when fruit flies are used to study the effects of crossover between homologous chromosomes). Model organisms are often bred for specific purposes and are subject to artificial selection pressures, so as to purify and *standardize* certain features (e.g., genetic defects or variants) that would not normally occur, or would occur only occasionally, in populations in the wild. As *Ankeny* and *Leonelli* put it, in their ideal form “model organisms are thought to be a relatively simplified form of the class of organism of interest” [1.3, p. 318]; yet it often takes considerable effort to work out the actual relationships between the model organism and its target system (whether it be a certain biological phenomenon or a specific class of target organisms). Tractability and various experimental desiderata – for example, a short life cycle (to allow for quick breeding) and a relatively small and compact genome (to allow for the quick identification of variants) – take precedence over theoretical questions in the choice of model organisms; unlike for the Ising model, there is no simple mathematical formula that one can rely on to study how one’s model behaves, only the messy world of real, living systems.

The Ising model of ferromagnetism and model organisms such as *Drosophila melanogaster* may be at opposite ends of the spectrum of scientific models. Yet the diversity among those models that occupy the middle ground between theoretical description and experimental system is no less bewildering. How, one might wonder, can a philosophical account of scientific models aspire to any degree of unity or generality in the light of such variety? One obvious strategy is to begin by drawing distinctions between different overarching types of models. Thus, *Black* [1.4] distinguishes between four such types:

1. Scale models

2. Analog models
3. Mathematical models
4. Theoretical models.

The basic idea of scale and analog models is straightforward: a scale model increases or decreases certain (e.g., spatial) features of the target system, so as to render them more manageable in the model; an analog model also involves the change of medium (as in once popular hydraulic models of the economy, where the flow of money was represented by the flow of liquids through a system of pumps and valves). Mathematical models are constructed by first identifying a number of relevant variables and then developing empirical hypotheses concerning the relations that may hold between the variables; through (often drastic) simplification, a set of mathematical equations is derived, which may then be evaluated analytically or numerically and tested against novel observations. Theoretical models, finally, begin usually by extrapolating imaginatively from a set of observed facts and regularities, positing new entities and mechanisms, which may be integrated into a possible theoretical account of a phenomenon; comparison with empirical data usually comes only at a later stage, once the model has been formulated in a coherent way.

*Achinstein* [1.5] includes mathematical models in his definition of *theoretical model*, and proposes an analysis in terms of sets of assumptions about a model’s target system. This allows him to include Bohr’s model of the atom, the DNA double-helix model (considered as a set of structural hypotheses rather than as a physical ball-and-stick model), the Ising model, and the Lotka–Volterra model among the class of theoretical systems. Typically, when a scientist constructs a theoretical model, she will help herself to certain established principles of a more fundamental theory to which she is committed. These will then be adapted or modified, notably by introducing various new assumptions specific to the case at hand. Typically, an inner structure or mechanism is posited which is thought to explain the features of the target system. At the same time, there is the (often explicit) acknowledgment that the target system is far more complex than the model is able to capture: in this sense, a theoretical model is believed by the practitioner to be false as a description of the target system. However, this acknowledgment of the limits of applicability of models also allows researchers to simultaneously use different models of the same target system alongside each other. Thus understood, theoretical models usually involve the combination of general theoretical principles and specific auxiliary assumptions, which may only be valid for a narrow range of parameters.

## 1.2 The Nature and Function of Models

The great variety of models employed in scientific practice, as illustrated by the long list given in the preceding section, suggests two things. First, it makes vivid just how central the use of models is to the scientific enterprise and to the self-image of scientists. As *von Neumann* put it, with some hyperbole [1.6, p. 492]: “The sciences do not try to explain, they hardly even try to interpret, they mainly make models.” Whatever shape and form the scientific enterprise might take without the use of models, it seems safe to say that it would not look anything like science as we presently know it. Second, one might wonder whether it is at all reasonable to look for a unitary philosophical account of models. Given the range of things we call *models*, and the diversity of uses to which they are being put, it may simply not be possible to give a one-size-fits-all answer to the question *what is a model?* This has led some commentators to propose quietism as the only viable attitude toward ontological questions concerning models and theories. As *French* puts it [1.7, p. 245],

“whereas positing the reality of quarks or genes may contribute to the explanation of certain features of the physical world, adopting a similar approach toward theories and models – that is, reifying them as entities for which a single unificatory account can be given – does nothing to explain the features of scientific practice.”

While there are good grounds for thinking that quietism should only be a position of last resort in philosophy, the sentiment expressed by *French* may go some way toward explaining why there has been a relative dearth of philosophical work concerning the ontology of models. The neglect of ontological questions concerning models has been remarked upon by a number of contributors, many of whom, like *Connessa*, find it [1.8, p. 194]

“surprising if one considers the amount of interest raised by analogous questions about the ontology and epistemology of mathematical objects in the philosophy of mathematics.”

A partial explanation of this discrepancy lies in the arguably greater heterogeneity in what the term *scientific models* is commonly thought to refer to, namely, anything from physical ball-and-stick models of chemical molecules to mathematical models formulated in terms of differential equations. (If we routinely included dividers, compasses, set squares, and other technical drawing tools among, say, the class of *geometrical entities*, the ontology of mathematical entities, too, would quickly become rather unwieldy!)

In the absence of any widely accepted unified account of models – let alone one that would provide a conclusive answer to ontological questions arising from models – it may be natural to assume, as indeed many contributors to the debate have done, that “if all scientific models have something in common, this is not their *nature* but their *function*” [1.8, p. 194]. One option would be to follow the quietist strategy concerning the ontology of models and “refuse to engage with this issue and ask, instead, how can we best represent these features [and functions of models] in order that we can understand” [1.7, p. 245] the practice of scientific modeling. Alternatively, however, one might simply accept that the function of models in scientific inquiry is our best – and perhaps only – guide when exploring answers to the question *what is a model?*. At the very least, it is not obvious that an exploration of the ontological aspects of models is necessarily fruitless or misguided. *Ducheyne* puts this nicely when he argues that [1.9, p. 120],

“if we accept that models are functional entities, it should come as no surprise that when we deal with scientific models ontologically, we cannot remain silent on how such models function as carriers of scientific knowledge.”

As a working assumption, then, let us treat scientific models as *functional entities* and explore how much ontological unity – over and above their *mere* functional role – we can give to the notion of *scientific model*.

Two broad classes of functional characterizations of models can be distinguished, according to which it is either *instantiation* or *representation* that lie at the heart of how models function. As *Giere* [1.10] sees it, on the *instantial view*, models instantiate the axioms of a theory, where the latter is understood as being comprised of linguistic statements, including mathematical statements and equations. (For an elaboration of how such an account might turn out, see Sect. 1.4.) By contrast, on the *representational view*, “language connects not directly with the world, but rather with a model, whose characteristics may be precisely defined”; the model then connects with the world “by way of similarity between a model and the designated parts of the world” [1.10, p. 156]. Other proponents of the representational view have de-emphasized the role of similarity, while still endorsing representation as one of the key functions of scientific models. Generally speaking, proponents of the representational view consider models to be “tools for *representing the world*,” whereas those who favor the *instantial view* regard them

primarily as “providing a means for interpreting formal systems” [1.10, p. 44].

Within the class of representational views, one can further distinguish between views that emphasize the *informational* aspects of models and those that take their *pragmatic* aspects to be more central. *Chakravartty* nicely characterizes the informational variety of the representational view as follows [1.11, p. 198]:

“The idea here is that a scientific representation is something that bears an objective relation to the thing it represents, on the basis of which it contains information regarding that aspect of the world.”

The term *objective* here simply means that the requisite relation obtains independently of the model user’s beliefs or intentions as well as independently of the specific representational conventions he or she might be employing. *Giere*’s similarity-based view of representation – according to which scientific models represent in virtue of their being similar to their target systems in certain specifiable ways – would be an example of such an informational view similarity, as construed by *Giere*, is a relation that holds between the model and its target, irrespective of a model user’s beliefs or intentions, and regardless of the cognitive uses to which he or she might put the model. Other philosophical positions that are closely aligned with the informational approach might posit that, for a model to represent its target, the two must stand in a relation of isomorphism, partial isomorphism, or homomorphism to one another.

By contrast, the *pragmatic* variety of the representational view of models posits that models function as representations of their targets in virtue of the cognitive uses to which human reasoners put them. The basic idea is that a scientific model facilitates certain cognitive activities – such as the drawing of inferences about a target system, the derivation of predictions, or perhaps a deepening of the scientific understanding – on the part of its user and, therefore, necessarily involves the latter’s cognitive interests, beliefs, or intentions. *Hughes* [1.12], for example, emphasizes the interplay of three cognitive–theoretical processes – denotation, demonstration, and interpretation – which jointly give rise to the representational capacity of (theoretical) models in science. On *Hughes*’ (aptly named) *DDI* account of model-based representation, *denotation* accounts for the fact that theoretical elements of a model

purport to refer to elements in the physical world. The possibility of *demonstration* from within a model – in particular, the successful mathematical derivation of results for models that lend themselves to mathematical derivation techniques – attests both to the models having a nontrivial internal dynamic and to its being a viable object of fruitful theoretical investigation. Through successful *interpretation*, a model user then relates the theoretically derived results back to the physical world, including the model’s target system. Clearly, the *DDI* account depends crucially on there being someone who engages in the activities of interpreting and demonstrating – that is, it depends on the cognitive activities of human agents, who will inevitably draw on their background knowledge, cognitive interests, and derivational skills in establishing the requisite relations for bringing about representation.

The contrast between informational and pragmatic approaches to model-based representation roughly maps onto another contrast, between what *Knuuttila* has dubbed *dyadic* and *triadic* approaches. The former takes “the model–target dyad as a basic unit of analysis concerning models and their epistemic values” [1.13, p. 142]. This coheres well with the informational approach which, as discussed, tends to regard models as (often abstract) structures that stand in a relation of isomorphism, or partial isomorphism, to a target system. By contrast, *triadic* accounts – in line with pragmatic views of model-based representation – based representation shift attention away from models and the abstract relations they stand in, toward modeling as a theoretical activity pursued by human agents with cognitive interests, intentions, and beliefs. On this account, model-based representation cannot simply be a matter of any abstract relationship between the model and a target system since one cannot, as *Suárez* puts it, “reduce the essentially intentional judgments of representation users to facts about the source and target object or systems and their properties” [1.14, p. 768]. Therefore, so the suggestion goes, the model–target dyad needs to be replaced by a three-place relation between the model, its target, and the model user. *Suárez*, for example, proposes an inferentialist account of model-based representation, according to which a successful model must allow “competent and informed agents to draw specific inferences regarding” [1.14, p. 773] the target system – thereby making the representational success of a model dependent on the qualities of a (putative) model user.

### 1.3 Models as Analogies and Metaphors

Some scholars trace the emergence of the concept of a *scientific model* to the second half of the nineteenth century [1.15]. Applying our contemporary concept of *model* to past episodes in the history of science, we can of course identify prior instances of models being employed in science; however, until the nineteenth century scientists were engaged in little systematic self-reflection on the uses and limitations of models. Philosophy of science took even longer to pay attention to models in science, focusing instead on the role and significance of scientific theories. Only from the middle of the twentieth century onward did philosophical interest in models acquire the requisite momentum to carry the debate forward. Yet in both science and philosophy, the term *model* underwent important transformations, so it will be important to identify some of these shifts, in order to avoid unnecessary ambiguity and confusion in our exploration of the question *What is a model?*

Take, for example, Duhem's dismissal, in 1914, of what he takes to be the excessive use of models in Maxwell's theory of electromagnetism, as presented in an English textbook published at the end of the nineteenth century [1.16, p. 7]:

“Here is a book intended to expound the modern theories of electricity and to expound a new theory. In it there are nothing but strings which move round pulleys which roll around drums, which go through pearl beads, which carry weights; and tubes which pump water while others swell and contract; toothed wheels which are geared to one another and engage hooks. We thought we were entering the tranquil and neatly ordered abode of reason, but we find ourselves in a factory.”

What Duhem is mocking in this passage, which is taken from a chapter titled *Abstract Theories and Mechanical Models*, is a style of reasoning that is dominated by the desire to *visualize* physical processes in purely mechanical terms. His hostility is thus directed at *mechanical* models only – as the implied contrast in the chapter title makes clear – and does not extend to the more liberal understanding of the term *scientific model* in philosophy of science today.

Indeed, when it comes to the use of *analogy* in science, Duhem is much more forgiving. The term *analogy*, which derives from the Greek expression for *proportion*, itself has multiple uses, depending on whether one considers its use as a rhetorical device or as a tool for scientific understanding. Its general form is that of “pointing to a resemblance between relations in two different domains, that is, *A* is related to *B* like *C* is related to *D*” [1.17, p. 110]. An analogy may be considered

merely *formal*, when only the relations (but not the relata) resemble another, or it may be *material*, when the relata from the two domains (i. e., *A* and *B* on one side, *C* and *D* on the other) have certain attributes or characteristics in common. Duhem's understanding of *analogy* is more specific, in that he conceives of analogy as being a relation between two sets of statements, such as between one theory and another [1.16, p. 97]:

“Analogies consist in bringing together two abstract systems; either one of them already known serves to help us guess the form of the other not yet known, or both being formulated, they clarify the other. There is nothing here that can astonish the most rigorous logician, but there is nothing either that recalls the procedures dear to ample but shallow minds.”

Consider the following example: When Christiaan Huygens (1629–1695) proposed his theory of light, he did so on the basis of *analogy* with the theory of sound waves: the relations between the various attributes and characteristics of light are similar to those described by acoustic theory for the rather different domain of sound. Thus understood, analogy becomes a legitimate instrument for learning about one domain on the basis of what we know about another. In modern parlance, we might want to say that sound waves provided Huygens with a good *theoretical model* – at least given what was known at the time – for the behavior of light.

There is, however, a risk of ambiguity in that last sentence – an ambiguity which, as Mellor [1.18, p. 283] has argued, it would be wrong to consider harmless. Saying that *sound waves provide a good model for the theory of light* appears to equate the model with the *sound waves* – as though one physical object (sound waves) could be identified with the model. At first sight, this might seem unproblematic, given that, as far as wave-like behavior is concerned, we do take light and sound to be relevantly analogous. However, while it is indeed the case that “some of the constructs called *analogy* in the nineteenth century would today be routinely referred to as *models*” [1.19, p. 46], it is important to distinguish between, on the one hand, *analogy* as the similarity relation that exists between a theory and another set of statements and, on the other hand, the latter set of statements as the *analog of the theory*. Furthermore, we need to distinguish between the analog (e.g., the theory of sound waves, in Huygens's case) and the set of entities *of which the analog is true* (e.g., the sound waves themselves). (On this point, see [1.18, p. 283].) What Duhem resents about the naïve use of what he refers to as *mechanical models* is the hasty conflation of the visualized entities – (imaginary) pulleys, drums,

pearl beads, and toothed wheels – with what is *in fact* scientifically valuable, namely the relation of analogy that exists between, say, the theory of light and the theory of sound.

This interpretation resolves an often mentioned tension – partly perpetuated by Duhem himself, through his identification of different styles of reasoning (the *English* style of physics with its emphasis on mechanical models, and the *Continental* style which prizes mathematical principles above all) – between Duhem’s account of models and that of the English physicist Norman Campbell. Thus, *Hesse*, in her seminal essay *Models and Analogies in Science* [1.20], imagines a dialogue between a *Campbellian* and a *Duhemist*. At the start of the dialogue, the *Campbellian* attributes to the *Duhemist* the following view: “I imagine that along with most contemporary philosophers of science, you would wish to say that the use of models or analogs is not essential to scientific theorizing and that [...] the theory as a whole does not require to be interpreted by means of any model.” To this, the *Duhemist*, who admits that “models may be useful guides in suggesting theories,” replies: “When we have found an acceptable theory, any model that may have led us to it can be thrown away. Kekulé is said to have arrived at the structure of the benzene ring after dreaming of a snake with its tail in its mouth, but no account of the snake appears in the textbooks of organic chemistry.” The *Campbellian*’s rejoinder is as follows: “I, on the other hand, want to argue that models in some sense are essential to the logic of scientific theories” [1.20, pp. 8–9]. The quoted part of *Hesse*’s dialogue has often been interpreted as suggesting that the bone of contention between Duhem and Campbell is the status of *models in general* (in the modern sense that includes theoretical models), with Campbell arguing in favor and Duhem arguing against. But we have already seen that Duhem, using the language of *analogy*, does allow for theoretical models to play an important role in science. This apparent tension can be resolved by being more precise about the target of Duhem’s criticism: “Kekulé’s snake dream might illustrate the use of a visualizable model, but it certainly does not illustrate the use of an analogy, in Duhem and Campbell’s sense” [1.18, p. 285]. In other words, Duhem is not opposed to scientific models in general, but to its mechanical variety in particular. And, on the point of over-reliance on mechanical models, *Campbell*, too, recognizes that dogmatic attachment to such a style of reasoning is *open to criticism*. Such a dogmatic view would hold “that theories are completely satisfactory only if the analogy on which they are based is mechanical, that is to say, if the analogy is with the laws of mechanics” [1.21, p. 154]. Campbell is clearly more sympathetic than Duhem toward our “craving for

mechanical theories,” which he takes to be firmly rooted in our psychology. But he insists that [1.21, p. 156]

“we should notice that the considerations which have been offered justify only the attempt to adopt some form of theory involving ideas closely related to those of force and motion; it does not justify the attempt to force all such theories into the Newtonian mold.”

To be sure, significant differences between Duhem and Campbell remain, notably concerning what *kinds* of uses of analogies in science (or, in today’s terminology, of scientific – including theoretical – models) are appropriate. For Duhem, such uses are limited to a heuristic role in the discovery of scientific theories. By contrast, *Campbell* claims that “in order that a theory may be valuable [...] it must display analogy” [1.21, p. 129] – though it should be emphasized again, not necessarily analogy *of the mechanical sort*. (As *Mellor* argues, Duhem and Campbell differ chiefly in their views of scientific theories and less so in their take on analogy, with Duhem adopting a more *static* perspective regarding theories and Campbell taking a more realist perspective [1.18].)

It should be said, though, that *Hesse*’s *Campbellian* and *Duhemist* are at least partly intended as caricatures and serve as a foil for *Hesse*’s own account of models as analogies. The account hinges on a three-part distinction between *positive*, *negative*, and *neutral* analogies [1.20]. Using the billiard ball model of gases as her primary example, *Hesse* notes that some characteristics are shared between the billiard balls and the gas atoms (or, rather, are ascribed by the billiard ball model to the gas atoms); these include velocity, momentum, and collision. Together, these constitute the *positive* analogy. Those properties we know to belong to billiard balls, but not to gas atoms – such as color – constitute the *negative* analogy of the model. However, there will typically be properties of the model (i. e., the billiard ball system) of which we do not (yet) know whether they also apply to its target (in this case, the gas atoms). These form the *neutral* analogy of the model. Far from being unimportant, the neutral analogy is crucial to the fruitful use of models in scientific inquiry, since it holds out the promise of acquiring new knowledge about the target system by studying the model in its place [1.20, p. 10]:

“If gases are really like collections of billiard balls, except in regard to the known negative analogy, then from our knowledge of the mechanics of billiard balls, we may be able to make new predictions about the expected behavior of gases.”

In dealing with scientific models we may choose to disregard the negative analogy (which results in what Hesse calls *model*<sub>1</sub>) and consider only the known positive and neutral analogies – that is, only those properties that are shared, or for all we know may turn out to be shared, between the target system and its analog. (On the terminology discussed in Sect. 1.1, due to Black and Achinstein, *model*<sub>1</sub> would qualify as a *theoretical model*.) This, Hesse argues, typically describes our use of models for the purpose of explanation: we resolve to treat *model*<sub>1</sub> as taking the place of the phenomena themselves. Alternatively, we may actively include the negative analogy in our considerations, resulting in what Hesse calls *model*<sub>2</sub> or a form of analog model. Given that, let us assume, the model system (e.g., the billiard balls) was chosen because it was observable – or, at any rate, more accessible than the target system (e.g., the gas) – *model*<sub>2</sub> allows us to study the similarities and dissimilarities between the two analogous domains; *model*<sub>2</sub>, qua being a model for its target, thus has a deeper structure than the system of billiard balls considered in isolation – and, like *model*<sub>1</sub>, importantly includes the neutral analogy, which holds out the promise of novel insights and predictions. As Hesse puts it, in the voice of her Campbellian interlocutor [1.20, pp. 12–13]:

“My whole argument is going to depend on these features [of the neutral analogy] and so I want to make it clear that I am not dealing with static and formalized theories, corresponding only to the known positive analogy, but with theories in the process of growth.”

Models have been discussed not only in terms of analogy, but also in terms of metaphor. *Metaphor*, more explicitly than *analogy*, refers to the linguistic realm:

a metaphor is a linguistic expression that involves at least one part that is being transferred from a domain of discourse where it is common to another – the target domain – where it is uncommon. The existence of an analogy may facilitate such a transfer of linguistic expression; at the same time, it is entirely possible that “it is the metaphor that prompts the recognition of analogy” [1.17, p. 114] – both are compatible with one another and neither is obviously prior to the other. Metaphorical language is widespread in science, not just in connection with models: for example, physicists routinely speak of *black holes* and *quantum tunneling* as important predictions of general relativity theory and quantum theory, respectively. Yet, as Soskice and Harré note, there is a special affinity between models and metaphor [1.22, p. 302]:

“The relationship of model and metaphor is this: if we use the image of a fluid to explicate the supposed action of the electrical energy, we say that the fluid is functioning as a model for our conception of the nature of electricity. If, however, we then go on to speak of the *rate of flow* of an *electrical current*, we are using metaphorical language based on the fluid model.”

In spite of this affinity, it would not be fruitful to simply equate the two – let alone jump to the conclusion that, in the notion of *metaphor*, we have found an answer to the question *What is a model?*. Models and metaphors both issue in descriptions, and as such they may draw on analogies we have identified between two otherwise distinct domains; more, however, needs to be said about the nature of the relations that need to be in place for something to be considered a (successful) model of its target system or phenomenon.

## 1.4 Models Versus the Received View: Sentences and Structures

Much of the philosophical debate about models is indebted to model theory as a branch of (first-order) mathematical logic. Two philosophical frameworks for thinking about scientific models and theories – the *syntactic view* of models and theories and its main competitor, the *semantic view* – can be traced back to these origins; they are the topic of this section. (For a more extensive discussion, see also other chapters in this handbook.) The syntactic view (Sect. 1.4.2) is closely aligned with logical positivism, which dominated much anglophone philosophy of science until the mid-1960s, and is sometimes referred to as *the received view*. Given

that less rigid approaches and an overarching movement toward pluralism have reshaped the philosophy of science over the past half-century or so, this expression is somewhat dated; to make matters worse, other contributors to the debate have, over time, come to apply the same label to the syntactic view’s main competitor, the semantic view of models and theories. Instead of adjudicating which position deserves this dubious honor, the present section will discuss how each view conceives of models. Before doing so, however, a few preliminaries are in order concerning the competing views’ joint origins in logical model theory.

### 1.4.1 Models and the Study of Formal Languages

Model theory originated as the study of formal languages and their interpretations, starting from a Tarski-style truth theory based only on notions from syntax and set theory. On a broader understanding, the restriction to formal languages may be dropped, so as to include scientific languages (which are often closer to natural language than to logic), or even natural languages. However, the distinction between the syntax and the semantics of a language, which is sharpest in logic, also provides a useful framework for studying scientific languages and has guided the development of both the syntactic and the semantic views of theories and models. The *syntax* of a language  $L$  is made up of the vocabulary of  $L$ , along with the rules that determine which sequence of symbols counts as a well-formed expression in  $L$ ; in turn, the *semantics* of  $L$  provides interpretations of the symbolic expressions in  $L$ , by mapping them onto another relational structure  $R$ , such that all well-formed expressions in  $L$  are rendered intelligible (e.g., via rules of composition) and can be assessed in terms of their truth or falsity in  $R$ .

The contrast between the syntax and the semantics of a language allows for two different approaches to the notion of a *theory*. A theory  $T$  may either be defined syntactically, as the set of all those sentences that can be derived, through a proper application of the syntactic rules, from a set of axioms (i. e., statements that are taken to be fundamental); or it may be defined semantically, as all those (first-order) sentences that a particular structure,  $M$ , satisfies. An example of the former would be Euclidean geometry, which consists of five axioms and all the theorems derivable from them using geometrical rules; an example of the latter would be group theory, which simply consists of all those first-order sentences that a set of groups – definable in terms of set-theoretic entities – satisfies. (This example, and much of the short summary in this section, is owed to [1.23]; for further discussion, see references therein.) The syntactic and semantic definitions of what a theory is are closely related: starting from the semantic definition, to see whether a particular structure  $M$  is a model of an axiomatizable first-order theory  $T$ , all that one needs to show is that  $M$  satisfies the axioms.

### 1.4.2 The Syntactic View of Theories

The syntactic view of theories originated from the combination of the insights – or, to put it a little more cautiously, fundamental tenets – of two research programs: the philosophical program, aligned with Pierre Duhem (Sect. 1.3) and Henri Poincaré, of treating

(physical) theories as systems of hypotheses designed to *save the phenomena*, and the mathematical program, pioneered by David Hilbert, which sought to formalize (mathematical) theories as axiomatic systems. By combining the two, it seemed possible to identify a theory with the set of logical consequences that could be derived from its fundamental principles (which were to be treated as axioms), using only the rules of the language in which the theory was formulated. In spite of its emphasis on syntax, the syntactic view is not entirely divorced from questions of semantics. When it comes to scientific theories, we are almost always dealing with *interpreted* sets of sentences, some of which – the fundamental principles or axioms – are more basic than others, with the rest derivable using syntactic rules. The question then arises at which level interpretation of the various elements of a theory is to take place. This is where the slogan *to save the phenomena* points us in the right direction: on the syntactic view, interpretation only properly enters at the level of matching singular theoretical predictions, formulated in strictly observational terms, with the observable phenomena. Higher level interpretations – for example, pertaining to purely theoretical terms of a theory (such as posited unobservable entities, causal mechanisms, laws, etc.) – would be addressed through *correspondence rules*, which offered at least a partial interpretation, so that *some* of the meaning of such higher level terms of a theory could be linked up with observational sentences.

As an example, consider the example of classical mechanics. Similar to how Euclidean geometry can be fully derived from a set of five axioms, classical mechanics is fully determined by Newton's laws of mechanics. At a purely formal level, it is possible to provide a fully syntactic axiomatization in terms of the relevant symbols, variables, and rules for their manipulation – that is, in terms of what Rudolf Carnap calls the *calculus of mechanics*. If one takes the latter as one's starting point, it requires interpretation of the results derived from within this formal framework, in order for the calculus to be recognizable as a theory of mechanics, that is, of physical phenomena. In the case of mechanics, we may have no difficulty stating the axioms in the form of the (physically interpreted) *Newtonian laws of mechanics*, but in other cases – perhaps in quantum mechanics – making this connection with observables may not be so straightforward. As Carnap notes [1.24, p. 57]:

“[t]he relation of this theory [= the physically interpreted theory of mechanics] to the calculus of mechanics is entirely analogous to the relation of physical to mathematical geometry.”

As in the Euclidean case, the syntactic view identifies the theory with a formal language or calculus (including, in the case of scientific theories, relevant correspondence rules), “whose interpretation – what the calculus is a theory of – is fixed at the point of application” [1.25, p. 125].

On the syntactic view of theories, models play at best a very marginal role as limiting cases or approximations. This is for two reasons. First, since the nonobservational part of the theory – that is, the *theory proper*, as one might put it – does not admit of direct interpretation, the route to constructing theoretical models on the basis of our directly interpreting the core ingredients of the theory is obstructed. Interpretation at the level of observational statements, while still available to us, is insufficient to imbue models with anything other than a purely *one-off* auxiliary role. Second, as *Cartwright* has pointedly argued in criticism directed at both the syntactic and the semantic views, there is a shared – mistaken – assumption that theories are a bit like vending machines [1.26, p. 247]:

“[Y]ou feed it input in certain prescribed forms for the desired output; it gurgitates for a while; then it drops out the sought-for-representation, plonk, on the tray, fully formed, as Athena from the brain of Zeus.”

This limits what we can do with models, in that there are only two stages [1.26, p. 247]:

“First, eyeballing the phenomenon, measuring it up, trying to see what can be abstracted from it that has the right form and combination that the vending machine can take as input; secondly, [...] we do either tedious deduction or clever approximation to get a facsimile of the output the vending machine would produce.”

Even if this caricature seems a little too extreme, the fact remains that, by modeling theories after first-order formal languages, the syntactic view limits our understanding of what theories and models are and what we can do with them.

### 1.4.3 The Semantic View

One standard criticism of the syntactic view is that it conflates scientific theories with their linguistic formulations. Proponents of the semantic view argue that by adding a layer of (nonlinguistic) structures between the linguistic formulations of theories and our assessment of them, one can side-step many of the problems faced by the syntactic view. According to the semantic view, a theory should be thought of as the set of set-theoretic structures that satisfy the different linguis-

tic formulations of the theory. A structure that provides an interpretation for, and makes true, the set of sentences associated with a specific linguistic formulation of the theory is called a *model of the theory*. Hence, the semantic view is often characterized as conceiving of theories as *collections of models*. This not only puts models – where these are to be understood in the logical sense outlined earlier – center stage in our account of scientific theories, but also renders the latter fundamentally *extra-linguistic* entities.

An apt characterization of the semantic view is given by *Suppe* as follows [1.27, pp. 82–83]:

“This suggests that theories be construed as propounded abstract *structures* serving as models for sets of interpreted sentences that constitute the linguistic formulations. [...] [W]hat the theory does is directly describe the behavior of abstract systems, known as *physical systems*, whose behaviors depend only on the selected parameters. However, physical systems are abstract replicas of actual phenomena, being what the phenomena *would have been* if no other parameters exerted an influence.”

According to a much-quoted remark by one of the main early proponents of the semantic view, *Suppes*, “the meaning of the concept of model is the same in mathematics and in the empirical sciences.” However, as *Suppe’s* quote above makes clear, models in science have additional roles to play, and it is perhaps worth noting that *Suppes* himself immediately continues: “The difference to be found in these disciplines is to be found in their use of the concept” [1.28, p. 289]. Supporters of the semantic view often claim that it is closer to the scientific practices of modeling and theorizing than the syntactic view. On this view, according to *van Fraassen* [1.29, p. 64],

“[t]o present a theory is to specify a family of structures, its *models*; and secondly, to specify certain parts of those models (the *empirical substructures*) as candidates for the direct representation of observable phenomena.”

Unlike what the syntactic view suggests, scientists do not typically formulate abstract theoretical axioms and only interpret them at the point of their application to observable phenomena; rather, “scientists build in their mind’s eye systems of abstract objects whose properties or behavior satisfy certain constraint (including law)” [1.23, p. 154] – that is, they engage in the construction of theoretical models.

Unlike the syntactic view, then, the semantic view appears to give a more definite answer to the question *what is a model?* In line with the account sketched so far, *a model of a theory is simply a (typically extra-*

linguistic) structure that provides an interpretation for, and makes true, the set of axioms associated with the theory (assuming that the theory is axiomatizable). Yet it is not clear that, in applying their view to actual scientific theories, the semanticists always heed their own advice to treat models as both *giving an interpretation*, and *ensuring the truth*, of a set of statements. More importantly, the model-theoretic account demands that, in a manner of speaking, a model should fulfil its truth-making function *in virtue of* providing an interpretation for a set of sentences. Other ways of ensuring truth – for example by limiting the domain of discourse for a set of fully interpreted sentences, thereby ensuring that the latter will happen to be true – should not qualify. Yet, as Thomson-Jones [1.30] has argued, purported applications of the semantic view often stray from the original model-theoretic motivation. As an example, consider Suppes’ *axiomatization* of Newtonian particle physics. (The rest of this subsection follows [1.30, pp. 530–531].) Suppes [1.31] begins with the following definition (in slightly modified form)

**Definition 1.1**

A system  $\beta = \langle P, T, s, m, f, g \rangle$  is a model of particle mechanics if and only if the following seven axioms are satisfied:

*Kinematical axioms:*

- 1 The set  $P$  is finite and nonempty
- 2 The set  $T$  is an interval of real numbers
- 3 For  $p$  in  $P$ ,  $s_p$  is twice differentiable.

*Dynamical axioms:*

- 4 For  $p$  in  $P$ ,  $m(p)$  is a positive real number
- 5 For  $p$  and  $q$  in  $P$  and  $t$  in  $T$ ,

$$f(p, q, t) = -f(q, p, t).$$

- 6 For  $p$  and  $q$  in  $P$  and  $t$  in  $T$ ,

$$s(p, t) \times f(p, q, t) = -s(q, t) \times f(q, p, t).$$

- 7 For  $p$  in  $P$  and  $t$  in  $T$ ,

$$m(p)D^2s_p(t) = \sum_{q \in P} f(p, q, t) + g(p, t).$$

At first sight, this presentation adheres to core ideas that motivate the semantic view. It sets out to define an extra-linguistic entity,  $\beta$ , in terms of a set-theoretical predicate; the entities to which the predicate applies are then to be singled out on the basis of the seven axioms. But as Thomson-Jones points out, a specific model  $S$  defined in this way “is not a serious interpreter of the

predicate or the axioms that compose it” [1.30, p. 531]; it merely fits a structure to the description provided by the fully interpreted axioms (1)–(7), and in this way ensures that they are satisfied, but it does not make them come out true in virtue of providing an interpretation (i. e., by invoking semantic theory). To Thomson-Jones, this suggests that identifying scientific models with truth-making structures in the model-theoretic sense may, at least in the sciences, be an unfulfilled promise of the semantic view; instead, he argues, we should settle for a less ambitious (but still informative) definition of a model as “a mathematical structure used to represent a (type of) system under study” [1.30, p. 525].

**1.4.4 Partial Structures**

Part of the motivation for the semantic view was its perceived greater ability to account for how scientists actually go about developing models and theories. Even so, critics have claimed that the semantic view is unable to accommodate the great diversity of scientific models and faces special challenges from, for example, the use of inconsistency in many models. In response to such criticisms, a philosophical research program has emerged over the past two decades, which seeks to establish a *middle ground* between the classical semantic view of models discussed in the previous section and those who are sceptical about the prospects of formal approaches altogether. This research program is often called the *partial structures approach*, which was pioneered by Newton da Costa and Steven French and whose vocal proponents include Otávio Bueno, James Ladyman, and others; see [1.32] and references therein.

Like many adherents of the semantic view, partial structures theorists hold that models are to be reconstructed in set-theoretic terms, as ordered  $n$ -tuples of sets: a set of objects with (sets of) properties, quantities and relations, and functions defined over the quantities. A *partial structure* may then be defined as  $\mathfrak{A} = \langle D, R_i \rangle_{i \in I}$ , where  $D$  is a nonempty set of  $n$ -tuples of just this kind and each  $R_i$  is a  $n$ -ary relation. Unlike on the traditional semantic view, the relations  $R_i$  need not be complete isomorphisms, but crucially are *partial relations*: that is, they need not be defined for all  $n$ -tuples of elements of  $D$ . More specifically, for each partial relation  $R_i$ , in addition to the set of  $n$ -tuples for which the relation holds and the set of  $n$ -tuples for which it does not hold, there is also a third set of  $n$ -tuples for which it is underdetermined whether or not it holds. (There is a clear parallel here with Hesse’s notion of positive, negative, and neutral analogies which, as da Costa and French put it, “finds a natural home in the context of partial structures” [1.32, p. 48].) A total structure is said to *extend* a partial structure, if it subsumes the first two

sets without change (i. e., includes all those objects and definite relations that exist in the partial structures) and renders each extended relation well defined for every  $n$ -tuple of objects in its domain. This gives rise to a hierarchy of structures and substructures, which together with the notion of partial isomorphism loosens the requirements on representation, since all that is needed for two partial models  $A$  and  $A'$  to be *partially* isomorphic is that a partial substructure of  $A$  be isomorphic to a partial substructure in  $A'$ .

Proponents of the partial structures approach claim that it “widens the framework of the model-theoretic approach and allows various features of models and theories – such as analogies, iconic models, and so on – to be represented,” [1.33, p. 306] that it can successfully contain the difficulties arising from inconsistencies in models, and that it is able to capture “the existence of a hierarchy of models stretching from the data up to the level of theory” [1.33]. Some critics have voiced criticism about such sweeping claims. One frequent criticism concerns the proliferation of partial isomorphisms, many of which will trivially obtain; however,

if partial relations are so easy to come by, how can one tell the interesting from the vast majority of irrelevant ones? (*Pincock* speaks in this connection of the “danger of trivializing our representational relationships” [1.34, p. 1254].) *Suárez* and *Cartwright* add further urgency to this criticism, by noting that the focus on set-theoretical structures obliterates all those uses of models and aspects of scientific practice that do not amount to the making of claims [1.35, p. 72]:

“So all of scientific practice that does not consist in the making of claims gets left out. [...] Again, we maintain that this inevitably leaves out a great deal of the very scientific practice that we are interested in.”

It is perhaps an indication of the limitations of the partial structures approach that, in response to such criticism, its proponents need to again invoke heuristic factors, which cannot themselves be subsumed under the proposed formal framework of models as set-theoretic structures with partial relations.

## 1.5 The Folk Ontology of Models

If we accept that scientific models are best thought of as functional entities (Sect. 1.2), perhaps something can be learnt about the ontology of scientific models from looking at their functional role in scientific inquiry. What one finds across a range of different kinds of models is the practice of taking models as stand-ins for systems that are not, in fact, instantiated. As *Godfrey-Smith* puts it, “modelers often *take* themselves to be describing imaginary biological populations, imaginary neural networks, or imaginary economies” [1.36, p. 735] – that is, they are aware that due to idealization and abstraction, model systems will differ in their descriptions from a full account of the actual world. A model, thus understood, may be thought of as a “description of a missing system,” and the corresponding research practice of describing and characterizing model systems *as though* they were real instantiated systems (even though they are not) may be called, following *Thomson-Jones*, the “face-value practice” of scientific modeling [1.37, pp. 285–286].

On the heels of the face-value practice of scientific modeling, it has been argued, comes a common – though perhaps not universally shared – understanding of *what models are* [1.36, p. 735]:

“[...] to use a phrase suggested by *Deena Skolnick*, the treatment of model systems as comprising

imagined concrete things is the *folk ontology* of at least many scientific modelers. It is the ontology embodied in many scientists’ unreflective habits of talking about the objects of their study-talk about what a certain kind of population will do, about whether a certain kind of market will clear. [...] One kind of understanding of model-based science requires that we take this *folk ontology* seriously, as part of the scientific strategy.”

The ontology of *imagined concrete things* – that is, of entities that, *if real*, would be on a par with concrete objects in the actual world – leads quickly into the thorny territory of fictionalism. *Godfrey-Smith* is explicit about this when he likens models to “something we are all familiar with, the imagined objects of literary fiction” [1.36] – such as *Sherlock Holmes*, *J.R.R. Tolkien’s Middle Earth*, and so on. Implicit in this suggestion is, of course, a partial answer to our question *What is a model?* – namely, that the ontological status of scientific models is *just like* that of literary (or other) fictions. The advantages and disadvantages of such a position will be discussed in detail in Sect. 1.6 of this chapter.

There is, however, another direction into which a closer analysis of the face-value practice can take us. Instead of focusing on the ontological status of the en-

tities we are imagining when we contemplate models as imagined concrete things, we can focus on the conscious processes that attend such imaginings (or, if one prefers a different way of putting it, the *phenomenology* of interacting with models). Foremost among these is the mental imagery that is conjured up by the descriptions of models. (Indeed, as we shall see in the next section, on certain versions of the fictionalist view, a model *prescribes* imaginings about its target system.) How much significance one should attach to the mental pictures that attend our conscious consideration of models has been a matter of much controversy: recall Duhem’s dismissal of mechanical imagery as a way of conceptualizing electromagnetic phenomena (Sect. 1.3).

Focusing on the mental processes that accompany the use of scientific models might lead one to propose an analysis of models in terms of their cognitive foundations. Nancy Nersessian has developed just such an analysis, which ties the notion of models in science closely to the cognitive processes involved in mental modeling. Whereas the traditional approach in psychology had been to think of reasoning as consisting of the mental application of logical rules to propositional representations, mounting empirical evidence of the role of heuristics and biases suggested that much of human reasoning proceeds via *mental models* [1.38], that is, by carrying out thought experiments on internal models. A *mental model*, on this account, is “a structural analog of a real-world or imaginary situation, event, or process” as constructed by the mind in reasoning (and, presumably, realized by certain underlying brain processes) [1.39, pp. 11–12]:

“What it means for a mental model to be a structural analog is that it embodies a representation of the spatial and temporal relations among, and the causal structures connecting the events and entities depicted and whatever other information that is relevant to the problem-solving talks. [...] The essential points are that a mental model can be non-linguistic in form and the mental mechanisms are such that they can satisfy the model-building and simulative constraints necessary for the activity of mental modeling.”

While this characterization of mental models may have an air of circularity, in that it essentially defines mental models as place-holders for *whatever it takes* to support *the activity of mental modeling*, it nonetheless suggests a place to look for the materials from which models are constructed: the mind itself, with its various types of content and mental representation. As *Nersessian* puts it: “Whatever the format of the model

itself, information in various formats, including linguistic, formulaic, visual, auditory, kinesthetic, can be used in its construction” [1.39, p. 12].

How does this apply to the case of *scientific* models? As an example, Nersessian considers James Clerk Maxwell’s famous molecular vortex model, which visualized the lines of magnetic force around a magnet as though they were vortices within a continuous fluid (Fig. 1.1).

As Nersessian sees it, Maxwell’s drawing “is a *visual* representation of an *analogical* model that is accompanied with instructions for *animating* it correctly in thought” [1.39, p. 13]. And indeed *Maxwell* gives detailed instructions regarding how to interpret, and bring to life, the model of which the reader is only given a momentary *snapshot* [1.40, p. 477]:

“Let the current from left to right commence in *AB*. The row of vortices *gh* above *AB* will be set in motion in the opposite direction to a watch [...]. We shall suppose the two of vortices *kl* still at rest, then the layer of particles between these rows will be acted on by the row *gh*,”

and so forth. It does seem plausible to say that such instructions are intended to prescribe certain mental models on the part of the reader. Convincing though this example may be, it still begs the question of what, *in general*, a mental model is. At the same time, it illustrates what is involved in conjuring up a mental model and which materials – in this case, spatial representations, along with intuitions about the mechanical motion of parts in a larger system – are involved in its constitution.

**Fig. 1.1** Maxwell’s drawing of the molecular vortex model (after [1.40])

## 1.6 Models and Fiction

As noted in the previous section, the face-value practice of scientific modeling and its concomitant folk ontology, according to which models are imagined concrete things, have a natural affinity to the way we think about fictions. As one proponent of models as fictions puts it [1.41, p. 253]:

“The view of model systems that I advocate regards them as imagined physical systems, that is, as hypothetical entities that, as a matter of fact, do not exist spatiotemporally but are nevertheless not purely mathematical or structural in that they would be physical things if they were real.”

Plausible though this may sound, the devil is in the details. A first – perhaps trivial – caveat concerns the restriction that model systems *would be physical things if they were real*. In order to allow for the notion of model to be properly applied to the social and cognitive sciences, such as economics and psychology, it is best to drop this restriction to physical systems. (On this point, see [1.30, p. 528].) This leaves as the gist of the folk-ontological view the thought that model systems, *if they were real*, would be *just as we imagine them* (or, more carefully, *just as the model instructs us to imagine them*).

In order to sharpen our intuitions about fictions, let us introduce an example of a literary fiction, such as the following statement from Doyle’s *The Adventure of the Three Garridebs* (1924) [1.42]: “Holmes had lit his pipe, and he sat for some time with a curious smile upon his face.” There is, of course, no actual human being that this statement represents: no one is sitting smilingly at 221B Baker Street, filling up the room with smoke from their pipe. (Indeed, until the 1930s, the address itself had no real-world referent, as the highest number on Baker Street then was No. 85.) And yet there is a sense in which this passage does seem to represent Sherlock Holmes and, within the context of the story, tells us something informative about him. In particular, it seems to lend support to certain statements about Sherlock Holmes as opposed to others. If we say *Holmes is a pipe smoker*, we seem to be asserting something true about him, whereas if we say *Holmes is a nonsmoker*, we appear to be asserting something false. One goal of the ontology of fictions is to make sense of this puzzle.

Broadly speaking, there are two kinds of philosophical approaches – realist and antirealist – regarding fictions. On the realist approach, even though Sherlock Holmes is not an actual human being, we must grant that he *does* exist in some sense. Following

*Meinong* [1.43], we might, for example, distinguish between *being* and *existence* and consider Sherlock Holmes to be an object that has all the requisite properties we normally attribute to him, except for the property of existence. Or we might take fictions to have existence, but only as abstract entities, not as objects in space and time. By contrast, antirealists about fictions deny that they have independent being or existence and instead settle for other ways of making sense of how we interpret fictional discourse. Following Bertrand Russell, we might paraphrase the statement *Sherlock Holmes is a pipe smoker and resides at 221B Baker Street* without the use of a singular term (*Sherlock Holmes*), solely in terms of a suitably quantified existence claim: *There exists one and only one x such that x is a pipe smoker and x resides at 221B Baker Street*. However, while this might allow us to parse the meaning of further statements about Sherlock Holmes more effectively, it does not address the puzzle that certain claims (such as *He is a pipe smoker*) ring true, whereas others do not – since it renders each part of the explicated statement false. This might not seem like a major worry for the case of literary fictions, but it casts doubt on whether we can fruitfully think about scientific models in those terms, given the epistemic role of scientific models as contributors to scientific knowledge.

In recent years, an alternative approach to fictions has garnered the attention of philosophers of science, which takes Walton’s notion of “games of make-believe” as its starting point. Walton introduces this notion in the context of his philosophy of art, where he characterizes (artistic) representations as “things possessing the social function of serving as props in games of make-believe” [1.44, p. 69]. In games of make-believe, participants engage in behavior akin to children’s pretend play: when a child uses a banana as a telephone *to call grandpa*, this action does not amount to actually calling her grandfather (and perhaps not even *attempting* to call him); rather, it is a move within the context of play – where the usual standards of realism are suspended – whereby the child resolves to treat the situation *as if* it were one of speaking to her grandfather on the phone.

The banana is simply a prop in this game of make-believe. The use of the banana as a make-believe telephone may be inspired by some physical similarity between the two objects (e.g., their elongated shape, or the way that each can be conveniently held to one’s ear and mouth at the same time), but it is clear that props can go beyond material objects to include, for example, linguistic representations (as would be the case with

the literary figure of Sherlock Holmes). While the rules governing individual pretend play may be ad hoc, communal games of make-believe are structured by shared normative principles which *authorize* certain moves as legitimate, while excluding other moves as illegitimate. It is in virtue of such principles that fictional truths can be generated: for example, a toy model of a bridge at the scale of 1 : 1000 prescribes that, “if part of the model has a certain length, then, fictionally, the corresponding part of the bridge is a thousand times that length” [1.45, p. 38] – in other words, even though the model itself is only a meter long, it *represents* the bridge as a thousand meters long. Note that the scale model could be a model of a bridge that is yet to be built – in which case it would still be true that, fictionally, the bridge is a thousand meters long: props, via the rules that govern them, *create* fictional truths.

One issue of contention has been what kinds of metaphysical commitments such a view of models entails. Talk of *imagined concrete things* as the material from which models are built has been criticized for amounting to an indirect account of modeling, by which [1.46, pp. 308, fn. 14]

“prepared descriptions and equations of motion ask us to imagine an *imagined concrete system* which then bears some other form of representation relation to the system being modelled.”

A more thoroughgoing direct view of models as fictions is put forward by *Toon*, who considers the following sentence from *Wells’s The War of the Worlds*: “The dome of St. Paul’s was dark against the sunrise, and injured, I saw for the first time, by a huge gaping cavity on its western side” [1.47, p. 229]. As *Toon* argues [1.46, p. 307]:

“There is no pressure on us to postulate a fictional, damaged, St. Paul’s for this passage to represent; the passage simply represents the actual St. Paul’s. Similarly, on my account, our prepared description and equation of motion do not give rise to a fictional, idealised bouncing spring since they represent the actual bouncing spring.”

By treating models as prescribing imaginings about *the actual objects* (where these exist and are the model’s target system), we may resolve to imagine all sorts of

things that are, as a matter of fact, false; however, so the direct view holds, this is nonetheless preferable to the alternative option of positing *independently existing* fictional entities [1.45, p. 42]. Why might one be tempted to posit, as the indirect view does, that fictional objects fitting the model descriptions must exist? An important motivation has to do with the assertoric force of our model-based claims. As *Giere* puts it: “If we insist on regarding principles as genuine statements, we have to find something that they describe, something to which they refer” [1.48, p. 745]. In response, proponents of the direct view have disputed the need “to regard theoretical principles formulated in modeling as genuine statements”; instead, as *Toon* puts it, “they are prescriptions to imagine” [1.45, p. 44].

One potential criticism the models as fictions view needs to address is the worry that, by focusing on the user’s imaginings, what a model is becomes an entirely subjective matter. A similar worry may be raised with respect to the mental models view discussed in Sect. 1.5: if a model is merely a place-holder for whatever is needed to sustain the activity of mental modeling (or imagining) on the part of an agent, how can one be certain that the same kinds of models (or props) reliably give rise to the same kinds of mental modeling (or imaginings)? In this respect, at least, the models as fictions view appears to be in a stronger position. Recall that, unlike in individual pretend play (or unconstrained imagining), in games of make-believe certain imaginations are sanctioned by the prop itself and the – public, shared – rules of the game. As a result, “someone’s imaginings are governed by intersubjective rules, which guarantee that, as long as the rules are respected, everybody involved in the game has the same imaginings” [1.41, p. 264] – though it should be added, not necessarily the same *mental images*.

In his 1963 book, *Models and Metaphors*, *Black* expressed his hope that an “exercise of the imagination, with all its promise and its dangers” may help pave the way for an “understanding of scientific models and archetypes” as “a reputable part of scientific culture” [1.4, p. 243]. Even though *Black* was writing in general terms (and perhaps for rhetorical effect), his characterization would surely be considered apt by the proponents of the models as fictions view, who believe that models allow us to imagine their targets to be a certain way, and that, by engaging in such imaginings, we can gain new scientific insights.

## 1.7 Mixed Ontologies: Models as Mediators and Epistemic Artifacts

In Sect. 1.1, a distinction was drawn between *informational* views of models, which emphasize the objective, two-place relation between the model and what it represents, and *pragmatic* views, according to which a model depends at least in part on the user's beliefs or intentions, thereby rendering model-based representation a three-place relation between model, target, and user. Unsurprisingly, which side one comes down on in this debate will also have an effect on one's take on the ontology of scientific models. Hence, structuralist approaches (e.g., the partial structures approach discussed in Sect. 1.4.4) are a direct manifestation of the informational view, whereas the models as fictions approach – especially insofar as it considers models to be props for the user's imagination – would be a good example of the pragmatic view. The pragmatic dimension of scientific representation has received growing attention in the philosophical literature, and while this is not the place for a detailed survey of pragmatic accounts of model-based representation in particular, the remainder of this section will be devoted to a discussion of the ontological consequences of several alternative pragmatic accounts of models. Particular emphasis will be placed on what I shall call *mixed ontologies*, that is, accounts of models that emphasize the heterogeneity and diversity of their components.

### 1.7.1 Models as Mediators

Proponents of pragmatic accounts of models usually take scientific practice as the starting point of their analysis. This often directly informs how they think about models; in particular, it predisposes them to treat models as the outcome of a process of model construction. On this view, it is not only the *function* of models – for example, their capacity to represent target systems – which depends on the beliefs, intentions, and cognitive interests of a model user, but also the very *nature* of models which is dependent on human agents in this way. In other words, what models are is crucially determined by their being the result of a deliberate process of model construction. Model construction, most pragmatic theorists of models insist, is marked by “piecemeal borrowing” [1.35, p. 63] from a range of different domains. Such conjoining of heterogeneous components to form a model cannot easily be accommodated by structuralist accounts, or so it has been claimed; at the very least, there is considerable tension between, say, the way that the partial structures approach allows for a nested *hierarchy* of models (connected with one another via partial isomorphisms) and the much more ad hoc manner in which modelers piece

together models from a variety of ingredients. (On this point, see especially [1.35, p. 76].)

A number of such accounts have coalesced into what has come to be called the *models as mediators* view (see [1.49] for a collection of case studies). According to this view, models are to be regarded neither as a merely auxiliary intermediate step in applying or interpreting scientific theories, nor as constructed purely from data. Rather, they are thought of as mediating between our theories and the world in a partly autonomous manner. As *Morrison* and *Morgan* put it, models “are *not* situated in the middle of an hierarchical structure between theory and the world,” but operate outside the hierarchical “theory-world axis” [1.50, pp. 17–18]. A central tenet of the models as mediators view is the thesis that models “are made up from a *mixture* of elements, including those from outside the domain of investigation”; indeed, it is thought to be precisely in virtue of this heterogeneity that they are able to retain “an element of independence from both theory and data (or phenomena)” [1.50, p. 23].

At one level, the models as mediators view appears to be making a descriptive point about scientific practice. As *Morrison* and *Morgan* [1.50] point out, there is “no *logical* reason why models should be constructed to have these qualities of partial independence” [1.50, p. 17], though in practice they do exhibit them, and examples that involve the integration of heterogeneous elements beyond theory and data “are not the exception but the rule” [1.50, p. 15]. Yet, there is also the further claim that models could not fulfil their epistemic function *unless* they are partially autonomous entities: “we can only expect to use models to learn about our theories or our world if there is at least partial independence of the model from both” [1.50, p. 17]. Given that models are functional entities (in the sense discussed in Sect. 1.2), this has repercussions for the ontological question of what kind of entities models are. More often than not, models will integrate – perhaps imperfectly, but in irreducible ways – heterogeneous components from disparate sources, including (but not limited to) “elements of theories and empirical evidence, as well as stories and objects which could form the basis for modeling decisions” [1.50, p. 15]. As proponents of the models as mediators view are at pains to show, even in cases where models initially seem to derive straightforwardly from fundamental theory or empirical data, closer inspection reveals the presence of other elements – such as “simplifications and approximations which have to be decided independently of the theoretical requirements or of data conditions” [1.50, p. 16].

For the models as mediators approach, any answer to the question *what is a model?* must be tailored to the specific case at hand: models in high-energy physics will have a very different composition, and will consist of an admixture of different elements, than, say, models in psychology. However, as a general rule, no model – or, at any rate, no *interesting* model – will ever be fully reducible to theory and data; attempts to *clean up* the ontology of scientific models so as to render them either purely theoretical or entirely empirical, according to the models as mediators view, misconstrue the very nature and function of models in science.

### 1.7.2 Models as Epistemic Artifacts

A number of recent pragmatic approaches take the models as mediators view as their starting point, but suggest that it should be extended in various ways. Thus, *Knuuttila* acknowledges the importance of mediation between theory and data, but a richer account of models is needed to account for how this partial independence comes about. For *Knuuttila*, *materiality* is the key enabling factor that imbues models with such autonomy: it is “the material dimension, and not just *additional elements*, that makes models able to mediate” [1.51, p. 48]. Materiality is also seen as explaining the various epistemic functions that models have in inquiry, not least by way of analogy with scientific experiments. For example, just as in experimentation much effort is devoted to minimizing unwanted external factors (such as noise), in scientific models certain methods of approximation and idealization serve the purpose of neutralizing undesirable influences. Models typically draw on variety of formats and representations, in a way that *enables* certain specific uses, but at the same time *constrains* them; this breaks with the traditional assumption that we can “clearly tell apart those features of our scientific representations that are attributable to the phenomena described from the conventions used to describe them” [1.52, p. 268].

On the account sketched thus far, attempting to characterize the nature and function of models in the

language of theories and data would, in the vast majority of cases, give a misleading impression; instead, models are seen as *epistemic tools* [1.52, p. 267]:

“Concrete artifacts, which are built by various representational means, and are constrained by their design in such a way that they enable the study of certain scientific questions and learning through constructing and manipulating them.”

This links the philosophical debate about models to questions in the philosophy of technology, for example concerning the ontology of artifacts, which are likewise construed as both material bodies and functional objects. It also highlights the constitutive role of design and construction, which applies equally to models with a salient material dimension – such as scale models in engineering or ball-and-stick models in chemistry – and to largely theoretical models. For example, it has been argued that mathematical models (e.g., in many-body physics) may be fruitfully characterized not only in theoretical terms (say, as a Hamiltonian) or as mathematical entities (as an operator equation), but also as the output of a *mature mathematical formalism* (in this case, the formalism of second quantization) – that is, a physically interpreted set of notational rules that, while embodying various theoretical assumptions, is not usually reducible to fundamental theory [1.53].

As in the case of the models as mediators approach, the ontological picture that emerges from the artifactual approach to models is decidedly mixed: models will typically consist of a combination of different materials, media and formats, and deploy different representational means (such as pictorial, symbolic, and diagrammatic notations) as well as empirical data and theoretical assumptions. Beyond merely acknowledging the heterogeneity of such a *mixture of elements*, however, the artifactual approach insists that it is *in virtue of their material dimension* that the various elements of a model, taken together, enable and constrain its representational and other epistemic functions.

## 1.8 Summary

As the survey in this chapter demonstrates, the term *model* in science refers to a great variety of things: physical objects such as scale models in engineering, descriptions and sets of sentences, set-theoretic structures, fictional objects, or an assortment of all of the above. This makes it difficult to arrive at a uniform characterization of models *in general*. However, by paying

close attention to philosophical accounts of model-based representation, it is possible to discern certain clusters of positions. At a general level, it is useful to think of models as functional entities, as this allows one to explore how different functional perspectives lead to different conceptions of the ontology of models. Hence, with respect to the representational function of mod-

els, it is possible to distinguish between *informational* views, which we found to be closely associated with structuralist accounts of models, and *pragmatic* views, which tend to give rise to more heterogeneous accounts, according to which models may be thought of as *props for the imagination*, as partly autonomous mediators between theory and data, or as epistemic artifacts consisting of an admixture of heterogeneous elements.

When nineteenth century physicists began to reflect systematically on the role of *analogy* in science,

they did so out of a realization that it may not always be possible to apply fundamental theory directly to reality, either because any attempt to do so faces insurmountable complexities, or because no such fundamental theory is as yet available. At the beginning of the twenty-first century, these challenges have not diminished, and scientists find themselves turning to an ever greater diversity of scientific models, a unified philosophical theory of which is still outstanding.

# Models and Theories

## 2. Models and Theories

Demetris Portides

Part A | 2

Both the received view (RV) and the semantic view (SV) of scientific theories are explained. The arguments against the RV are outlined in an effort to highlight how focusing on the syntactic character of theories led to the difficulty in characterizing theoretical terms, and thus to the difficulty in explicating how theories relate to experiment. The absence of the representational function of models in the picture drawn by the RV becomes evident; and one does not fail to see that the SV is in part a reaction to – what its adherents consider to be an – excessive focus on syntax by its predecessor and in part a reaction to the complete absence of models from its predecessor's philosophical attempt to explain the theory–experiment relation. The SV is explained in an effort to clarify its main features but also to elucidate the differences between its different versions. Finally, two kinds of criticism are explained that affect all versions of the SV but which do not affect the view that models have a warranted degree of importance in scientific theorizing.

Scientists use the term *model* with reference to iconic or scaled representations, analogies, and mathematical (or abstract) descriptions. Although all kinds of models in science may be philosophically interesting, mathematical models stand out. Representation with iconic or scale models, for instance, mostly applies to a particular state of a system at a particular time, or it requires the mediation of a mathematical (or abstract) model in order to relate to theories. Representation via mathematical models, on the other hand, is of utmost interest because it applies to *types* of target systems and it can be used to draw inferences about the time-evolution of such systems, but more importantly for our purposes because of its obvious link to scientific theories.

In the history of philosophy of science, there have been two systematic attempts to explicate the relation of such models to theory. The first is what had been labeled the *received view* (RV) of scientific theories

that grew out of the logical positivist tradition. According to this view, theories are construed as formal axiomatic calculi whose logical consequences extend to observational sentences. Models are thought to have no representational role; their role is understood metamathematically, as interpretative structures of subsets of sentences of the formal calculus. Ultimately it became clear that such a role ascribed to models does not do justice to how science achieves theoretical representations of phenomena. This conclusion was reached largely due to the advent of the second systematic attempt to explore the relation between theory and models, the *semantic view* (SV) or model-theoretic view of scientific theories. The semantic view regards theories as classes of models that are directly defined without resort to a formal calculus. Thus, models in this view are integral parts of theories, but they are also the devices by which representation of phenomena is achieved.

Although, the SV recognized the representational capacity of models and exposed that which was concealed by the logical positivist tradition, namely that one of the primary functions of scientific models is to apply the abstract theoretical principles in ways that actual physical systems can be represented, it also generated a debate concerning the complexities involved in scientific representation. This recent debate has significantly enhanced our understanding of the representational role of scientific models. At the same time it gave rise, among other things, to questions regarding the relation between models and theory. The adherents of the SV claim that a scientific theory is identified with a class of models, hence that models are constitutive parts of theory and thus they represent by means of the conceptual apparatus of theory. The critics of the SV, however, argue that those models that are successful representations of physical systems utilize a much richer conceptual apparatus than that provided by theory and thus claim that they should be understood as partially autonomous from theory.

A distinguishing characteristic of this debate is the notion of representational model, that is, a scientific entity which possesses the necessary features that render it representational of a physical system. In the SV, theoretical models, that is, mathematical models that are constitutive parts of theory structure, are considered to be representational of physical systems. Its critics, however, argue that in order to provide a model with the capacity to represent actual physical systems, the theoretical principles from which the model arises

are typically supplemented with ingredients that derive from background knowledge, from semiempirical results and from experiment. In order to better understand the character of successful representational models, according to this latter view, we must move away from a purely theory-driven view of model construction and also place our emphasis on the idea that representational models are entities that consist of assortments of the aforementioned sorts of conceptual ingredients.

In order to attain insight into how models could relate to theory and also be able to use that insight in addressing other issues regarding models, in what follows, I focus on the RV and the SV of scientific theories. Each of the two led to a different conception of the nature of theory structure and subsequently to a different suggestion for what scientific models are, what they are used for, and how they function. In the process of explicating these two conceptions of theory structure, I will also review the main arguments that have been proposed against them. The RV has long been abandoned for reasons that I shall explore in Sect. 2.1, but the SV lives on despite certain inadequacies that I shall also explore in Sect. 2.2. Toward the end of Sect. 2.2, in Sect. 2.2.4, I shall very briefly touch upon the more recent view that the relation between theory and models is far more complex than advocates of the RV or the SV have claimed, and that models in science demonstrate a certain degree of partial autonomy from the theory that prompts their construction and because of this a unitary account of models obscures significant features of scientific modeling practices.

## 2.1 The Received View of Scientific Theories

What has come to be called the RV of scientific theories is a conception of the structure of scientific theories that is associated with logical positivism, and which was the predominant view for a large part of the twentieth century. It is nowadays by and large overlooked hence it is anything but received. Despite its inappropriate label, clarifying its major features as well as understanding the major philosophical arguments that revealed its inadequacies would not only facilitate acquaintance with the historical background of the debate about the structure of scientific theories and give the reader a flavor of the difficulties involved in characterizing theory structure, but it would also be helpful in understanding some characteristics of contemporary views and how models came to occupy central stage in current debates on how theories represent and explain phenomena. With this intention in mind, I proceed in this section by briefly explaining the major features of the RV and continue with sketching the

arguments that exposed its weaknesses in Sects. 2.1.1–2.1.6.

The RV construes scientific theories as Hilbert-style formal axiomatic calculi, that is, axiomatized sets of sentences in first-order predicate calculus with identity. A scientific theory is thus identified with a formal language,  $L$ , having the following features. The nonlogical terms of  $L$  are divided into two disjoint classes: (1) the theoretical terms that constitute the theoretical vocabulary,  $V_T$ , of  $L$  and (2) the observation terms that constitute the observation vocabulary,  $V_O$ , of  $L$ . Thus,  $L$  can be thought of as consisting of an observation language,  $L_O$ , that is, a language that consists only of observation terms, a theoretical language,  $L_T$ , that is, a language that consists only of theoretical terms, and a part that consists of mixed sentences that are made up of both observation and theoretical terms. The theoretical postulates or the axioms of the theory,  $T$  (i. e., what we, commonly, refer to as the high-level scientific

laws), consist only of terms from  $V_T$ . This construal of theories is a syntactic system, which naturally requires semantics in order to be useful as a model of scientific theories.

It is further assumed that the terms of  $V_O$  refer to directly observable physical objects and directly observable properties and relations of physical objects. Thus the semantic interpretation of such terms, and the sentences belonging to  $L_O$ , is provided by direct observation. The terms of  $V_T$ , and subsequently all the other sentences of  $L$  not belonging to  $L_O$ , are partially interpreted via the theoretical postulates,  $T$ , and – a finite set of postulates that has come to be known as – the *correspondence rules*,  $C$ . The latter are mixed sentences of  $L$ , that is, they are constructed with at least one term from each of the two classes  $V_T$  and  $V_O$ . (The reader could consult *Suppe* [2.1] for a detailed exposition of the RV, but also for a detailed philosophical study of the developments that the RV underwent under the weight of several criticisms until it reached, what Suppe calls, the “final version of the RV”).

We could synopsise how scientific theories are conceived according to the RV as follows: The scientific laws, which as noted constitute the axioms of the theory, specify relations holding between the theoretical terms. Via a set of *correspondence rules*, theoretical terms are reduced to, or defined by, observation terms. Observation terms refer to objects and relations of the physical world and thus are interpreted. Hence, a scientific theory, according to the RV, is a formal axiomatic system having as point of departure a set of theoretical postulates, which when augmented with a set of correspondence rules has deductive consequences that stretch all the way to terms, and sentences consisting of such terms, that refer to the directly observable physical objects. Since according to this view, the backbone of a scientific theory is the set of theoretical postulates,  $T$ , and a partial interpretation of  $L$  is given via the set of correspondence rules,  $C$ , let  $TC$  (i. e., the union set of  $T$  and  $C$ ) designate the scientific theory.

From this sketch, it can be inferred that the RV implies several philosophically interesting things. For the purposes of this chapter, it suffices to limit the discussion only to those implications of the RV that are relevant to the criticisms that have contributed to its downfall. These implications, which in one way or another relate to the difficulty in characterizing  $V_T$  terms, are:

1. It relies on an observational–theoretical distinction of the terms of  $L$ .
2. It embodies an analytic–synthetic distinction of the sentences of  $L$ .

3. It employs the obscure notion of correspondence rules to account for the interpretation of theoretical terms and to account for theory application.
4. It does not assign a representational function to models.
5. It assigns a deductive status to the relation between empirical theories and experiment.
6. It commits to a theory consistency condition and to a meaning invariance condition.

### 2.1.1 The Observation–Theory Distinction

The separation of  $L$  into  $V_O$  and  $V_T$  terms implies that the RV requires an observational–theoretical distinction in the terms of the vocabulary of the theory. This idea was criticized in two ways. The first kind of objection to the observation–theory distinction relied on a twofold argument. On the one hand, the critics claim that an observation–theory distinction of scientific terms cannot be drawn; and on the other, that a classification of terms following such a distinction would give rise to a distinction of observational–theoretical statements, which also cannot be drawn for scientific languages. The second kind of objection to the distinction relies on attempts to establish accounts of *observation* that are incompatible with the observation–theory distinction and on showing that observation statements are theory laden.

#### The Untenability of the Observation–Theory Distinction

The argument of the first kind that focuses on the untenability of the observation–theory distinction is due to *Achinstein* [2.2, 3] and *Putnam* [2.4]. Achinstein explores the sense of observation relevant to science, that is, “the sense in which observing involves visually attending to something,” and he claims that this sense exhibits the following characteristics:

1. Observation involves attention to the various aspects or features of an item depending on the observer’s concerns and knowledge.
2. Observation does not necessarily involve recognition of the item.
3. Observation does not imply that whatever is observed is in the visual field or in the line of sight of the observer.
4. Observation could be achieved indirectly.
5. The description of what one observes can be done in different ways (The reader could refer to *Achinstein* [2.3, pp. 160–165] for an explication of these characteristics of observation by the use of specific examples).

If now one urges an observation–theory distinction by simply constructing lists of observable and unobservable terms (as proponents of the RV according to Achinstein do), the distinction becomes untenable. For example, according to typical lists of unobservables, *electron* is a theoretical term. But based on points (3) and (4) above, Achinstein claims, this could be rejected. Similarly based on point (5), Achinstein also rejects the tenability of such a distinction at the level of statements, because “what scientists as well as others observe is describable in many different ways, using terms from both vocabularies” [2.3, p. 165].

Furthermore, if, as proponents of the RV have often claimed, (For instance, *Hempel* [2.5], *Carnap* [2.6] and [2.7]), items in the observational list are directly observable whereas those in the theoretical list are not, then *Achinstein* [2.3, pp. 172–177] claims that a close construal of *directly observable* reveals that the desired classification of terms into the two lists fails. He explains that *directly observable* could mean that it can be observed without the use of instruments. If this is what advocates of the RV require, then it does not warrant the distinction. First, it is not precise enough to classify things seen by images and reflections. Second, if something is not observable without instruments means that no aspect of it is observable without instruments then things like temperature and mass would be observables, since some aspects of them are detected without instruments. If however directly observable means that no instruments are required to detect its presence, then it would be insufficient because one cannot talk about the presence of temperature. Finally, if it means that no instruments are required to measure it or its properties, then such terms as volume, weight, etc. would have to be classified as theoretical terms. Hence, Achinstein concludes that the notion of direct observability is unclear and thus fails to draw the desired observation–theory distinction.

Along similar lines, *Putnam* [2.4] argues that the distinction is completely *broken-backed* mainly for three reasons. First, if an observation term is one that only refers to observables then there are no observation terms. For example, the term *red* is in the observable class but it was used by Newton to refer to a theoretical term, namely red corpuscles. Second, many terms that refer primarily to the class of unobservables are not theoretical terms. Third, some theoretical terms, that are of course the outcome of a scientific theory, refer primarily to observables. For example, the theory of evolution, as put forward by Darwin, referred to observables by employing theoretical terms.

What these arguments accomplish is to highlight the fact that scientific languages employ terms that cannot clearly and easily be classified into observational or

theoretical. They do not however show the untenability of the observation–theory distinction as employed by the RV. As *Suppe* [2.8] correctly observes, what they show is that the RV needs a sufficiently rich artificial language for science, no matter how complex it may turn out to be. Such a language, in which presumably the observation–theory distinction is tenable, must have a plethora of terms, such that, to use his example, the designated term *red<sub>o</sub>* will refer to the observable occurrences of the predicate *red*, and the designated term *red<sub>t</sub>* will refer to the unobservable occurrences.

### The Theory–Ladenness of Observation

Hanson’s argument is a good example of the second kind, in which an attempt is made to show that there is no theory-neutral observation language and that observation is theory-laden and thus establish an account of *observation* that is incompatible with the observation–theory distinction required by the RV (*Hanson* [2.9, pp. 4–30], *Hanson* [2.10, pp. 59–198]. Also *Suppe* [2.1, pp. 151–166]). He does this by attempting to establish that an observation language that intersubjectively can be given a theory-independent semantic interpretation, as the RV purports, cannot exist.

He begins by asking whether two people see the same things when holding different theories. We could follow his argument by reference to asking whether Kepler and Tycho Brahe see the same thing when looking at the sun rising. Kepler, of course, holds that the earth revolves around the sun, while Tycho holds that the sun revolves around the earth. Hanson addresses this question by considering ambiguous figures, that is, figures that sometimes can be seen as one thing and other times as another. The most familiar example of this kind is the duck–rabbit figure.

When confronted with such figures, viewers see either a duck or a rabbit depending on the perspective they take, but in both cases they see the same distal object (i. e., the object that emits the rays of light that impinge the retina). Hanson uses this fact to develop a sequence of arguments to counter the standard interpretations of his time. There were two standard interpretations at the time. The first was that the perceptual system delivers the same visual representation and then cognition (thought) interprets this either as a duck or as a rabbit. The other was that the perceptual system outputs both representations and then cognition chooses one of the two. Both interpretations are strongly linked with the idea that the perceptual process and the cognitive process function independently of one another, that is, the perceptual system delivers its output independent of any cognitive influences. However, Hanson challenges the assumption that the two observers see the same thing and via thought they in-

interpret it differently. He claims that perception does not deliver either a duck or a rabbit, or an ambiguous figure, and then via some other independent process thought chooses one or the other. On the contrary, the switch from seeing one thing to seeing the other seems to take place spontaneously and moreover a process of back and forth seeing without any thinking seems to be involved. He goes on to ask, what could account for the difference in what is seen? His answer is that what changes is the organization of the ambiguous figure as a result of the conceptual background of each viewer. This entails that what one sees, the percept, depends on the conceptual background that results from one's experience and knowledge, which means that thought affects the formation of the percept; thus perception and cognition become intertwined. When Tycho and Kepler look at the sun, they are confronted with the same distal object but they see different things because their conceptual organizations of their experiences are vastly different. In other words, Hanson's view is that the percept depends on background knowledge, which means that cognition influences perceptual processing. Consequently, observation is theory laden, namely, observation is conditional on background knowledge.

By this argument, Hanson undermines the RV's position, which entails that Kepler and Brahe see the same thing but interpret it differently; and also establishes that conceptual organizations are features of *seeing* that are indispensable to scientific observation and thus that Kepler and Brahe see two different things because perception inherently involves interpretation, since the former is conditional on background knowledge. It is, however, questionable whether Hanson's arguments are conclusive. Fodor [2.11–13], Pylyshyn [2.14, 15], and Raftopoulos [2.16–18], for example, have extensively argued on empirical grounds that perception, or at least a part of it, is theory independent and have proposed explanations of the ambiguous figures that do not invoke cognitive effects in explaining the percept and the switch between the two interpretations of the figure. This debate, therefore, has not yet reached its conclusion; and many today would argue that fifty or so years after Hanson the arguments against the theory ladenness of observation are much more tenable.

### 2.1.2 The Analytic–Synthetic Distinction

The RV's dependence on the observation–theory distinction is intimately linked to the requirement for an analytic–synthetic distinction. An argument to defend this claim is given by Suppe [2.1, pp. 68–80]. Here is a sketch of that argument. The analytic–synthetic distinction is embodied in the RV, because (as suggested by Carnap [2.19]) implicit in *TC* are meaning postu-

lates (or semantical rules) that specify the meanings of sentences in *L*. However, if meaning specification were the only function of *TC* then *TC* would be analytic, and in such case it would not be subject to empirical investigation. *TC* must therefore have a factual component, and the meaning postulates must separate the meaning from the factual component. This would imply an analytic–synthetic separation, if those sentences in *L* that are logical truths or logical consequences of the meaning postulates are analytic and all nonanalytic sentences are understood to be synthetic. Moreover, any nonanalytic sentence in *L* taken in conjunction with the class of meaning postulates would have certain empirical consequences. If the conjunction is refuted or confirmed by directly observable evidence, this will reflect only on the truth value of the conjunction and not on the meaning postulates. Hence such conjunctive sentences can only be synthetic. Thus every nonanalytic sentence of *L<sub>0</sub>* and every sentence of *L* constituted by a mixed vocabulary is synthetic. So the observation–theory distinction supports an analytic–synthetic distinction of the sentences of *L*.

The main criticism against the analytic–synthetic distinction consists of attempts to show its untenability. Quine [2.20] points out that there are two kinds of analytic statements: (a) logical truths, which remain true under all interpretations, and (b) statements that are true by virtue of the meaning of their nonlogical terms, for example, *No bachelor is married*. He then argues that the analyticity of statements of the second kind cannot be established without resort to the notion of synonymy, and that the latter notion is just as problematic as the notion of analyticity. The argument runs roughly as follows. Given that meaning (or intension) is clearly distinguished from its extension, that is, the class of entities to which it refers, a theory of meaning is primarily concerned with cognitive synonymy (i. e., the synonymy of linguistic forms). For example, to say that *bachelor* and *unmarried man* are cognitively synonymous is to say that they are interchangeable in all contexts without change of truth value. If such were the case then the statement *No bachelor is married* would become *No unmarried man is married*, which would be a logical truth. In other words, statements of kind (b) are reduced to statements of kind (a) if only we could interchange synonyms for synonyms. But as Quine argues, the notion of interchangeability *salva veritate* is an extensional concept and hence does not help with analyticity. In fact, no analysis of the interchangeability *salva veritate* account of synonymy is possible without recourse to analyticity, thus making such an effort circular, unless interchangeability is “[...] relativized to a language whose extent is specified in relevant respects” [2.20, p. 30]. That is to say,

we first need to know what statements are analytic in order to decide which expressions are synonymous; hence appeal to synonymy does not help with the notion of analyticity.

Similarly White [2.21] argues that an artificial language,  $L_1$ , can be constructed with appropriate definitional rules, in which the predicates  $P_1$  and  $Q_1$  are synonymous whereas  $P_1$  and  $Q_2$  are not; hence making such sentences as  $\forall x (P_1(x) \rightarrow Q_1(x))$  logical truths and such sentences as  $\forall x (P_1(x) \rightarrow Q_2(x))$  synthetic. In a different artificial language  $L_2$ ,  $P_1$  could be defined to be synonymous to  $Q_2$  and not to  $Q_1$ , hence making the sentence  $\forall x (P_1(x) \rightarrow Q_2(x))$  a logical truth and the sentence  $\forall x (P_1(x) \rightarrow Q_1(x))$  synthetic. This relies merely upon convention. However, he asks, in a natural language what rules are there that dictate what choice of synonymy can be made such that one formula is a synthetic truth rather than analytic? The key point of the argument is therefore that in a natural language or in a scientific language, which are not artificially constructed and which do not contain definitional rules, the notion of analyticity is unclear.

Nevertheless, it could be argued that such arguments as the above are not entirely conclusive, primarily because the RV is not intended as a description of actual scientific theories. Rather, the RV is offered as a *rational reconstruction* of scientific theories, that is, an explication of the structure of scientific theories. It does not aim to describe how actual theories are formulated, but only to indicate a logical framework (i. e., a canonical linguistic formulation) in which theories can be essentially reformulated. Therefore, all that proponents of the RV, needed to show was that the analytic–synthetic distinction is tenable in some artificial language (with meaning postulates) in which scientific theories could potentially be reformulated. In view of this, in order for the RV to overcome the obscurity of the notion of analyticity, pointed out by Quine and White, it would require the conclusion of a project that Carnap begun: To spell out a clear way by which to characterize meaning postulates for a specified theoretical language (This is clearly Carnap’s intention in his [2.19]).

### 2.1.3 Correspondence Rules

In order to distinguish the character and function of theoretical terms from speculative metaphysical ones (e.g., *unicorn*), logical positivists sought for a connection of theoretical to observational terms by giving an analysis of the empirical nature of theoretical terms contrary to that of metaphysical terms. This connection was formulated in what we can call, following Achinstein [2.22], the *Thesis of Partial Interpretation*, which is basically the following: As indicated above, in the brief sketch of

the main features of the RV, the RV allows that a complete empirical semantic interpretation in terms of directly observables is given to  $V_O$  terms and to sentences that belong to  $L_O$ . However, no such interpretation is intended for  $V_T$  terms and consequently for sentences of  $L$  containing them. It is  $TC$  as a whole that supplies the empirical content of  $V_T$  terms. Such terms receive a partial observational meaning indirectly by being related to sets of observation terms via correspondence rules. To use one of Achinstein’s examples [2.22, p. 90]:

“it is in virtue of [a correspondence-rule] which connects a sentence containing the theoretical term *electron* to a sentence containing the observational term *spectral line* that the former theoretical term gains empirical meaning within the Bohr theory of the atom”

Correspondence rules were initially introduced to serve three functions in the RV:

1. To define theoretical terms.
2. To guarantee the cognitive significance of theoretical terms.
3. To specify the empirical procedures for applying theory to phenomena.

In the initial stages of logical positivism it was assumed that if observational terms were cognitively significant, then theoretical terms were cognitively significant if and only if they were explicitly defined in terms of observational terms. The criteria of explicit definition and cognitive significance were abandoned once proponents of the RV became convinced that dispositional terms, which are cognitively significant, do not admit of explicit definitions (Carnap [2.23, 24], also Hempel [2.25, pp. 23–29], and Hempel [2.5]). Consider, for example, the dispositional term *tearable* (let us assume all the necessary conditions for an object to be torn apart hold), if we try to explicitly define it in terms of observables we end up with something like this:

“An object  $x$  is tearable if and only if, if it is pulled sharply apart at time  $t$  then it will tear at  $t$  (assuming for simplicity that pulling and tearing occur simultaneously).”

The above definition could be rendered as  $\forall x (T(x) \leftrightarrow \forall t (P(x, t) \rightarrow Q(x, t)))$ , where,  $T$  is the theoretical term *tearable*,  $P$  is the observational term *pulled apart*, and  $Q$  is the observational term *tears*. But this does not correctly define the actual dispositional property *tearable*, because the right-hand side of the biconditional will be true of objects that are never pulled apart. As a result, some objects that are not tearable and have never being pulled apart will by definition have the property *tearable*.

Because of this, Carnap [2.23, 24] proposed to replace the construal of correspondence rules as explicit definitions, by *reduction sentences* that partially determine the observational content of theoretical terms. A reduction sentence defined the dispositional property tearable as follows:  $\forall x \forall t (P(x, t) \rightarrow (Q(x, t) \leftrightarrow T(x)))$ . That is, (Carnap calls such sentences *bilateral reduction sentences* [2.23, 24]):

“If an object  $x$  is pulled-apart at time  $t$ , then it tears at time  $t$  if and only if it is tearable.”

Unlike the explicit definition case, if  $a$  is a non-tearable object that is never pulled apart then it is not implied that  $T(a)$  is true. What will be implied, in such case, is that  $\forall t (P(a, t) \rightarrow (Q(a, t) \leftrightarrow T(a)))$ , is true. Thus the above shortcoming of explicit definitions is avoided, because a reduction sentence does not completely define a disposition term. In fact, this is also the reason why correspondence rules supply only partial observational content, since many other reduction sentences can be used to supply other empirical aspects of the term *tearable*, for example, being torn by excessively strong shaking. Consequently, although correspondence rules were initially meant to provide explicit definitions and cognitive significance to  $V_T$  terms, these functions were abandoned and substituted by *reduction sentences* and *partial interpretation* (A detailed explication of the changes in the use of correspondence rules through the development of the RV can be found in [2.1]).

Therefore, in its most defensible version the RV could be construed to assign the following functions to correspondence rules: First, they specify empirical procedures for the application of theory to phenomena and second, as a constitutive part of  $TC$ , they supply  $V_T$  and  $L_T$  with partial interpretation. Partial interpretation in the above sense is all the RV needs since, given its goal of distinguishing theoretical from speculative metaphysical terms, it only needs a way to link the  $V_T$  terms to the  $V_O$  terms. The version of the RV that employs correspondence rules for these two purposes motivated two sorts of criticisms. The first concerns the idea that correspondence rules provide partial interpretation to  $V_T$  terms, and the second concerns the function of correspondence rules for providing theory application.

The thesis of partial interpretation came under attack from Putnam [2.4] and Achinstein [2.3, 22]. The structure of their arguments is similar. They both think that partial interpretation is unclear and they attempt to clarify the concept. They do so by suggesting plausible explications for *partial interpretation*. Then they show that for each plausible explication that each of them suggests partial interpretation is either an incoherent notion or inadequate for the needs of the RV. Thus,

they both conclude that any attempt to elucidate the notion of partial interpretation is problematic and that partial interpretation of  $V_T$  terms cannot be adequately explicated. For example, Putnam gives the following plausible explications for *partial interpretation*:

1. To partially interpret  $V_T$  terms is to specify a class of intended models.
2. To partially interpret a term is to specify a verification–refutation procedure that applies only to a proper subset of the extension of the term.
3. To partially interpret a formal language  $L$  is to interpret only part of the language.

In similar spirit, Achinstein gives three other plausible explications. One of Putnam’s counterexamples is that (1) above cannot meet its purpose because the class of intended models, that is, the semantic structures or interpretations that satisfy  $TC$  and which are so intended by scientists, is not well defined (A critical assessment of these arguments can be found in [2.1]).

The other function of correspondence rules, that of specifying empirical procedures for theory application to phenomena, also came under criticism. Suppe [2.1, pp. 102–109] argued that the account of correspondence rules inherent in the RV is inadequate for understanding actual science on the following three grounds:

1. They are mistakenly viewed as components of the theory rather than as auxiliary hypotheses.
2. The sorts of connections (e.g., explanatory causal chains) that hold between theories and phenomena are inadequately captured.
3. They oversimplify the ways in which theories are applied to phenomena.

The first argument is that the RV considers  $TC$  as postulates of the theory. Hence  $C$  is assumed to be an integral part of the theory. But, if a new experimental procedure is discovered it would have to be incorporated into  $C$ , and the result would be a new set of rules  $C'$  that subsequently leads to a new theory  $TC'$ . But obviously the theory does not undergo any change. When new experimental procedures are discovered we only improve our knowledge of how to apply theory to phenomena. So we must think of correspondence rules as auxiliary hypotheses distinct from theory.

The second argument is based upon Schaffner’s [2.26] observation that there is a way in which theories are applied to phenomena, which is not captured by the RV’s account of correspondence rules. This is the case when various auxiliary theories (independent of  $T$ ) are used to describe a *causal sequence*, which obtains between the states described by  $T$  and the observation reports. These causal sequences are descriptions of the mechanisms involved within physical systems to

cause the measurement apparatus to behave as it does. Thus, they supplement theoretical explanations of the observed behavior of the apparatus by linking the theory to the observation reports via a causal story. For example, such auxiliary hypotheses are used to establish a causal link between the motion of an electron ( $V_T$  term) and the spectral line ( $V_O$  term) in a spectrometer photograph. Schaffner's point is that the relation between theory and observation reports is frequently achieved by the use of these auxiliary hypotheses that establish explanations of the behavior of physical systems via causal mechanisms. Without recognizing the use of these auxiliaries the RV may only describe a type of theory application whereby theoretical states are just correlated to observational states. If these kinds of auxiliaries were to be viewed as part of  $C$  then it is best that  $C$  is dissociated from the core theory and is regarded as a separate set of auxiliary hypotheses required for establishing the relation between theory and experiment, because such auxiliaries are obviously not theory driven, but if they are not to be considered part of  $C$  then  $C$  does not adequately explain the theory–experiment relation.

Finally, the third argument is based on Suppes' [2.27, 28] analysis of the complications involved in relating theoretical predictions to observation reports. Suppes observes that in order to reach the point where the two can meaningfully be compared, several epistemologically important modifications must take place on the side of the observation report. For example, Suppes claims, on the side of theory we typically have predictions derived from continuous functions, and on the side of an observation report we have a set of discrete data. The two can only be compared after the observation report is modified accordingly. Similarly, the theory's predictions may be based on the assumption that certain idealizing conditions hold, for example, no friction. Assuming that in the actual experiment these conditions did not hold, it would mean that to achieve a reasonable comparison between theory and experiment the observational data will have to be converted into a corresponding set that reflects the result of an *ideal* experiment. In other words, the actual observational data must be converted into what they would have been had the idealizing conditions obtained. According to Suppes, these sorts of conversion are obtained by employing appropriate *theories of data*. So, frequently, there will not be a direct comparison between theory and observation, but a comparison between theory and observation-altered-by-theory-of-data.

By further developing Suppes' analysis, Suppe [2.8] argues that because of its reliance on the observation–theory distinction, the RV employs correspondence rules in such a way as to blend together unrelated as-

pects of the scientific enterprise. Such aspects are the design of experiments, the interpretation of theories, the various calibration procedures, the employment of results and procedures of related branches of science, etc. All these unrelated aspects are compounded into the correspondence rules. Contrary to the implications of the RV, Suppe claims, in applying a theory to phenomena we do not have any direct link between theoretical terms and observational terms. In a scientific experiment we collect data about the phenomena, and often enough the process of collecting the data involves rather sophisticated bodies of theory. Experimental design and control, instrumentation, and reliability checks are necessary for the collection of data. Moreover, sometimes generally accepted laws or theories are also employed in collecting these data. All these features of experimentation and data collection are then employed in ways as to structure the data into forms (which Suppe calls, *hard data*) that allow meaningful comparison to theoretical predictions. In fact, theory application according to Suppe involves contrasting theoretical predictions to *hard data*, and not to something directly observed [2.8, p. 11]:

“Accordingly, the correspondence rules for a theory should not correlate direct-observation statements with theoretical statements, but rather should correlate *hard data* with theoretical statements.”

In a nutshell, although both Suppes' and Suppe's arguments do not establish with clarity how the theory–experiment relation is achieved they do make the following point: Actual scientific practice, and in particular theory–application, is far more complex than the description given by the RV's account of correspondence rules.

#### 2.1.4 The Cosmetic Role of Models According to the RV

The objection that the RV obscures several epistemologically important features of scientific theories is implicitly present in all versions of the SV of theories. Suppe, however, brings this out explicitly in the form of a criticism (Suppe [2.1, 29, 30]). To clarify the sort of criticism presented by Suppe, we need to make use of some elements of the alternative picture of scientific theories given by the SV, which we shall explore in detail in Sect. 2.2.

The reasoning behind Suppe's argument is the following. Science, he claims, has managed so far to go about its business without involving the observation–theory distinction and all the complexities that it gives rise to. Since, he suggests, the distinction is not required by science, it is important to ask not only whether an

analysis of scientific theories that employs the distinction is adequate or not, that is, the issue on which (as we have seen so far) many of the criticisms of the RV have focused, but whether or not the observation–theory distinction which leads to the notion of correspondence rules subsequently steers toward obscuring epistemological aspects of scientific theorizing.

The sciences, he argues, do not deal with all the detailed features of phenomena and not with phenomena in all their complexity. Rather they isolate a certain number of physical parameters by abstraction and idealization and use these parameters to characterize *physical systems* (Suppe’s terminology is idiosyncratic, he uses the term *physical system* to refer to the abstract entity that an idealized model of the theory represents and not to the actual target physical system), which are highly abstract and idealized replicas of phenomena. A classical mechanical description of the earth–sun system of our solar system, would not deal with the actual system, but with a physical system in which some relevant parameters are abstracted (e.g., mass, displacement, velocity) from the complex features of the actual system. And in which some other parameters are ignored, for example, the intensity of illumination by the sun, the presence of electromagnetic fields, the presence of organic life. In addition, these abstracted parameters are not used in their full complexity to characterize the physical system. Indeed, the description would idealize the physical system by ignoring certain factors or features of the actual system that may plausibly be causally relevant to the actual system. For instance, it may assume that the planets are point masses, or that their gravitational fields are uniform, or that there are no disturbances to the system by external factors and that the system is in a vacuum. What scientific theories do is attempt to characterize the behavior of such physical systems not the behavior of directly observable phenomena.

Although this is admittedly a rough sketch of Suppe’s view, it is not hard to see that the aim of the argument is to lead to the conclusion that the directly observable phenomena are connected to a scientific theory via the physical system. That is to say, (if we put together this idea with the one presented at the end of Sect. 2.1.3 above) the connection between the theory and the phenomena, according to Suppe, requires an analysis of theories and of theory–application that involves a two-stage move. The first move involves the connection between raw phenomena and the *hard data* about the particular target system in question. The second move involves the connection between the *physical system* that represents the *hard data* and the theoretical postulates of the theory. According to Suppe’s understanding of the theory–experiment

relation, the physical system plays the intermediate role between phenomena and theory and this role, which is operative in theory–application, is what needs to be illuminated. The RV implies that the correspondence rules “[...] amalgamate together the two sorts of moves [...] so as to eliminate the physical system” [2.29, p. 16], thus obscuring this important epistemological feature of scientific theorizing.

So, according to Suppe, correspondence rules must give way to this two-stage move, if we are to identify and elucidate the epistemic features of *physical systems*. Suppe’s suggestion is that the only way to accommodate physical systems into our understanding of how theories relate to phenomena is to give models of the theory their representational status. The representational means of the RV are linguistic entities, for example, sentences. Models, within the RV, are denied any representational function. They are conceived exclusively as interpretative devices of the formal calculus, that is, as structures that satisfy subsets of sentences of the theory. This reduces models to meta-mathematical entities that are employed in order to make intelligible the abstract calculus, which amounts to treating them as more or less *cosmetic* aspects of science. But this understanding of the role of models leads to the incapacity of the RV to elucidate the epistemic features of physical systems, and thus obscures – what Suppe considers to be – epistemologically important features of scientific theorizing.

### 2.1.5 Hempel’s Provisos Argument

In one of his last writings, *Hempel* [2.31] raises a problem that suggests a flaw in interpreting the link between empirical theories and experimental reports as mere deduction. Assuming that a theory is a formal axiomatic system consisting of  $T$  and  $C$ , as we did so far, consider Hempel’s example. If we try to apply the theory of magnetism for a simple case we are faced with the following inferential situation. From the observational sentence *b is a metal bar to which iron filings are clinging* ( $S_{O1}$ ), by means of a suitable correspondence rule we infer the theoretical sentence *b is a magnet* ( $S_{T1}$ ). Then by using the theoretical postulates in  $T$ , we infer *if b is broken into two bars, then both are magnets and their poles will attract or repel each other* ( $S_{T2}$ ). Finally using further correspondence rules we derive the observational sentence *if b is broken into two shorter bars and these are suspended, by long thin threads, close to each other at the same distance from the ground, they will orient themselves so as to fall into a straight line* ( $S_{O2}$ ) ([2.31, p. 20]). If the inferential structure is assumed to be deductive then the above structure can be read as follows:  $S_{O1}$  in

combination with the theory deductively implies  $S_{O2}$ . Hempel concludes that this deductivist construal faces a difficulty, which he calls *the problem of provisos*.

To clarify the problem of provisos, we must look into the third inferential step from  $S_{T2}$  to  $S_{O2}$ . What is necessary here is for the theory of magnetism to provide correspondence rules that would turn this step into a deductive inference. The theory however, as Hempel points out, clearly does not do this. In fact, the theory allows for the possibility that the magnets orient themselves in a way other than a straight line, for example, if an external magnetic field of suitable strength and direction is present. This leads to recognizing that the third inferential step presupposes the additional assumption that there are no disturbing influences to the system of concern. Hempel uses the term *provisos*, “[...] to refer to assumptions [of this kind] [...], which are essential, but generally unstated, presuppositions of theoretical inferences” [2.31, p. 23]. Therefore, provisos are presupposed in the application of a theory to phenomena (The problem we saw in Sect. 2.1.3 which Suppes raises, namely that in science theoretical predictions are not confronted with raw observation reports but with observation-altered-by-theory-of-data reports, neighbors this problem but it is not the same. Hempel’s problem of provisos concerns whether it is possible to deductively link theory to observational statements no matter how the latter are constructed).

What is the character of provisos? Hempel suggests we may view provisos as *assumptions of completeness*. For example, in a theoretical inference from a sentence  $S_1$  to another  $S_2$ , a proviso is required that asserts that in a given case “[...] no factors other than those specified in  $S_1$  are present that could affect the event described by  $S_2$ ” [2.31, p. 29]. As, for example, is the case in the application of the Newtonian theory to a two-body system, where it is presupposed that their mutual gravitational attraction are the only forces the system is subjected to. It is clear that [2.31, p. 26]:

“[...] a proviso as here understood is not a clause that can be attached to a theory as a whole and vouchsafe its deductive potency by asserting that in all particular situations to which the theory is applied, disturbing factors are absent. Rather, a proviso has to be conceived as a clause that pertains to some particular application of a given theory and asserts that in the case at hand, no effective factors are present other than those explicitly taken into account.”

Thus, if a theory is conceived as a deductively closed set of statements and its axioms conceived as empirical universal generalizations, as the RV purports, then to apply theory to phenomena, that is, to de-

ductively link theoretical to observational statements, provisos are required. However, in many theory applications there would be an indefinitely large number of provisos, thus trivializing the concept of scientific laws understood as empirical universal generalizations. In other cases, some provisos would not even be expressible in the language of the theory, thus making the deductive step impossible. Hempel’s challenge is that theory–applications presuppose provisos and this does not cohere with the view that theory relates to observation sentences deductively (For an interesting discussion of Hempel’s problem of provisos, see [2.32–35]).

### 2.1.6 Theory Consistency and Meaning Invariance

Feyerabend criticized the logical positivist conception of scientific theories on the ground that it imposes on them a *meaning invariance condition* and a *consistency condition*. By the consistency condition he meant that [2.36, p. 164]

“[...] only such theories are [...] admissible in a given domain which either *contain* the theories already used in this domain, or which are at least *consistent* with them inside the domain.”

By the condition of meaning invariance he meant that [2.36, p. 164]:

“[...] meanings will have to be invariant with respect to scientific progress; that is, all future theories will have to be framed in such a manner that their use in explanations [or reductions] does not affect what is said by the theories, or factual reports to be explained”

Feyerabend’s criticisms are not aimed directly at the RV, but rather at two other claims of logical positivism that are intimately connected to the RV, namely the theses of *the development of theories by reduction* and *the covering law model of scientific explanation*.

A brief digression, in order to look into the aforementioned theses, would be helpful. The development of theories by reduction involves the reduction of one theory (secondary) into a second more inclusive theory (primary). In such developments, the former theory may employ [2.37, p. 342]

“[...] in its formulations [...] a number of distinctive descriptive predicates that are not included in the basic theoretical terms or in the associated rules of correspondence of the primary [theory] [...].”

That is to say, the  $V_T$  terms of the secondary theory are not necessarily all included in the theoretical vocabulary of the primary theory. Nagel builds up his

case based on the example of the reduction of thermodynamics to statistical mechanics. There are several requirements that have to be satisfied for theory reduction to take place, two of which are: (1) the  $V_T$  terms for both theories involved in the reduction must have unambiguously fixed meanings by codified rules of usage or by established procedures appropriate to each discipline, for example, theoretical postulates or correspondence rules. (2) for every  $V_T$  term in the secondary theory that is absent from the theoretical vocabulary of the primary theory, assumptions must be introduced that postulate suitable relations between these terms and corresponding theoretical terms in the primary theory. (See Nagel [2.37, pp. 345–358]. In fact Nagel presents a larger set of conditions that have to hold in order for reduction to take place [2.37, pp. 336–397], but these are the only two relevant to Feyerabend's arguments).

The covering law model of scientific explanation is, in a nutshell, explanation in terms of a deductively valid argument. The sentence to be explained (explanandum) is a logical consequence of a set of law-premises together with a set of premises consisting of initial conditions or other particular facts involved (explanans). For the special case when the explanandum is a scientific theory,  $T'$ , the covering law model can be formulated as follows: A theory  $T$  explains  $T'$  if and only if  $T$  together with initial conditions constitute a deductively valid inference with consequence  $T'$ . In other words, if  $T'$  is derivable from  $T$  together with statements of particular facts involved then  $T'$  is explained by  $T$ . It seems that reduction and explanation of theories go hand in hand, that is, if  $T'$  is reduced to  $T$ , then  $T$  explains  $T'$  and conversely.

Feyerabend points out that Nagel's two assumptions – (1) and (2) above – for theory reduction respectively impose a condition of meaning invariance and a consistency condition to scientific progress. The thesis of development of theories by reduction condemns science to restrict itself to theories that are mutually consistent. But the consistency condition requires that terms in the admissible theories for a domain must be used with the same meanings. Similarly, it can be shown that the covering law model of explanation also imposes these two conditions. In fact, the consistency condition follows from the requirement that the explanandum must be a logical consequence of the explanans, and since the meanings of the terms and statements in a logically valid argument must remain constant, an obvious demand for explanation – imposed

by the covering law model – is that meanings must be invariant. Feyerabend objects to the meaning invariance and the consistency conditions and argues his case inductively by drawing from historical examples of theory change. For example, the concept of mass does not have the same meaning in relativity theory as it does in classical mechanics. Relativistic mass is a relational concept between an object and its velocity, whereas in classical mechanics mass is a monadic property of an object. Similarly, Galileo's law asserts that acceleration due to gravity is constant, but if Newton's law of gravitation is applied to the surface of the earth it yields a variable acceleration due to gravity. Hence, Galileo's law cannot be derived from Newton's law. By such examples, he attempts to undermine Nagel's assumptions (1) and (2) above and establish that neither meaning invariance nor the related notion of theory consistency characterize actual science and scientific progress (see Feyerabend [2.36, 38–40]. Numerous authors have criticized Feyerabend's views. For instance, objections to his views have been raised based on his idiosyncratic analysis of *meaning*, on which his arguments rely. His views are hence not presented here as conclusive criticisms of the RV; but only to highlight that they cast doubt on the adequacy of the theses of theory development by reduction and the covering law model of explanation).

### 2.1.7 General Remark on the Received View

The RV is intended as an explicative and not a descriptive view of scientific theories. We have seen that even as such it is vulnerable to a great deal of criticism. One way or another, all these criticisms rely on one weakness of the RV: Its inability to clearly spell out the nature of theoretical terms (and how they acquire their meaning) and its inability to specify how sentences consisting of such terms relate to experimental reports. This is a weakness that has been understood by the RV's critics to stem from the former's focus on syntax. By shifting attention away from the representational function of models and attempting to characterize theory structure in syntactic terms, the RV makes itself vulnerable to such objections. Despite all of the above criticisms pointing to the difficulty in explicating how theoretical terms relate to observation, I do not think that any one of them is conclusive in the ultimate sense of rebutting the RV. Nevertheless, the subsequent result was that under the weight of all of these criticisms together the RV eventually made room for its successor.

## 2.2 The Semantic View of Scientific Theories

The SV has for the last few decades been the standard-bearer of the view that theories are families of models. The slogan *theories are families of models* was meant by the philosophers that originally put forward the SV to stand for the claim that it is more suitable – for understanding scientific theorizing – that the structure of theory is identified with, or presented as, classes of models. A logical consequence of identifying theory structure with classes of models is that models and modeling are turned into crucial components of scientific theorizing. Indeed, this has been one of the major contributions of the SV, since it unquestionably assisted in putting models and modeling at the forefront of philosophical attention. However, identifying theory structure with classes of models is not a logical consequence of the thesis that models (and modeling) are important components of scientific theorizing. Some philosophers who came to this conclusion have since defended the view that although models are crucial to scientific theorizing, the relation between theory and models is much more complex than that of set-theoretical inclusion. I shall proceed in this section by articulating the major features of the SV; in the process I shall try to clarify the notion of model inherent in the view and also explain – what I consider to be – the main difference among its proponents, and finally I will briefly discuss the criticisms against it, which, nevertheless, do not undermine the importance of models in science.

Patrick Suppes was the first to attempt a model-theoretic account of theory structure. He was one of the major denouncers of the attempts by the logical positivists to characterize theories as first-order calculi supplemented by a set of correspondence rules. (See [2.27, 28, 41–43]; much of the work developed in these papers is included in [2.44]). His objections to the RV led him on the one hand to suggest that in scientific practice the theory–experiment relation is more sophisticated than what is implicit in the RV and that theories are not confronted with raw experimental data (as we have seen in Sect. 2.1) but with, what has since been dubbed, *models of data*. On the other hand, he proposed that theories be construed as collections of models. The models are possible realizations (in the Tarskian sense) that satisfy sets of statements of theory, and these models, according to Suppes, are entities of the appropriate set-theoretical structure. Both of these insights have been operative in shaping the SV.

Suppes urged against standard formalizations of scientific theories. First, no substantive example of a scientific theory is worked out in a formal calculus, and second the [2.28, p. 57]

“[...] very sketchiness [of standard formalizations] makes it possible to omit both important properties of theories and significant distinctions that may be introduced between different theories.”

He opts for set-theoretical axiomatization as the way by which to overcome the shortcomings of standard formalization. As mentioned by *Gelfert*, Chap. 1, Suppe’s example of a set-theoretical axiomatization is classical particle mechanics (CPM). Three axioms of kinematics and four axioms of dynamics (explicitly stated in Chap. 1 of this volume: *The Ontology of Models*) are articulated by the use of predicates that are defined in terms of set theoretical notions. The structure  $\wp = \langle P, T, s, m, f, g \rangle$  can then be understood to be a model of CPM if and only if it satisfies those axioms [2.41, p. 294]. Such a structure is what logicians would label a (semantic) model of the theory, or more accurately a class of models. In general, the model–theoretic notion of a structure,  $S$ , is that of an entity consisting of a nonempty set of individuals,  $D$ , and a set of relations defined upon the former,  $R$ , that is,  $S = \langle D, R \rangle$ . The set  $D$  specifies the domain of the structure and the set  $R$  specifies the relations that hold between the individuals in  $D$ . (Note that as far as the notion of a structure is concerned, it only matters how many individuals are there and not what they are, and it only matters that the relations in  $R$  hold between such and such individuals of  $D$  and not what the relations are. For more on this point and a detailed analysis of the notion of structure *Frigg* and *Nguyen*, Chap. 3).

Models of data, according to Suppes, are possible realizations of the experimental data. It is to models of data that models of the theory are contrasted. The RV would have it that the theoretical predictions have a *direct analogue* in the observation statements. This view however, is, according to Suppes, a distorting simplification. As we have seen in Sect. 2.1.3, Suppes defends the claim that by the use of theories of experimental design and other auxiliary theories, the raw data are regimented into a structural form that bears a relation to the models of the theory. To structure the data, as we saw earlier, various influencing factors that the theory does not account for, but are known to influence the experimental data, must be accommodated by an appropriate conversion of the data into canonical form. This regimentation results in a finished product that Suppes dubbed *models of data*, which are structures that could reasonably be contrasted to the models of the theory. Suppes’ picture of science as an enterprise of theory construction and empirical testing of theories involves establishing a *hierarchy of models*,

roughly consisting of the general categories of models of the theory and models of the data. Furthermore, since the theory–experiment relation is construed as no more than a comparison (i. e., a mapping) of mathematical structures, he invokes the mathematical notion of *isomorphism* of structure to account for the link between theory and experiment. (An isomorphism between structures  $U$  and  $V$  exists, if there is a function that maps each element of  $U$  onto each element of  $V$ ). Hence, Suppes can be read as urging the thesis that defining the models of the theory and checking for isomorphism with models of data, is a rational reconstruction that does more justice to actual science than the RV does.

The backbone of Suppes’ account is the sharp distinction between models of theory and models of data. In his view, the traditional syntactic account of the relation between theory and evidence, which could be captured by the schema:  $(T\&A) \rightarrow E$  (where,  $T$  stands for theory,  $A$  for auxiliaries,  $E$  for empirical evidence), is replaced by theses (1), (2), and (3) below:

1.  $M_T \subseteq TS$ , where  $M_T$  stands for model of the theory  $TS$  for the theory structure, and  $\subseteq$  for the relation of inclusion
2.  $(A\&E\&D) \mapsto M_D$ , where  $M_D$  stands for model of data,  $A$  for auxiliary theories,  $E$  for theories of experimental design etc.,  $D$  for raw empirical data, and  $\mapsto$  for *... used in the construction of...*
3.  $M_T \approx M_D$ , where  $\approx$  stands for mapping of the elements and relations of one structure onto the other.

$M_T \subseteq TS$  expresses Suppes’ view that by defining a theory structure a class of models is laid down for the representation of physical systems.  $(A\&E\&D) \mapsto M_D$  is meant to show how Suppes distances himself from past conceptions of the theory–experiment relation, by claiming that theories are not directly confronted with raw experimental data (collected from the target physical systems) but rather that the latter are used, together with much of the rest of the scientific inventory, in the construction of data structures,  $M_D$ . These data structures are then contrasted to a theoretical model, and the theory–experiment relation consists in an isomorphism, or more generally in a mapping of a data onto a theoretical structure, that is,  $M_T \approx M_D$ . The proponents of the SV would, I believe, concur to the above three general theses. Furthermore, they would concur with two of the theses’ corollaries: that scientific representation of phenomena can be explicated exclusively by mapping of structures, and that all scientific models constructed within the framework of a particular scientific theory are united under a common mathematical or relational structure. We shall look into these two contentions of

the SV toward the end of this section. For now, let me turn our attention to some putative differences between the various proponents of the SV.

Despite agreeing about focusing on the mathematical structure of theories for giving a unitary account of models, it is not hard to notice in the relevant literature that different proponents of the SV have spelled out the details of thesis (1) in different ways. This is because different proponents of the SV have chosen different mathematical entities with which to characterize theory structure. As we saw above, Suppes chooses set theoretical predicates a choice that seems to be shared by *da Costa* and *French* [2.45, 46]. *Van Fraassen* [2.47] on the other hand prefers state-spaces, and *Suppe* [2.30] uses relational systems.

Let us, by way of example, briefly look into van Fraassen’s state-space approach. The objects of concern of scientific theories are physical systems. Typically, mathematical models represent physical systems that can generally be conceived as admitting of a certain set of states. *State-spaces* are the mathematical spaces the elements of which can be used to represent the states of physical systems. It is a generic notion that refers to what, for example, physicists would label as phase space in classical mechanics or Hilbert space in quantum mechanics. A simple example of a state-space would be that of an  $n$ -particle system. In CPM, the state of each particle at a given time is specified by its position  $\mathbf{q} = (q_x, q_y, q_z)$  and momentum  $\mathbf{p} = (p_x, p_y, p_z)$  vectors. Hence the state-space of an  $n$ -particle system would be a Euclidean  $6n$ -dimensional space, whose points are the  $6n$ -tuples of real numbers

$$\langle q_{1x}, q_{1y}, q_{1z}, \dots, q_{nx}, q_{ny}, q_{nz}, \\ p_{1x}, p_{1y}, p_{1z}, \dots, p_{nx}, p_{ny}, p_{nz} \rangle.$$

More generally, a state-space is the collection of mathematical entities such as, vectors, functions, or numbers, which is used to specify the set of possible states for a particular physical system. A model, in van Fraassen’s characterization of theory structure, is a particular sequence of states of the state-space over time, that is, the state of the modeled physical system evolves over time according to the particular sequence of states admitted by the model. State-spaces unite clusters of models of a theory, and they can be used to single out the class of intended models just as set-theoretical predicates would in Suppes’ approach. The presentation of a scientific theory, according to van Fraassen, consists of a description of a *class of state-space types*. As *van Fraassen* explains [2.47, p. 44]:

“[w]henver certain parameters are left unspecified in the description of a structure, it would be more

accurate to say [...] that we described a structure type.”

The Bohr model of the atom, for example, does not refer to a single structure, but to a structure type. Once the necessary characteristics are specified, it gives rise to a structure for the hydrogen atom, a structure for the helium atom, and so forth.

The different choices of different authors on how theory structure is characterized, however, belong to the realm of personal preference and do not introduce any significant differences on the substance of thesis (1) of the SV, which is that all models of the theory are united under an all-inclusive theory structure. So, irrespective of the particular means used to characterize theory structure, the SV construes models as structures (or structure types) and theories as collections of such structures. Neither have disagreements been voiced regarding thesis (2). On the contrary, there seems to be a consensus among adherents of the SV that models of theory are confronted with models of data and not the direct result of an experimental setup (Not much work has been done to convincingly analyze particular scientific examples and to show the details of the use of *models of data* in science; rather, adherents of the SV repeatedly use the notion with reference to something very general with unclear applications in actual scientific contexts).

### 2.2.1 On the Notion of Model in the SV

An obvious objection to thesis (1) would be that a standard formalization could be used to express the theory and subsequently define the class of semantic models metamathematically, as the class of structures that satisfy the sentences of the theory, despite Suppes suggestion that such a procedure would be unnecessarily complex and tedious.

In fact, proponents of the SV have often encouraged this objection. *Van Fraassen* and *Suppe* are notable examples as the following quotations suggest [2.48, p. 326]:

“There are natural interrelations between the two approaches [i. e., the RV and the SV]: An axiomatic theory may be characterized by the class of interpretations which satisfy it, and an interpretation may be characterized by the set of sentences which it satisfies; though in neither case is the characterization unique. These interrelations [...] would make implausible any claim of philosophical superiority for either approach. But the questions asked and methods used are different, and with respect to fruitfulness and insight they may not be on a par with specific contexts or for special purposes.”

*Suppe* [2.30, p. 82]:

“This suggests that theories be construed as propounded abstract structures serving as models for sets of interpreted sentences that constitute the linguistic formulations. These structures are meta-mathematical models of their linguistic formulations, where the same structure may be the model for a number of different, and possibly nonequivalent, sets of sentences or linguistic formulations of the theory.”

From such remarks, one is justifiably led to believe that propounding a theory as a class of models directly defined, without recourse to its syntax, only aims at convenience in avoiding the hustle of constructing a standard formalization, and at easier adaptability of our reconstruction with common scientific practices. Epigrammatically, the difference – between the SV and the RV – would then be methodological and heuristic. Reasons such as this have led some authors to question the *logical* difference between defining the class of models directly as opposed to metamathematically.

Examples are *Friedman* and *Worrall* who in their separate reviews of *van Fraassen* [2.47] ask whether the class of models that constitutes the theory, according to the proponents of the SV, is to be identified with an elementary class, that is, a class that contains all the models (structures) that satisfy a first-order theory. They both notice that not only does *van Fraassen* and other proponents of the SV offer no reason to oppose such a supposition, but also they even encourage it (as in the above quotations). But if that is the case [2.49, p. 276]:

“[t]hen the completeness theorem immediately yields the equivalence of *van Fraassen*’s account and the traditional syntactic account [i. e., that of the RV].”

In other words [2.50, p. 71]:

“So far as logic is concerned, syntax and semantics go hand-in-hand – to every consistent set of first-order sentences there corresponds a nonempty set of models, and to every normal (elementary) set of models there corresponds a consistent set of first-order sentences.”

If we assume (following *Friedman* and *Worrall*) that the proponents of the SV are referring to the elementary class of models then the preceding argument is sound. The SV, in agreement with the logical positivists, retains formal methods as the primary tool for philosophical analysis of science. The only new elements of its own would be the suggestions that first it is more convenient that rather than developing these methods

using proof–theory we should instead use formal semantics (model–theory), and second we should assign to models (i. e., the semantic interpretations of sets of sentences) a representational capacity.

Van Fraassen, however, resists the construal of the class of models of the SV with an elementary class (See *van Fraassen* [2.51, pp. 301–303] and his [2.52]). Let me rehearse his argument. The SV claims that to present a theory is to define a class  $M$  of models. This is the class of structures the theory makes available for modeling its domain. For most scientific theories, the real number continuum would be included in this class. Now his argument goes, if we are able to formalize what is meant to be conveyed by  $M$  in some appropriate language, then we will be left with a class  $N$  of models of the language, that is, the class of models in which the axioms and theorems of the language are satisfied. Our hope is that every structure in  $M$  occurs in  $N$ . However, the real number continuum is infinite and [2.52, p. 120]:

“[t]here is no elementary class of models of a denumerable first-order language each of which includes the real numbers. As soon as we go from mathematics to metamathematics, we reach a level of formalization where many mathematical distinctions cannot be captured.”

Furthermore, “[t]he Löwenheim–Skolem theorems [...] tell us [...] that  $N$  contains many structures not isomorphic to any member of  $M$ ” [2.51, p. 302]. Van Fraassen relies, here, on the following reasoning: The Löwenheim–Skolem theorem tells us that all satisfiable first-order theories that admit infinite models will have models of all different infinite cardinalities. Now models of different cardinality are nonisomorphic. Consequently, every theory that makes use of the real number continuum will have models that are not isomorphic to the intended models (i. e., nonstandard interpretations) but which satisfy the axioms of the theory. So van Fraassen is suggesting that  $M$  is the intended class of models, and since the limitative meta-theorems tell us that it cannot be uniquely determined by any set of first-order sentences we can only define it directly. Here is his concluding remark [2.51, p. 302]:

“The set  $N$  contains [...] [an] image  $M^*$  of  $M$ , namely, the set of those members of  $N$  which consist of structures in  $M$  accompanied by interpretations therein of the syntax. But, moreover, [...]  $M^*$  is not an elementary class.”

Evidently, van Fraassen’s argument aims to establish that the directly defined class of models is not an elementary class. It is hard, however, to see that defining the models of the theory directly without resort to formal syntax yields only the intended models of theory

(i. e., excludes all nonstandard models), despite the possibility that one could see the prospect of the SV being heuristically superior to the RV. (Of course, we must not forget that this superiority would not necessarily be the result of thesis (1) of the SV, but it could be the result of its consequence of putting particular emphasis on the significance of scientific models that, as noted earlier, does not logically entail thesis (1)).

Let us, for the sake of argument, ignore the Friedman–Worrall argument. Now, according to the SV, models of theory have a dual role. On the one hand, they are devices by which phenomena are represented, and on the other, they are structures that would satisfy a formal calculus were the theory formalized. The SV requires this dual role. First because the representational role of models is the way by which the SV accounts for scientific representation without the use of language; and second because the role of interpreting a set of axioms ensures that a unitary account of models is given. Now, *Thompson-Jones* [2.53] notices that the notion of model implicit in the SV is either that of an interpretation of a set of sentences or a mathematical structure (the disjunction is of course inclusive). He analyzes the two possible notions and argues that the SV becomes more tenable if the notion of model is only understood as that of a mathematical structure that functions as a representation device. If that were the case then the adherents of the SV could possibly claim that defining the class of structures directly indeed results in something distinct from the metamathematical models of a formal syntax. *Thompson-Jones*’ suggestion, however, would give rise to new objections. Here is one. It would give rise to the following question: How could a theory be identified with a class of models (i. e., mathematical structures united under an all-inclusive theory structure) if the members of such a class do not attain membership in the class because they are interpretations of the same set of theory axioms? In other words, the proponents of the SV would have to explain what it is that *unites* the mathematical models other than the satisfaction relation they have to the theoretical axioms. To my knowledge, proponents of the SV have not offered an answer to this question. If *Thompson-Jones*’ suggestion did indeed offer a plausible way to overcome the Friedman–Worrall argument then the SV would have to abandon the quest of giving a unitary account of models. Given the dual aim of the SV, namely to give a unitary account of models and to account for scientific representation by means of structural relations, it seems that the legitimate notion of model integral to this view must have these two-hard to reconcile-roles; namely, to function both as an interpretation of sets of sentences and as a representation of phenomena. (Notice that this dual function of models is

an aspect of all versions of the SV, independent of how one chooses to characterize theory structure and of how one chooses to interpret that structure).

### 2.2.2 The Difference Between Various Versions of the SV

The main difference among the various versions of the SV relates to two intertwined issues that relate to thesis (3), namely how the theory structure is construed and how the theory–experiment mapping relation is construed. To a first approximation we could divide the different versions of the SV, from the perspective of these two issues, into two sorts. Those in which particular emphasis is given to the presence of abstraction and idealization in scientific theorizing for explicating the theory–experiment (or model–experiment) relation, and those in which the significance of this nature of scientific theorizing is underrated.

#### Idealization and Abstraction Underrated

*Van Fraassen* (Suppes most probably could be placed in this group too), for example, seems to be a clear case of this sort. Here is how he encapsulates his conception of scientific theories and of how theory relates to experiment [2.47, p. 64]:

“To present a theory is to specify a family of structures, its *models*; and secondly, to specify certain parts of those *models* (*the empirical substructures*) as candidates for the direct representation of observable phenomena. The structures which can be described in experimental and measurement reports we can call *appearances*: The theory is empirically adequate if it has some model such that all appearances are isomorphic to empirical substructures of that model.”

Appearances (which is van Fraassen’s term for *models of data*) are relational structures of measurements of observable aspects of the target physical system, for example, relative distances and velocities. For example, in the Newtonian description of the solar system, as *van Fraassen* points out, the relative motions of the planets “[...] form relational structures defined by measuring relative distances, time intervals, and angles of separation” [2.47, p. 45]. Within the theoretical model for this physical system, “[...] we can define structures that are meant to be exact reflections of those appearances [...]” [2.47, p. 45]. Van Fraassen calls these *empirical substructures*. When a theory structure is defined each of its models, which are candidates for the representation of phenomena, includes empirical substructures. So within representational models we could specify a division between observable/nonobservable features

(albeit this division is not drawn in linguistic terms), and the empirical substructures of such models are assumed to be isomorphic to the observable aspects of the physical system. In other words, the theory structure is interpreted as having distinctly divided observable and nonobservable features, and the theory–experiment relation is interpreted as being an isomorphic relation between the data model and the observable parts of the theoretical model. Now, the state-space is a class of models, it thus includes – for CPM – many models in which the world is a Newtonian mechanical system. In fact, it seems that the state-space includes (unites) all logically possible models, as the following dictum suggests ([2.52, p. 111], [2.54, p. 226]):

“In one such model, nothing except the solar system exists at all; in another the fixed stars also exist, and in a third, the solar system exists and dolphins are its only rational inhabitants.”

According to van Fraassen, the theory is empirically adequate if we can find a model of the theory in which we can specify empirical substructures that are isomorphic to the data model. The particular view of scientific representation that resides within this idea is this: *A model represents its target if and only if it is isomorphic to a data model constructed from measurements of the target*. Not much else seems to matter for a representation relation to hold but the *isomorphism condition*. Many would argue, however, that such a condition for the representation relation is too strong to explicate how actual scientific models relate to experimental results and would object to this view on the ground that for isomorphism to occur it would require that target physical systems occur under highly idealized conditions or in isolated circumstances. (Admittedly, it would not be such a strong requirement for models that would only describe observable aspects of the world. In such cases isomorphism could be achieved, but at the expense of the model’s epistemic significance. I do not think, for instance, that such models would be of much value to a science like Physics as, more often than not, they would be useless in predicting the future behavior of their targets).

#### Idealization and Abstraction Highlighted

In the second camp of the SV, we encounter several varieties. One of these is *Suppe* [2.30], who interprets theory structure and the theory–experiment relation as follows. Theories characterize particular classes of target systems. However, target systems are not characterized in their full complexity, as already mentioned in Sect. 2.1.4. Instead, Suppe’s understanding is that certain parameters are abstracted and employed in this characterization. In the case of CPM, these are the posi-

tion and momentum vectors. These two parameters are abstracted from all other characteristics that target systems may possess. Furthermore, once the factors, which are assumed to influence the class of target systems in the theory's intended scope, have been abstracted the characterization of physical systems (as mentioned in Sect. 2.1.4, physical systems in Suppe's terminology refer to the abstract entities that models of the theory represent and not to the actual target systems) still does not *fully* account for target systems. Physical systems are not concerned with the actual values of the parameters the particulars possess, for example, actual velocities, but with the values of these parameters under certain conditions that obtain only within the physical system itself. Thus in CPM, where the behavior of dimensionless point-masses are studied in isolation from outside interactions, physical systems characterize this behavior only by reference to the positions and momenta of the point-masses at given times.

An example can serve to demonstrate Suppe's idea in bit more detail. The linear harmonic oscillator, that is, a *mathematical instrument*, is expressed by the following equation of motion  $\ddot{x} + (k/m)x = 0$ , which is the result of applying Newton's second law to a linear restoring force. The mathematical model is interpreted (and thus characterizes a *physical system*) as follows: Periodic oscillations are assumed to take place with respect to time,  $x$  is the displacement of an oscillating mass-point, and  $k$  and  $m$  are constant coefficients that may be replaced by others. When the mathematical parameters in the above equation are linked to features of a specific object, the equation can be used to model for instance the torsion pendulum, that is, an elastic rod connected to a disk that oscillates about an equilibrium position. This sort of linking of mathematical terms to features of objects could be understood to be a manifestation of what Giere calls identification. Giere introduces a useful distinction between *interpretation* and *identification* [2.55, p. 75]:

“[...] [Interpretation] is the linking of the mathematical symbols with *general terms*, or concepts, such as *position*[...] [Identification] is the linking of a mathematical symbol with some feature of a *specific object*, such as *the position of the moon*.”

In the torsion pendulum model,  $x$  is identified with the angle of twist,  $k$  with the torsion constant, and  $m$  with the moment of inertia. By linking the mathematical symbols of a model to features of a target system we can reasonably assume, according to Suppe, that the model could be associated with an actual system of the world; the model characterizes, as Suppe would say in his own jargon, “a causally possible physical system.”

However, even when a certain mathematical product of theory is identified with a causally possible physical system, we still know that typically the situation described by the physical system does not obtain. The actual torsion pendulum apparatus is subject to a number of different factors (or may have a number of different characteristics) that may or may not influence the process of oscillation. Some influencing factors are the amplitude of the angle of oscillation, the mass distribution of the rod and disc, the nonuniformity of the gravitational field of the earth, the buoyancy of the rod and disc, the resistance of the air and the stirring up of the air due to the oscillations. In modeling the torsion pendulum by means of the linear harmonic oscillator the physical system is abstracted from factors assumed to influence the oscillations in the same manner as from those assumed not to. Therefore, the replicating relation between the physical system,  $P$ , and the target system,  $S$ , which Suppe urges cannot be understood as one of identity or isomorphism. *Suppe* is explicit about this [2.30, p. 94]:

“The attributes in  $P$  determine a sequence of states over time and thus indicate a possible behavior of  $S$  [...] Accordingly,  $P$  is a kind of *replica* of  $S$ ; however, it need not replicate  $S$  in any straight-forward manner. For the state of  $P$  at  $t$  does not indicate what attributes the particulars in  $S$  possess at  $t$ ; rather, it indicates what attributes they *would have* at  $t$  were the abstracted parameters the only ones influencing the behavior of  $S$  and were certain idealized conditions met. In order to see how  $P$  replicates  $S$  we need to investigate these abstractive and idealizing conditions holding between them.”

In summary, the replicating relation is counterfactual: If the conditions assumed to hold for the description of the physical system were to hold for the target system, then the target system would behave in the way described by the physical system. The behavior of actual target systems, however, may be subject to other unselected parameters or other conditions, for which the theory does not account.

The divergence of Suppe's view from that of van Fraassen is one based primarily on the representation relation of theory to phenomena. Suppe understands the theory structure as being a highly abstract and idealized representation of the complexities of the real world. Van Fraassen disregards this because he is concerned with the observable aspects of theories and assumes that these can, to a high degree of accuracy, be captured by experiments. Thus van Fraassen regards theories as containing empirical substructures that stand in isomorphic relations to the observable aspects of the world. Suppe's

understanding of theory structure, however, points to a significant drawback present in van Fraassen's view: How can isomorphism obtain between a data model and an empirical substructure of the model, given that the model is abstract and idealized? Suppe's difference with van Fraassen's view of the representation relation and of the epistemic inferences that can be drawn from it is this, if indeed it is the case that isomorphism obtains between a data model and an empirical substructure, then it is so for either of two reasons: (1) the experiment is highly idealized, or (2) the data model is converted to what the measurements *would have been* if the influences that are not accounted by the theory did not have any effect on the experimental setup. This is a significantly different claim from what van Fraassen would urge, to wit that the world or some part of it is isomorphic to the model. According to Suppe's understanding of theory structure, no part of the world is or can be isomorphic to a model of the theory, because abstraction and idealization are involved in scientific theorizing.

*Geire* [2.55] is another example of a version of the SV that places the emphasis on abstraction and idealization. Following Suppes and van Fraassen, Geire understands theories as classes of models. He does not have any special preference about the mathematical entities by which theory structure is characterized, but he is interested in looking at the characteristics of actual science and how these could be captured by the SV. This leads him to a similar claim as Suppe. He claims that although he does not see any logical reason why a real target system could not be isomorphic to a model, nevertheless for the examples of models found in mechanics texts, typically, no claim of isomorphism is made, indeed "[...] the texts often explicitly note respects in which the model fails to be isomorphic to the real system" [2.55, p. 80]. He attributes this to the abstract and idealized nature of models of the theory. His solution is to substitute the strict criterion of isomorphism, as a way by which to explicate the theory–experiment relation, with that of similarity in relevant respects and degrees between the model and its target.

Finally, there is another example of a version of the SV that also gives attention to idealization and abstraction, namely the version advocated by *da Costa* and *French* in [2.45, 46, 56]. They do this indirectly by interpreting theories as partial structures, that is, structures consisting of a domain of individuals and a set of partial relations defined on the domain, where a partial relation is one that is not defined for all the  $n$ -tuples of individuals of the domain for which it presumably holds. If models of theory are interpreted in this manner and if it is assumed that models of data are also partial structures, then the theory–experiment relation

is explicated by *da Costa* and *French* [2.46] as a partial isomorphism. A partial isomorphism between two partial structures  $U$  and  $V$  exists when a partial substructure of  $U$  is isomorphic to a partial substructure of  $V$ . In other words, partial isomorphism exists when some elements of the set of relations in  $U$  are mapped onto elements of the set of relations in  $V$ . If a model of theory is partially isomorphic to a data model then, *da Costa* and *French* claim, the model is partially true. The notion of partial truth is meant to convey a pragmatic notion of truth, which plausibly could avoid the problems of correspondence or complete truth, and capture the commonplace idea that theories (or models) are incomplete or imperfect or abstract or idealized descriptions of target systems.

In conclusion, if we could speak of *different* versions of the SV and not just different formulations of the same idea, if, in other words, the proposed versions of the semantic conception of theories can be differentiated in any significant way amongst them, it is on the basis of how thesis (3) is conceived: There are those that understand the representation relation,  $M_T \approx M_D$ , as a strict isomorphic relation, and those that construe it more liberally, for example, as a similarity relation. In particular, van Fraassen prefers an isomorphic relation between theory and experiment, whereas Suppe and others understand theories as being abstract and idealized representations of phenomena. It would seem therefore that particular criticisms would not necessarily target both versions. This has not been the case however, as we shall examine in the next two subsections. Critics of the SV have either targeted theses (1) and (2) and the unitary account of models implicit in the SV, or thesis (3) and the representation relation however the latter is conceived. The arguments against the unitary account of scientific models, which obviously aim indiscriminately at all versions of the SV, will be explored in Sect. 2.2.4. The arguments against the nature of the representation relation implied by the SV, which shall be explored in Sect. 2.2.3, if properly adapted affect both versions of the SV.

### 2.2.3 Scientific Representation Does not Reduce to a Mapping of Structures

*Suarez* [2.57] presents five arguments against the idea that scientific representation can be explicated by appealing to a structural relation (like isomorphism or similarity) that may hold between the representational device and the represented target. (*Suarez* [2.57] also develops his arguments for other suggested interpretations of theses (3), such as partial isomorphism). These arguments, which are summarized below, imply that

the representational capacity of scientific models cannot derive from having a structural relation with its target. Suarez's first argument is that in science many disparate things act as representational devices, for example, a mathematical equation, or a Feynman diagram, or an architect's model of a building, or the double helix macro-model of the DNA molecule. Neither isomorphism nor similarity can be applied to such disparate representational devices in order to explicate their representational function. A similar point is also made by *Downes* [2.58], who by also exploring some examples of scientific models, argues that models in science relate to their target systems in various ways, and that attempts to explicate this relation by appeal to isomorphism or similarity does little to serve the purpose of understanding the theory–experiment relation.

The second argument concerns the logical properties of representation vis-a-vis those of isomorphism and similarity. Suarez explains that representation is nonsymmetric, nonreflexive and nontransitive. If scientific representation is a type of representation then any attempt to explicate scientific representation cannot imply different logical features from representation. But appeal to a structural relation does not accomplish this, because “[...] similarity is reflexive and symmetric, and isomorphism is reflexive, symmetric and transitive” [2.55, p. 233].

His third argument is that any explication of representation must allow for misrepresentation or inaccurate representation. Misrepresentation, he explains, occurs either when the target of a representation is mistaken or when a representation is inaccurate because it is either incomplete or idealized. Neither isomorphism nor similarity allows for the first kind of misrepresentation and isomorphism does not allow for the second kind. Although, similarity does account for the second kind of representation, Suarez argues, it does so in a restrictive sense. That is, if we assume that an incomplete representation is given according to theory *X* then similarity does account for misrepresentation. However, if a complete representation were given according to theory *X* (i. e., if we have similarity in all relevant respects that *X* dictates) but the predictions of this representation still diverge from measurements of the values of the target's attributes then similarity does not account for this kind of misrepresentation.

The fourth argument is that neither isomorphism nor similarity is necessary for representation. Our intuitions about the notion of representation allow us to accept the representational device derived from theory *X* as a *representation* of its target, even though we may know that isomorphism or similarity does not obtain because, for example, an alternative theory *Y* not only gives us better predictions about the target but

also tells us why *X* fails to produce representational devices that are isomorphic or similar to their targets. A different argument but with the same conclusion is given by *Portides* [2.59], who argues that isomorphism, or other forms of structural mapping, is not necessary for representation because it is possible to explicate the representational function of some successful quantum mechanical models, which are not isomorphic to their targets. Suarez's final argument is that neither isomorphism nor similarity is sufficient for representation. In other words, even though there may not be a representation relation between *A* and *B*, *A* and *B* may, however, be isomorphic or similar.

Aiming at the same feature of the SV as Suarez, *Frigg* [2.60] reiterates some of the arguments above and gives further reasons to fortify them, but he also presents two more arguments that undermine the notion of representation as dictated by thesis (3) of the SV. Employed in his first argument is a particular notion of abstractness of concepts advocated by *Cartwright* [2.61]. A concept is considered abstract in relation to a set of more concrete concepts if for the former to apply it is necessary that one of its concrete instances apply. One of *Frigg's* intuitive examples is that the concept of traveling is more abstract than the concept of sitting in a moving train. So according to this sense of *abstractness* the concept of traveling applies whenever one is sitting in a moving train and that the abstract concept does not apply if one is not performing some action that belongs to the set of concrete instances of traveling. *Frigg* then claims, “[...] that possessing a structure is abstract in exactly this sense and it therefore does not apply without some more concrete concepts applying as well” [2.60, p. 55]. He defends this claim with the following argument. Since to have a structure means to consist of a set of individuals which enter into some relations, then it follows that whenever the concept of possessing a structure applies to *S* the concept of being an individual applies to members of a set of *S* and the concept of being in a relation applies to some parts of that set. The concepts of being an individual and being in a relation are abstract in the above sense. For example, given the proper context, for *being an individual* to apply, *occupying a certain space-time region* has to apply. Similarly, given the proper context, for *being in a relation* to apply it must be the case that *being greater than* applies. Therefore, both being an individual and being in a relation are abstract. Thus *Frigg* concludes, *possessing a structure* is abstract; hence for it to apply, it must be the case that a concrete description of the target applies. Because, the claim that the representation relation can be construed as an isomorphism (or similarity) of structures presupposes that the target possesses a structure, *Frigg* concludes that such a claim “[...] pre-

supposes that there is a more concrete description that is true of the [target] system” [2.60, p. 56]. This argument shows that to reduce the representation relation to a mapping of structures the proponents of the SV need to invoke nonstructural elements into their account of representation, so pure and simple reduction fails.

Frigg’s second argument, as he states, is inductive. He examines several examples of systems from different contexts in order to support the claim that a target system does not have a unique structure. For a system to have a structure it must be made of individuals and relations, but slicing up the physical systems of the world into individuals and relations is dependent on how we conceptualize the world. The world itself does not provide us with a unique slicing. “Because different conceptualizations may result in different structures there is no such thing as the one and only structure of a system” [2.60, p. 57]. One way that Frigg’s argument could be read is this: Thesis (2) of the SV implies that the measurements of an experiment are structured to form a data model. But, according to Frigg, this structuring is not unique. So the claim of thesis (3), that there is, for example, an isomorphism between a theoretical model and a data model is not epistemically informative since there may be numerous other structures that could be constructed from the data that are not isomorphic to the theoretical model.

### 2.2.4 A Unitary Account of Models Does not Illuminate Scientific Modeling Practices

The second group of criticisms against the SV consists of several heterogeneous arguments stemming from different directions and treating a variety of features and functions of models. Despite this heterogeneity, they can be grouped together because they all indirectly undermine the idea that the unitary account of scientific models given by employing a set theoretical (or other mathematical) characterization of theory structure is adequate for understanding the notion of representational model and the model–experiment relation. This challenge to the SV is indirect because the main purpose of these arguments is to illuminate particular features of actual scientific models. In highlighting these features, these arguments illustrate that actual representational models in science are constructed in ways that are incompatible with the SV, they function in ways that the SV does not adequately account for and they represent in ways that is incompatible with the SV’s account of representation; furthermore, they indicate that models in science are complex entities that cannot be thoroughly understood by unitary accounts such as set-theoretical inclusion. In other words, a conse-

quence of most of these arguments is that the unitary account of models that the SV provides through thesis (1) that all models are constitutive parts of theory structure, obscures the particular features that representational scientific models demonstrate.

One such example is *Morrison* [2.62], who argues that models are partially autonomous from the theories that may be responsible for instigating their construction. This partial autonomy is something that may derive from the way they function but also from the way they are constructed. She discusses Prandtl’s hydrodynamic model of the boundary layer in order to mark out that the inability of theory to provide an explanation of the phenomenon of fluid flow did not hinder scientific modeling. Prandtl constructed the model with little reliance on high-level theory and with a conceptual apparatus that was partially independent from the conceptual resources of theory. This partial independence in construction, according to Morrison, gives rise to functional independence and renders the model partially autonomous from theory. Furthermore, *Morrison* raises another issue (see [2.62], as well as [2.63]); that theories, and hence theoretical models as direct conceptual descendants of theory, are highly abstract and idealized descriptions of phenomena, and therefore they represent only the general features of phenomena and do not explain the specific mechanisms at work in physical systems. In contrast, actual representational scientific models – that she construes as partially autonomous mediators between theories and phenomena – are constructed in ways that allow them to function as explanations of the specific mechanisms and thus function as sources of knowledge about corresponding target systems and their constitutive parts. (As she makes clear in *Morrison* [2.64], to regard a model as partially independent from theory does not mean that theory plays an unimportant role in its construction). This argument, in which representational capacity is correlated to the explanatory power of models, is meant to achieve two goals. Firstly, to offer a way by which to go beyond the narrow understanding of scientific representation as a mapping relation of structure, and second, to offer a general way to understand the representational function of both kinds of models that physicists call theory-driven and phenomenological (In *Portides* [2.65] a more detailed contrast between Morrison’s view of the representation relation and that of the SV is offered). *Cartwright* et al. [2.66] and *Portides* [2.67] have also argued that by focusing exclusively on theory-driven models and the mapping relation criterion, the SV obscures the representational function of phenomenological models and also many aspects of scientific theorizing that are the result of phenomenological methods.

It is noteworthy that the unitary account that the SV offers may be applicable to theory-driven models. Whether that is helpful or not is debatable. However, more often than not representation in science is achieved by the use of phenomenological models or phenomenological elements incorporated into theory-driven models. One aspect of Morrison's argument is that if we are not to dismiss the representational capacity of such models we should give up unitary accounts of models. Cartwright makes a similar point but her approach to the same problem is from another angle.

*Cartwright* [2.61, 68] claims that theories are highly abstract and thus do not and cannot represent what happens in actual situations. Cartwright's observation seems similar to versions of the SV such as Suppe's, however her approach is much more robust. To claim that theories represent what happens in actual situations, she argues, is to overlook that the concepts used in them – such as, *force functions* and *Hamiltonians* – are abstract. Such abstract concepts could only apply to the phenomena whenever more concrete descriptions (as those present in models) can stand-in for them and for this to happen the bridge principles of theory must mediate. Hence the abstract terms of theory apply to actual situations via bridge principles, and this makes bridge principles an operative aspect of theory-application to phenomena. It is only when bridge principles sanction the use of theoretical models that we are led to the construction of a model – with a relatively close relation to theory – that represents the target system. But Cartwright observes that there are only a small number of such theoretical models that can be used successfully to construct representations of physical systems and this is because there are only a handful of theory bridge principles. In most other cases, where no bridge principles exist that enable the use of a theoretical model, concrete descriptions of phenomena are achieved by constructing phenomenological models. Phenomenological models are constructed with minimal aid from theory, and surely there is no deductive (or structural) relation between them and theory. The relation between the two should be sought in the nature of the abstract–concrete distinction between scientific concepts, according to Cartwright. Models in science, whether constructed phenomenologically or by the use of available bridge principles, encompass descriptions that are in some way independent from theory because they are made up of more concrete conceptual ingredients. A weak reading of this argument is that the SV could be a plausible suggestion for understanding the structure of scientific theories for use in foundational work. But in the context of utilizing the theory to construct representations of phenomena, focusing on the structure of theory does not illuminate

much because it is not sufficient as to account for the abstract–concrete distinction that exists between theory and models. A stronger reading of the argument is that the structure of theories is completely irrelevant to how theories represent the world, because they just do not represent it at all. Only models represent pieces of the world and they are partially independent from theory because they are constituted by concrete concepts that apply only to particular physical systems.

Other essays in the volume by *Morgan* and *Morrison* [2.69] discuss different aspects of partial independence of models from theory. Here are two brief examples that aim to show the partial independence of model construction from theory. *Suarez* [2.70] explains how simplifications and approximations that are introduced into representational models (such as the London brothers model of superconductivity) are decided independently of theory and of theoretical requirements. This process gives rise to a model that mediates in the sense that the model itself is the means by which corrections are established that may be incorporated into theory in order to facilitate its applications. But even in cases of models that are strongly linked to theory such as the MIT-bag model of quark confinement, *Hartmann* [2.71] argues, many parts of the model are not motivated by theory but by an accompanying *story* about quarks. From the empirical fact that quarks were not observed physicists were eventually led to the hypothesis that quarks are confined. But confinement is not something that follows from theory. Nevertheless, via the proper amalgam of theory and *story* about quarks the MIT-bag model was constructed to account for quark confinement.

I mentioned earlier in Sect. 2.2.2 that *Giere* [2.55] is also an advocate of the SV. However, his later writings [2.72, 73] suggest that he makes a gradual shift from his earlier conception of representational models in science to a view that neighbors that of Morrison and Cartwright. Even in *Giere* [2.55] the reader notices that he, unlike most other advocates of the SV, is less concerned with the attempt to give a unitary account of models and more concerned with the importance of models in actual scientific practices. But in [2.72] and [2.73] this becomes more explicit. *Giere* [2.55] espouses the idea that the laws of a theory are definitional devices of theoretical models. This view is compatible with the use of scientific laws in the SV. However, in *Giere* [2.72, p. 94] he suggests that scientific laws “[...] should be understood as rules devised by humans to be used in building models to represent specific aspects of the natural world.” It is patent that operating as rules for building models is quite a different thing from understanding laws to be the means by which models are defined. The latter view is in line with the three

theses of the SV; the former however is only in line with the view that models are important in scientific theorizing. Moreover, in *Giere* [2.73] he makes a more radical step in distinguishing between the abstract models (which he calls *abstract objects*) defined by the laws and those models used by scientists to represent physical systems (which he calls *representational models*). The latter [2.73, p. 63]

“[...] are designed for use in representing aspects of the world. The abstract objects defined by scientific principles [i. e., scientific laws] are, on my view, not intended directly to represent the world.”

Giere points to the important difference between the SV and its critics. The SV considers the models that the theory directly delivers representations of target systems of the world. Its critics do not think that; they argue that many successful representational models are constructed by a variety of conceptual ingredients and thus have a degree of autonomy from theory. But if each representational model is partially autonomous from the theory that prompted its construction then a unitary account of representational models does not seem to be much enlightening in enhancing our understanding of why models are so important in scientific theorizing.

### 2.2.5 General Remark on the Semantic View

Just like its predecessor the SV employs formal methods for the philosophical analysis of scientific theories. In the SV, models of the theory are directly defined by the laws of the theory, and are thus united under a common mathematical structure. Of course, mathematical equations satisfy a structure, no one disputes that mathematically formulated theories can be presented in terms of mathematical structures. Nonetheless, keen to overcome the philosophical problems associated with the RV and its focus on the syntactic elements of theories, the proponents of the SV take the idea of presenting theories structurally one step further. They claim that the SV not only offers a canonical structural formulation for theories, into which any theory can be given an equivalent reformulation (an idea that, no doubt, is useful for the philosophy of mathematics), but they also contend that a scientific theory represents phenomena *because* this structure can be linked to empirical data. To defend this assertion, the proponents of the SV assume that in science there is a sharp distinction between models of theory and models of data and argue

that scientific representation is no more than a mapping relation between these two kinds of structures. As we have seen, serious arguments against the idea that representation can be reduced to structural mapping have surfaced; and these arguments counter the SV independently of how the details of the mapping relation is construed.

Furthermore, the SV implies that by defining a theory structure an indefinite number of models that are thought to be antecedently available for modeling the theory's domain are laid down. Neither this position has gone unnoticed. Critics of the SV claim that this idea does not do justice to actual science because it undervalues the complexities involved in actual scientific model construction and the variety of functions that models have in science, but more importantly because it obscures the features of representational models that distinguish them from the models that are direct descendants of theory.

I claimed that the SV employs a notion of model that has two functions – interpretation and representation. In addition, it requires models that have this dual role to be united under a common structure. It is hard to reconcile these two ideas and do justice to actual science. The devices by which the theoretical models are defined, according to the SV, are the laws of the theory. Hence the laws of the theory provide the constraints that determine the structure of these models. Now, it is not hard to see that models viewed as interpretations are indeed united under a common structure determined by the laws of the theory. What is problematic, however, is that the SV assumes that models that are interpretations also function as representations and this means that models functioning as representations can be united under a common structure. The truth value of the conjunction *models are interpretations and representations* is certainly not a trivial issue. When scientists construct representational models, they continuously impose constraints that alter their initial structure. The departure of the resulting constructs from the initial structure is such that it is no longer easily justified to think of them all as united under a common theory structure. Indeed, in many scientific cases this departure of individual representational models is such that they end up having features that may be incompatible with other models that are also instigated by the same theory. These observations lead to the thought that the model-theory and the model-experiment relations may in the end be too complex for our formal tools to capture.

# Models and Representation

## 3. Models and Representation

Roman Frigg, James Nguyen

Models are of central importance in many scientific contexts. We study models and thereby discover features of the phenomena they stand for. For this to be possible models must be representations: they can instruct us about the nature of reality only if they represent the selected parts or aspects of the world we investigate. This raises an important question: In virtue of what do scientific models represent their target systems? In this chapter we first disentangle five separate questions associated with scientific representation and offer five conditions of adequacy that any successful answer to these questions must meet. We then review the main contemporary accounts of scientific representation – similarity, isomorphism, inferentialist, and fictionalist accounts – through the lens of these questions. We discuss each of their attributes and highlight the problems they face. We finally outline our own preferred account, and suggest that it provides the most promising way of addressing the questions raised at the beginning of the chapter.

Models play a central role in contemporary science. Scientists construct models of atoms, elementary particles, polymers, populations, genetic trees, economies, rational decisions, airplanes, earthquakes, forest fires, irrigation systems, and the world's climate – there is hardly a domain of inquiry without models. Models are essential for the acquisition and organization of scientific knowledge. We often study a model to discover features of the thing it stands for. How does this work? The answer is that a model can instruct us about the

nature of its subject matter if it represents the selected part or aspect of the world that we investigate. So if we want to understand how models allow us to learn about the world, we have to come to understand how they represent.

The problem of representation has generated a sizeable literature, which has been growing fast in particular over the last decade. The aim of this chapter is to review this body of work and assess the strengths and weaknesses of the different proposals. This enterprise

faces an immediate difficulty: Even a cursory look at the literature on scientific representation quickly reveals that there is no such thing as *the* problem of scientific representation. In fact, we find a cluster of interrelated problems. In Sect. 3.1 we try to untangle this web and get clear on what the problems are and on how they relate to one another (for a historical introduction to the issue, see [3.1]). The result of this effort is a list with five problems and five conditions of adequacy, which provides the analytical lens through which we look at the different accounts. In Sect. 3.2 we discuss Griceanism and *stipulative fiat*. In Sect. 3.3 we look at the time-honored similarity approach, and in Sect. 3.4 we examine its modern-day cousin, the structuralist approach. In Sect. 3.5 we turn to inferentialism, a more recent family of conceptions. In Sect. 3.6 we discuss the fiction view of models, and in Sect. 3.7 we consider the conception of representation-as.

Before delving into the discussion, a number of caveats are in order. The first is that our discussion in no way presupposes that models are the sole unit of scientific representation, or that all scientific representation is model-based. Various types of images have their place in science, and so do graphs, diagrams, and drawings (*Perini* [3.2–4] and *Elkins* [3.5] provide discussions of visual representation in the sciences). In some contexts scientists use what *Warmbröd* [3.6] calls *natural forms of representation* and what *Peirce* [3.7] would have classified as indices: tree rings, fingerprints, disease symptoms. These are related to thermometer readings and litmus paper indications, which are commonly classified as measurements. Measurements also provide representations of processes in nature, sometimes together with the subsequent condensation of measurement results in the form of charts, curves, tables and the like (*Tal* [3.8] provides a discussion of measurement). And, last but not least, many would hold that theories represent too. At this point the vexing problem of the nature of theories and the relation between theories and models rears its head again. We refer the reader to *Portides'* contribution to this volume, Chap. 2, for a discussion of this issue. Whether these other forms of scientific representation have features in common with how models represent is an interesting question, but this is a problem for another day. Our aim here is a more modest one: to understand how models represent. To make the scope of our investigation explicit we call the kind of representation we are interested in *model-representation*.

The second point to emphasize is that our discussion is not premised on the claim that *all* models are representational; nor does it assume that representation is the only (or even primary) function of models. It has been emphasized variously that models

perform a number of functions other than representation. To mention but few: *Knuuttila* [3.9, 10] points out that the epistemic value of models is not limited to their representational function and develops an account that views models as epistemic artifacts that allow us to gather knowledge in diverse ways; *Morgan* and *Morrison* [3.11] emphasize the role models play in the mediation between theories and the world; *Hartmann* [3.12] discusses models as tools for theory construction; *Peschard* [3.13] investigates the way in which models may be used to construct other models and generate new target systems; and *Bokulich* [3.14] and *Kennedy* [3.15] present nonrepresentational accounts of model explanation (*Woody* [3.16] and *Reiss* [3.17] provide general discussions of the relation between representation and explanation). Not only do we not see projects like these as being in conflict with a view that sees some models as representational; we think that the approaches are in fact complementary.

Finally, there is a popular myth according to which a representation is a mirror image, a copy, or an imitation of the thing it represents. In this view representation is ipso facto realistic representation. This is a mistake. Representations can be realistic, but they need not. And representations certainly need not be copies of the real thing. This, we take it, is the moral of the satire about the cartographers who produce maps as large as the country itself only to see them abandoned. The story has been told by Lewis Carroll in *Sylvie and Bruno* and Jorge Luis Borges in *On Exactitude in Science*. Throughout this review we encounter positions that make room for nonrealistic representation and hence testify to the fact that representation is a much broader notion than mirroring.

There is, however, a sense in which we presuppose a minimal form of realism. Throughout the discussion we assume that target systems exist independently of human observers, and that they are how they are irrespective of what anybody thinks about them. That is, we assume that the targets of representation exist independently of the representation. This is a presupposition not everybody would share. Constructivists (and other kinds of metaphysical antirealists) assume that there is no phenomenon independent of its representation: representations constitute the phenomena they represent (this view is expounded for instance by *Lynch* and *Wooglar* [3.18]; *Giere* [3.19] offers a critical discussion). It goes without saying that an assessment of the constructivist program is beyond the scope of this review. It is worth observing, though, that many of the discussions to follow are by no means pointless from a constructivist perspective. What in the realist idiom is conceptualized as the representation of an object in the world by a model would, from the constructivist

perspective, turn into the study of the relation between a model and another representation, or an object constituted by another representation. This is because even from a constructivist perspective, models and their tar-

gets are not identical, and the fact that targets are representationally constituted would not obliterate the differences between a target representation and scientific model.

### 3.1 Problems Concerning Model-Representation

In this section we say what questions a philosophical account of model-representation has to answer and reflect on what conditions such an answer has to satisfy. As one would expect, different authors have framed the problem in different ways. Nevertheless, recent discussions about model-representation have tended to cluster around a relatively well-circumscribed set of issues. The aim of this section is to make these issues explicit and formulate five problems that an account of model-representation has to answer. These problems will help us in structuring the discussion in later sections and put views and positions into perspective. In the course of doing so we also articulate five conditions of adequacy that every account of model-representation has to satisfy.

Models are representations of a selected part or aspect of the world. This is the model's *target system*. The first and most fundamental question about a model therefore is: In virtue of what is a model a representation of something else? Attention has been drawn to this issue by Frigg ([3.20, p. 17], [3.21, p. 50]), Morrison [3.22, p. 70], and Suárez [3.23, p. 230]. To appreciate the thrust of this question it is instructive to briefly ponder the same problem in the context of pictorial representation. When seeing, say, Soutine's *The Groom or the Bellboy* we immediately realize that it depicts a man in a red dress. Why is this? Per se the painting is a plane surface covered with pigments. How does an arrangement of pigments on a surface represent something outside the picture frame? Likewise, models, before being representations of atoms, populations, or economies, are equations, structures, fictional scenarios, or mannerly physical objects. The problem is: what turns equations and structures, or fictional scenarios and physical objects into representations of something beyond themselves? It has become customary to phrase this problem in terms of necessary and sufficient conditions and throughout this review we shall follow suit (some may balk at this, but it's worth flagging that the standard arguments against such an analysis, e.g., those surveyed in Laurence and Margolis [3.24], lose much of their bite when attention is restricted to core cases as we do here). The question then is: What fills the blank in *M is a model-representation of T iff \_\_\_\_\_*, where *M* stands for model and *T* for target system?

To spare ourselves difficulties further down the line, this formulation needs to be adjusted in light of

a crucial condition of adequacy that any account of model-representation has to meet. The condition is that models represent in a way that allows us to form hypotheses about their target systems. We can generate claims about a target system by investigating a model that represents it. Many investigations are carried out on models rather than on reality itself, and this is done with the aim of discovering features of the things models stands for. Every acceptable theory of scientific representation has to account for how reasoning conducted on models can yield claims about their target systems. Let us call this the *surrogate reasoning condition*.

The term *surrogate reasoning* was introduced by Swoyer [3.25, p. 449], and there seems to be widespread agreement on this point (although Callender and Cohen [3.26], whose views are discussed in Sect. 3.3, provide a noteworthy exception). To mention just a few writers on the subject: Bailer-Jones [3.27, p. 59] emphasizes that models “*tell us* something about certain features of the world” (original emphasis). Boliskna [3.28] and Contessa [3.29] both call models *epistemic representations*; Frigg ([3.21, p. 51], [3.30, p. 104]) sees the potential for learning as an essential explanandum for any theory of representation; Liu [3.31, p. 93] emphasizes that the main role for models in science and technology is epistemic; Morgan and Morrison [3.11, p. 11] regard models as *investigative tools*; Suárez ([3.23, p. 229], [3.32, p. 772]) submits that models license specific inferences about their targets; and Weisberg [3.33, p. 150] observes that the “model-world relation is the relationship in virtue of which studying a model can tell us something about the nature of a target system”. This distinguishes models from lexicographical representations such as words. Studying the internal constitution of a model can provide information about the target. Not so with words. The properties of a word (consisting of so and so many letters and syllables, occupying this or that position in a dictionary, etc.) do not matter to its functioning as a word; and neither do the physical properties of the ink used to print words on a piece of paper. We can replace one word by another at will (which is what happens in translations from one language to another), and we can print words with other methods than ink on paper. This is possible because the properties of a word as an object do not matter to its semantic function.

This gives rise to a problem for the schema *M is a model-representation of T iff \_\_\_\_*. The problem is that any account of representation that fills the blank in a way that satisfies the *surrogative reasoning condition* will almost invariably end up covering other kinds of representations too. Geographical maps, graphs, diagrams, charts, drawings, pictures, and photographs often provide epistemic access to features of the items they represent, and hence are likely to fall under an account of representation that explains this sort of reasoning. This is a problem for an analysis of model-representation in terms of necessary and sufficient conditions because if something that is not *prima facie* a model (for instance a map or a photograph) satisfies the conditions of an account of model-representation, then one either has to conclude that the account fails because it does not provide necessary conditions, or that first impressions are wrong and other representations (such as maps or photographs) are in fact model-representations.

Neither of these options is appealing. To avoid this problem we follow a suggestion of *Contessa's* [3.29] and broaden the scope of the investigation. Rather than analyzing the relatively narrow category of model-representation, we analyze the broader category of *epistemic representation*. This category comprises model-representations, but it also includes other representations that allow for surrogative reasoning. The task then becomes to fill the blank in *M is an epistemic representation of T iff \_\_\_\_*. For brevity we use  $R(M, T)$  as a stand in for *M is an epistemic representation of T*, and so the biconditional becomes  $R(M, T) \text{ iff } \_\_\_\_\_\_$ . We call the general problem of figuring out in virtue of what something is an epistemic representation of something else the *epistemic representation problem (ER-problem, for short)*, and the above biconditional the *ER-scheme*. So one can say that the ER is to fill the blank in the ER-scheme. *Frigg* [3.21, p. 50] calls this the “enigma of representation” and in *Suárez's* [3.23, p. 230] terminology this amounts to identifying the *constituents* of a representation (although he questions whether both necessary *and* sufficient conditions can be given; see Sect. 3.5 for further discussion on how his views fit into the ER-framework).

Analyzing the larger category of epistemic representation and placing model-representations in that category can be seen as giving rise to a demarcation problem for scientific representations: How do scientific model-representations differ from other kinds of epistemic representations? We refer to this question as the *representational demarcation problem*. *Callender and Cohen* [3.26, p. 69] formulate this problem, but then voice skepticism about our ability to solve it [3.26, p. 83]. The representational demarcation problem has

received little, if any, attention in the recent literature on scientific representation, which would suggest that other authors either share Callender and Cohen's skepticism, or regard it as a nonissue to begin with. The latter seems to be implicit in approaches that discuss scientific representation alongside pictorial representation such as *Elgin* [3.34], *French* [3.35], *Frigg* [3.21], *Suárez* [3.32], and *van Fraassen* [3.36]. But a dismissal of the problem is in no way a neutral stance. It amounts to no less than the admission that model-representations are not fundamentally different from other epistemic representations, or that we are unable to pin down what the distinguishing features are. Such a stance should be made explicit and, ideally, justified.

Two qualifications concerning the ER-scheme need to be added. The first concerns its flexibility. Some might worry that posing the problem in this way pre-judges what answers can be given. The worry comes in a number of variants. A first variant is that the scheme presupposes that representation is an intrinsic relation between *M* and *T* (i. e., a relation that only depends on intrinsic properties of *M* and *T* and on how they relate to one another rather than on how they relate to other objects) or even that it is naturalisable (a notion further discussed in Sect. 3.3). This is not so. In fact, *R* might depend on any number of factors other than *M* and *T* themselves, and on ones that do not qualify as natural ones. To make this explicit we write the ER-scheme in the form  $R(M, T) \text{ iff } C(M, T, x_1, \dots, x_n)$ , where *n* is a natural number and *C* is an (*n* + 2)-ary relation that grounds representation. The *x<sub>i</sub>* can be anything that is deemed relevant to epistemic representation, for instance a user's intentions, standards of accuracy, and specific purposes. We call *C* the *grounding relation* of an epistemic representation.

Before adding a second qualification, let us introduce the next problem in connection with model-representation. Even if we restrict our attention to scientific epistemic representations (if they are found to be relevantly different to nonscientific epistemic representations as per the demarcation problem above), not all representations are of the same kind. In the case of visual representations this is so obvious that it hardly needs mention: An Egyptian mural, a two-point perspective ink drawing, a pointillist oil painting, an architectural plan, and a road map represent their respective targets in different ways. This pluralism is not limited to visual representations. Model-representations do not all seem to be of the same kind either. *Woody* [3.37] argues that chemistry as a discipline has its own ways to represent molecules. But differences in style can also appear in models from the same discipline. *Weizsäcker's* liquid drop model represents the nucleus of an atom in a manner that seems to be different from the one of the shell

model. A scale model of the wing of a plane represents the wing in a way that is different from how a mathematical model of its cross section does. Or Phillips and Newlyn's famous hydraulic machine and Hicks' mathematical models both represent a Keynesian economy but they seem to do so in different ways. This gives rise to the question: What styles are there and how can they be characterized? This is the *problem of style* [3.21, p. 50]. There is no expectation that a *complete* list of styles be provided in response. Indeed, it is unlikely that such a list can ever be drawn up, and new styles will be invented as science progresses. For this reason a response to the problem of style will always be open-ended, providing a taxonomy of what is currently available while leaving room for later additions.

With this in mind we can now turn to the second qualification concerning the ER-scheme. The worry is this: The scheme seems to assume that representation is a monolithic concept and thereby make it impossible to distinguish between different kinds of representation. The impression is engendered by the fact the scheme asks us to fill a blank, and blank is filled only once. But if there are different kinds of representations, we should be able to fill the blank in different ways on different occasions because a theory of representation should not force upon us the view that the different styles are all variations of one overarching concept of representation.

The ER-scheme is more flexible than it appears at first sight. There are at least three ways in which different styles of representations can be accommodated. For the sake of illustration, and to add some palpability to an abstract discussion, let us assume that we have identified two styles: analogue representation and idealized representation. The result of an analysis of these relations is the identification of their respective grounding relations. Let  $C_A(M, T, \dots)$  and  $C_1(M, T, \dots)$  be these relations. The first way of accommodating them in the ER-scheme is to fill the blank with the disjunction of the two:  $R(M, T) \text{ iff } C_A(M, T, \dots) \text{ or } C_1(M, T, \dots)$ . In plain English:  $M$  represents  $T$  if and only if  $M$  is an analogue representation of  $T$  or  $M$  is an idealized representation of  $T$ . This move is possible because, first appearances notwithstanding, nothing hangs on the grounding relation being homogeneous. The relation can be as complicated as we like and there is no prohibition against disjunctions. In the above case we have  $C = [C_A \text{ or } C_1]$ . Furthermore, the grounding relation could even be an open disjunction. This would help accommodating the above observation that a list of styles is potentially open-ended. In that case there would be a grounding relation for each style and the scheme could be written as  $R(M, T) \text{ iff } C_1(M, T, \dots) \text{ or } C_2(M, T, \dots) \text{ or } C_3(M, T, \dots) \text{ or } \dots$ , where the  $C_i$  are the grounding relations for different styles. This

is not a new scheme; it's the old scheme where  $C = [C_1 \text{ or } C_2 \text{ or } C_3 \text{ or } \dots]$  is spelled out.

Alternatively one could formulate a different scheme for every kind of representation. This would amount to changing the scheme slightly in that one does not analyze epistemic representation per se. Instead one would analyze different kinds of epistemic representations. Consider the above example again. Let  $R_1(M, T)$  stand for  $M$  is an analogue epistemic representation of  $T$  and  $R_2(M, T)$  for  $M$  is an idealized epistemic representation of  $T$ . The response to the ER-problem then consists in presenting the two biconditionals  $R_1(M, T) \text{ iff } C_A$  and  $R_2(M, T) \text{ iff } C_1$ . This generalizes straightforwardly to the case of any number of styles, and the open-endedness of the list of styles can be reflected in the fact that an open-ended list of conditionals of the form  $R_i(M, T) \text{ iff } C_i$  can be given, where the index ranges over styles.

In contrast with the second option, which pulls in the direction of more diversity, the third aims for more unity. The crucial observation here is that the grounding relation can in principle be an abstract relation that can be concretized in different ways, or a determinable that can have different determinates. On the third view, then, the concept of representation is like the concept of force (which is abstract in that in a concrete situation force is gravity or electromagnetic attraction or some other specific force), or like color (where a colored object must be blue or green or \_\_\_\_). This view would leave  $R(M, T) \text{ iff } C(M, T, x_1, \dots, x_n)$  unchanged and take it as understood that  $C$  is an abstract relation.

At this point we do not adjudicate between these options. Each has its own pros and cons, and which one is the most convenient to work with depends on one's other philosophical commitments. What matters is that the ER-scheme does have the flexibility to accommodate different representational styles, and that it can in fact accommodate them in at least three different ways.

The next problem in line for the theory of model-representation is to specify standards of accuracy. Some representations are accurate; others aren't. The Schrödinger model is an accurate representation of the hydrogen atom; the Thomson model isn't. On what grounds do we make such judgments? In Morrison's words: "how do we identify what constitutes an accurate representation?" [3.22, p. 70]. We call this the problem of *standards of accuracy*. Answering this question might make reference to the purposes of the model and model user, and thus it is important to note that by *accuracy* we mean something that can come in degrees and may be context dependent. Providing a response to the problem of accuracy is a crucial aspect of an account of epistemic representation.

This problem goes hand in hand with a second condition of adequacy: the *possibility of misrepresentation*. Asking what makes a representation an accurate representation already presupposes that inaccurate representations are representations too. And this is how it should be. If  $M$  does not accurately portray  $T$ , then it is a misrepresentation but not a nonrepresentation. It is therefore a general constraint on a theory of epistemic representation that it has to make misrepresentation possible. This can be motivated by a brief glance at the history of science, but is plausibly also part of the concept of representation, and as such is found in discussions of other kinds of representation (*Stitch and Warfield* [3.38, pp. 6–7], for instance, suggest that a theory of mental representation should be able to account for misrepresentation, as do *Sterelny and Griffiths* [3.39, p. 104] in their discussion of genetic representation). A corollary of this requirement is that representation is a wider concept than accurate representation and that representation cannot be analyzed in terms of accurate representation.

A related condition concerns models that misrepresent in the sense that they lack target systems. Models of ether, phlogiston, four-sex populations, and so on, are all deemed scientific models, but ether, phlogiston, and four-sex populations don't exist. Such models lack (actual) target systems, and one hopes that an account of epistemic representation would allow us to understand how these models work. We call this the problem of targetless models (or models without targets).

The fourth condition of adequacy for an account of model-representation is that it must account for the directionality of representation. Models are about their targets, but (at least in general) targets are not about their models. So there is an essential directionality to representations, and an account of model-representation has to identify the root of this directionality. We call this the *requirement of directionality*.

Many scientific models are highly mathematized, and their mathematical aspects are crucial to their cognitive as well as their representational function. This forces us to reconsider a time-honored philosophical puzzle: the applicability of mathematics in the empirical sciences. Even though the problem can be traced back at least to Plato's *Timaeus*, its canonical modern expression is due to *Wigner*, who famously remarked that “the enormous usefulness of mathematics in the natural sciences is something bordering on the mysterious and that there is no explanation for it” [3.40, p. 2]. One need not go as far as seeing the applicability of mathematics as an inexplicable miracle, but the question remains: How does mathematics hook onto the world?

The recent discussion of this problem has taken place in a body of literature that grew out of the philos-

ophy of mathematics (see *Shapiro* [3.41, Chap. 8] for a review). But, with the exception of *Bueno and Colyvan* [3.42], there has been little contact with the literature on scientific modeling. This is a regrettable state of affairs. The question of how a mathematized model represents its target implies the question of how mathematics applies to a physical system. So rather than separating the question of model-representation from the problem of the applicability of mathematics and dealing with them in separate discussions, they should be seen as the two sides of the same coin and be dealt with in tandem. For this reason, our fifth and final condition of adequacy is that an account of representation has to explain how mathematics is applied to the physical world. We call this the *applicability of mathematics condition*.

In answering the above questions one invariably runs up against a further problem, the *problem of ontology*: What kinds of objects are models? Are they structures in the sense of set theory, fictional entities, descriptions, equations or yet something else? Or are there no models at all? While some authors develop an ontology of models, others reject an understanding of models as *things* and push a program that can be summed up in the slogan *modeling without models* [3.43]. There is also no presupposition that all models be of the same kind. Some models are material objects, some are things that one holds in one's head rather than one's hands (to use *Hacking's* phrase [3.44, p. 216]). For the most part, the focus in debates about representation has been on nonmaterial models, and we will follow this convention. It is worth emphasizing, however, that also the seemingly straightforward material models raise interesting philosophical questions: *Rosenblueth and Wiener* [3.45] discuss the criteria for choosing an object as a model; *Ankeny and Leonelli* [3.46] discuss issues that arise when using organisms as models; and the contributors to [3.47] discuss representation in the laboratory.

A theory of representation can recognize different kinds of models, or indeed no models at all. The requirement only asks us to be clear on our commitments and provide a list with things, if any, that we recognize as models and give an account of what they are in case these entities raise questions (what exactly do we mean by something that one holds in one's head rather than one's hands?).

In sum, an account of model-representation has to do the following:

1. Provide an answer to the *epistemic representation problem* (filling the blank in ER-scheme:  $M$  is an epistemic representation of  $T$  iff . . .).
2. Take a stand on the *representational demarcation problem* (the question of how scientific epistemic

representations differ from other kinds of epistemic representations).

3. Respond to the *problem of style* (what styles are there and how can they be characterized?).
4. Formulate *standards of accuracy* (how do we identify what constitutes an accurate representation?).
5. Address the *problem of ontology* (what kinds of objects are models?).

Any satisfactory answer to these five issues will have to meet the following five conditions of adequacy:

1. *Surrogative reasoning condition* (models represent their targets in a way that allows us to generate hypotheses about them).
2. *Possibility of misrepresentation* (if  $M$  does not accurately represent  $T$ , then it is a misrepresentation but not a nonrepresentation).

3. *Targetless models* (what are we to make of scientific representations that lack targets?).
4. *Requirement of directionality* (models are about their targets, but targets are not about their models).
5. *Applicability of mathematics condition* (how the mathematical apparatus used in  $M$  latches onto the physical world).

To frame the problem in this way is not to say that these are separate and unrelated issues, which can be dealt with one after the other in roughly the same way in which we first buy a ticket, walk to the platform and then take a train. This division is analytical, not factual. It serves to structure the discussion and to assess proposals; it does not imply that an answer to one of these questions can be dissociated from what stance we take on the other issues.

## 3.2 General Griceanism and Stipulative Fiat

*Callender* and *Cohen* [3.26] submit that the entire debate over scientific representation has started on the wrong foot. They claim that scientific representation is not different from “artistic, linguistic, and culinary representation” and in fact “there is no special problem about scientific representation” [3.26, p. 67]. Underlying this claim is a position *Callender* and *Cohen* call *General Griceanism* (GG). The core of GG is the reductive claim that most representations we encounter are “derivative from the representational status of a privileged core of representations” [3.26, p. 70]. GG then comes with a practical prescription about how to proceed with the analysis of a representation [3.26, p. 73]:

“The General Gricean view consists of two stages. First, it explains the representational powers of derivative representations in terms of those of fundamental representations; second, it offers some other story to explain representation for the fundamental bearers of content.”

Of these stages only the second requires serious philosophical work, and this work is done in the philosophy of mind because the fundamental form of representation is mental representation.

Scientific representation is a derivative kind of representation [3.26, pp. 71,75] and hence falls under the first stage of the above recipe. It is reduced to mental representation by an act of stipulation [3.26, pp. 73–74]:

“Can the salt shaker on the dinner table represent Madagascar? Of course it can, so long as you stipulate that the former represents the latter. [...] Can your left hand represent the Platonic form of

beauty? Of course, so long as you stipulate that the former represents the latter. [...] On the story we are telling, then, virtually anything can be stipulated to be a representational vehicle for the representation of virtually anything [...]; the representational powers of mental states are so wide-ranging that they can bring about other representational relations between arbitrary relata by dint of mere stipulation. The upshot is that, once one has paid the admittedly hefty one-time fee of supplying a metaphysics of representation for mental states, further instances of representation become extremely cheap.”

So explaining any form of representation other than mental representation is a triviality – all it takes is an act of “stipulative fiat” [3.26, p. 75]. This supplies their answer to the ER-problem:

### *Definition 3.1 Stipulative fiat*

A scientific model  $M$  represents a target system  $T$  iff a model user stipulates that  $M$  represents  $T$ .

On this view, scientific representations are cheap to come by. The question therefore arises why scientists spend a lot of time constructing and studying complex models if they might just as well take a salt shaker and turn it into a representation of, say, a Bose–Einstein condensate by an act of fiat. *Callender* and *Cohen* admit that there are useful and not so useful representations, and that salt shakers belong the latter group. However, they insist that this has nothing to do with representation [3.26, p. 75]:

“The questions about the utility of these representational vehicles are questions about the pragmatics of things that are representational vehicles, not questions about their representational status per se.”

So, in sum, scientific representation [3.26, p. 78]

“is constituted in terms of a stipulation, together with an underlying theory of representation for mental states, isomorphism, similarity, and inference generation are all idle wheels.”

The first question we are faced with when assessing this account is the relation between GG and stipulative fiat (Definition 3.1). Callender and Cohen do not comment on this issue, but that they mention both in the same breath would suggest that they regard them as one and the same doctrine, or at least as the two sides of the same coin. This is not so. Stipulative fiat (Definition 3.1) is just one way of fleshing out GG, which only requires that there be *some* explanation of how derivative representations relate to fundamental representations; GG does not require that this explanation be of a particular kind, much less that it consists of nothing but an act of stipulation ([3.48, pp. 77–78], [3.49, p. 244]). Even if GG is correct, it doesn’t follow that stipulative fiat is a satisfactory answer to the ER-problem. Model-representation can, in principle, be *reduced* to fundamental representation in many different ways (some of which we will encounter later in this chapter). Conversely, the failure of stipulative fiat does not entail that we must reject GG: one can uphold the idea that an appeal to the intentions of model users is a crucial element in an account of scientific representation even if one dismisses stipulative fiat (Definition 3.1).

Let us now examine stipulative fiat (Definition 3.1). Callender and Cohen emphasize that anything can be a representation of anything else [3.26, p. 73]. This is correct. Things that function as models don’t belong to a distinctive ontological category, and it would be a mistake to think that that some objects are, intrinsically, representations and other are not. This point has been made by others too (including Frigg [3.50, p. 99], Giere [3.51, p. 269], Suárez [3.32, p. 773], Swoyer [3.25, p. 452], and Teller [3.52, p. 397]) and, as we shall see, it is a cornerstone of several alternative accounts of representation.

But just because anything can, in principle, be a representation of anything else, it doesn’t follow that a mere act of stipulation suffices to turn *M* into a representation of *T*. Furthermore, it doesn’t follow that an object elevated to the status of a representation by an act of fiat represents its target in a way that can appropriately be characterized as an instance of epistemic

representation. We discuss both concerns in reverse order.

Stipulative fiat (Definition 3.1) fails to meet the surrogative reasoning condition: it fails to provide an account of how claims about Madagascar could be extracted from reasoning about the salt shaker. Even if we admit that stipulative fiat (Definition 3.1) establishes that models denote their targets (and as we will see soon, there is a question about this), denotation is not sufficient for epistemic representation. Both the word *Napoleon* and Jacques-Louis David’s portrait of Napoleon serve to denote the French general. But this does not imply that they represent him in the same way, as noted by Toon [3.48, pp. 78–79]. *Bueno* and *French* [3.53, pp. 871–874] gesture in the same direction when they point to Peirce’s distinction between icon, index and symbol and dismiss Callender and Cohen’s views on grounds that they cannot explain the obvious differences between different kinds of representations.

Supporters of stipulative fiat (Definition 3.1) could try to mitigate the force of this objection in two ways. First, they could appeal to additional facts about the object, as well as its relation to other items, in order to account for surrogative reasoning. For instance, the salt shaker being to the right of the pepper mill might allow us to infer that Madagascar is to the east of Mozambique. Moves of this sort, however, invoke (at least tacitly) a specifiable relation between features of the model and features of the target (similarity, isomorphism, or otherwise), and an invocation of this kind goes beyond mere stipulation. Second, the last quotation from Callender and Cohen suggests that they might want to relegate surrogative reasoning into the realm of pragmatics and deny that it is part of the relation properly called epistemic representation. This, however, in effect amounts to a removal of the surrogative reasoning condition from the desiderata of an account of scientific representation, and we have argued in Sect. 3.1 that surrogative reasoning is one of the hallmarks of scientific representation. And even if it were *pragmatics*, we still would want an account of how it works.

Let us now turn to our first point, that a mere act of stipulation is insufficient to turn *M* into a representation of *T*. We take our cue from a parallel discussion in the philosophy of language, where it has been pointed out that it is not clear that stipulation is sufficient to establish a denotational relationship (which is weaker than epistemic representation). A position similar to stipulative fiat (Definition 3.1) faces what is known as the *Humpty Dumpty problem*, named in reference to Lewis Carroll’s discussion of Humpty using the word *glory* to mean *a nice knockdown argument* [3.54, 55] (it’s worth noting that this debate concerns meaning,

rather than denotation, but it's plausible that it can be reconstructed in terms of the latter). If stipulation is all that matters, then as long as Humpty simply stipulates that *glory* means *a nice knockdown argument*, then it does so. And this doesn't seem to be the case. Even if the utterance *glory* could mean *a nice knockdown argument* – if, for example, Humpty was speaking a different language – in the case in question it doesn't, irrespective of Humpty's stipulation. In the contemporary philosophy of language the discussion of this problem focuses more on the denotation of demonstratives rather than proper names, and work in that field focuses on propping up existing accounts so as to ensure that a speaker's intentions successfully establish the denotation of demonstratives uttered by the speaker [3.56]. Whatever the success of these endeavors, their mere existence shows that successfully establishing denotation requires moving beyond a bare appeal to stipulation, or brute intention. But if a brute appeal to intentions fails in the case of demonstratives – the sorts of terms that such an account would most readily be applicable to – then we find it difficult to see how stipulative fiat (Definition 3.1) will establish a representational relationship between models and their targets. Moreover, this whole discussion supposed that an intention-based account of denotation is the correct one. This is controversial – see Reimer and Michaelson [3.57] for an overview of discussions of denotation in the philosophy of language. If this is not the correct way to think about denotation,

then stipulative fiat (Definition 3.1) will fail to get off the ground at all.

It now pays that we have separated GG from stipulative fiat (Definition 3.1). Even though stipulative fiat (Definition 3.1) does not provide an adequate answer to the ER-problem, one can still uphold GG. As Callender and Cohen note, all that it requires is that there is a privileged class of representations (they take them to be mental states but are open to the suggestion that they might be something else [3.26, p. 82]), and that other types of representations owe their representational capacities to their relationship with the primitive ones. So philosophers need an account of how members of this privileged class of representations represent, and how derivative representations, which includes scientific models, relate to this class.

This is a plausible position, and when stated like this, many recent contributors to the debate on scientific representation can be seen as falling under the umbrella of GG. As we will see below, the more developed versions of the similarity (Sect. 3.3) and isomorphism (Sect. 3.4) accounts of scientific representation make explicit reference to the intentions and purposes of model users, even if their earlier iterations did not. And so do the accounts discussed in the latter sections, where the intentions of model users (in a more complicated manner than that suggested by stipulative fiat (Definition 3.1)) are invoked to establish epistemic representation.

### 3.3 The Similarity Conception

Moving on from the Gricean account we now turn to the similarity conception of scientific representation (in aesthetics the term *resemblance* is used more commonly than *similarity*, but there does not seem to be a substantive difference between the notions, and we use the terms as synonyms throughout). Similarity and representation initially appear to be two closely related concepts, and invoking the former to ground the latter has a philosophical lineage stretching back at least as far as Plato's *The Republic*.

In its most basic guise the similarity conception of scientific representation asserts that scientific models represent their targets in virtue of being similar to them. This conception has universal aspirations in that it is taken to account for epistemic representation across a broad range of different domains. Paintings, statues, and drawings are said to represent by being similar to their subjects, (see Abell [3.58] and Lopes [3.59] for relatively current discussions of similarity in the context of visual representation). And recently Giere, one of the

view's leading contemporary proponents, proclaimed that it covers scientific models alongside “words, equations, diagrams, graphs, photographs, and, increasingly, computer-generated images” [3.60, p. 243] (see also Giere [3.61, p. 272], and for further discussion Toon [3.49, pp. 249–250]). So the similarity view repudiates the demarcation problem and submits that the same mechanism, namely similarity, underpins different kinds of representation in a broad variety of contexts. (Sometimes the similarity view is introduced by categorizing models as icons in Peirce's sense, and, as Kraleman and Lattmann point out, icons represent “on the basis of a similarity relation between themselves and their objects” [3.62, p. 3398].)

The view also offers an elegant account of surrogate reasoning. Similarities between model and target can be exploited to carry over insights gained in the model to the target. If the similarity between  $M$  and  $T$  is based on shared properties, then a property found in  $M$  would also have to be present in  $T$ ; and if the similar-

ity holds between properties themselves, then  $T$  would have to instantiate properties similar to  $M$  (however, it is worth noting that this kind of knowledge transfer can cause difficulties in some contexts, Frigg et al. [3.63] discuss these difficulties in the context of nonlinear dynamic modeling).

However, appeal to similarity in the context of representation leaves open whether similarity is offered as an answer to the ER-problem, the problem of style, or whether it is meant to set standards of accuracy. Proponents of the similarity account typically have offered little guidance on this issue. So we examine each option in turn and ask whether similarity offers a viable answer. We then turn to the question of how the similarity view deals with the problem of ontology.

### 3.3.1 Similarity and ER-Problem

Understood as response to the ER-problem, a similarity view of representation amounts to the following:

#### *Definition 3.2 Similarity 1*

A scientific model  $M$  represents a target  $T$  iff  $M$  and  $T$  are similar.

A well-known objection to this account is that similarity has the wrong logical properties. Goodman [3.64, pp. 4–5] submits that similarity is symmetric and reflexive yet representation isn't. If object  $A$  is similar to object  $B$ , then  $B$  is similar to  $A$ . But if  $A$  represents  $B$ , then  $B$  need not (and in fact in most cases does not) represent  $A$ : the Newtonian model represents the solar system, but the solar system does not represent the Newtonian model. And everything is similar to itself, but most things do not represent themselves. So this account does not meet our third condition of adequacy for an account of scientific representation insofar as it does not provide a direction to representation. (Similar problems also arise in connection with other logical properties, e.g., transitivity; see Frigg [3.30, p. 31] and Suárez [3.23, pp. 232–233].)

Yaghmaie [3.65] argues that this conclusion – along with the third condition itself – is wrong: epistemic representation is symmetric and reflexive (he discusses this in the context of the isomorphism view of representation, which we turn to in the next section, but the point applies here as well). His examples are drawn from mathematical physics, and he presents a detailed case study of a symmetric representation relation between quantum field theory and statistical mechanics. His case raises interesting questions, but even if one grants that Yaghmaie has identified a case where representation is reflexive and symmetrical it does not follow that representation *in general* is. The photograph in

Jane's passport represents Jane; but Jane does not represent her passport photograph; and the same holds true for myriads of other representations. Goodman is correct in pointing out that typically representation is not symmetrical and reflexive: a target  $T$  does not represent model  $M$  just because  $M$  represents  $T$ .

A reply diametrically opposed to Yaghmaie's emerges from the writings of Tversky and Weisberg. They accept that representation is not symmetric, but dispute that similarity fails on this count. Using a gradual notion of similarity (i. e., one that allows for statements like *A is similar to B to degree d*), Tversky found that subjects in empirical studies judged that North Korea was more similar to China than China was to North Korea [3.66]; similarly Poznic [3.67, Sect. 4.2] points out with reference to the characters in a Polanski movie that the similarity relation between a baby and the father need not be symmetric.

So allowing degrees into ones notion of similarity makes room for an asymmetry (although degrees by themselves are not sufficient for asymmetry; metric-based notions are still symmetric). This raises the question of how to analyze similarity. We discuss this thorny issue in some detail in the next subsection. For now we concede the point and grant that similarity need not always be symmetrical. However, this does not solve Goodman's problem with reflexivity (as we will see on Weisberg's notion of similarity everything is maximally similar to itself); nor does it, as will see now, solve other problems of the similarity account.

However the issue of logical properties is resolved, there is another serious problem: similarity is too inclusive a concept to account for representation. In many cases neither one of a pair of similar objects represents the other. Two copies of the same book are similar but neither represents the other. Similarity between two items is not enough to establish the requisite relationship of representation; there are many cases of similarity where no representation is involved. And this won't go away even if similarity turns out to be non-symmetric. That North Korea is similar to China (to some degree) does not imply that North Korea represents China, and that China is not similar to North Korea to the same degree does not alter this conclusion.

This point has been brought home in a now-classical thought experiment due to Putnam [3.68, pp. 1–3] (but see also Black [3.69, p. 104]). An ant is crawling on a patch of sand and leaves a trace that happens to resemble Winston Churchill. Has the ant produced a picture of Churchill? Putnam's answer is that it didn't because the ant has never seen Churchill and had no intention to produce an image of him. Although *someone else* might see the trace as a depiction of Churchill, the trace itself does not represent Churchill. This, Putnam concludes,

shows that “[s]imilarity [...] to the features of Winston Churchill is not sufficient to make something represent or refer to Churchill” [3.68, p. 1]. And what is true of the trace and Churchill is true of every other pair of similar items: similarity on its own does not establish representation.

There is also a more general issue concerning similarity: it is too easy to come by. Without constraints on what counts as similar, any two things can be considered similar to any degree [3.70, p. 21]. This, however, has the unfortunate consequence that anything represents anything else because any two objects are similar in some respect. Similarity is just too inclusive to account for representation. An obvious response to this problem is to delineate a set of relevant respects and degrees to which  $M$  and  $T$  have to be similar. This suggestion has been made explicitly by *Giere* [3.71, p. 81] who suggests that models come equipped with what he calls *theoretical hypotheses*, statements asserting that model and target are similar in relevant respects and to certain degrees. This idea can be molded into the following definition:

#### **Definition 3.3 Similarity 2**

A scientific model  $M$  represents a target  $T$  iff  $M$  and  $T$  are similar in relevant respects and to the relevant degrees.

On this definition one is free to choose one’s respects and degrees so that unwanted similarities drop out of the picture. While this solves the last problem, it leaves the others untouched: similarity in relevant respects and to the relevant degrees is reflexive (and symmetrical, depending on one’s notion of similarity); and presumably the ant’s trace in the sand is still similar to Churchill in the relevant respects and degrees but without representing Churchill. Moreover, similarity 2 (Definition 3.3) introduces three new problems.

First, a misrepresentation is one that portrays its target as having properties that are not similar in the relevant respects and to the relevant degrees to the true properties of the target. But then, on similarity 2 (Definition 3.3),  $M$  is not a representation at all. *Ducheyne* [3.72] embraces this conclusion when he offers a variant of a similarity account that explicitly takes the *success* of the hypothesized similarity between a model and its target to be a necessary condition on the model representing the target. In Sect. 3.2 we argued that the possibility of misrepresentation is a condition of adequacy for any acceptable account of representation and so we submit that misrepresentation should not be conflated with nonrepresentation ([3.20, p. 16], [3.23, p. 235]).

Second, similarity in relevant respects and to the relevant degrees does not guarantee that  $M$  represents the right target. As *Suárez* points out [3.23, pp. 233–234], even a regimented similarity can obtain with no corresponding representation. If John dresses up as Pope Innocent X (and he does so perfectly), then he resembles Velázquez’s portrait of the pope (at least in as far as the pope himself resembled the portrait). In cases like these, which Suárez calls *mistargeting*, a model represents one target rather than another, despite the fact that both targets are relevantly similar to the model. Like in the case of Putnam’s ant, the root cause of the problem is that the similarity is accidental. In the case of the ant, the accident occurs at the representation end of the relation, whereas in the case of John’s dressing up the accidental similarity occurs at the target end. Both cases demonstrate that similarity 2 (Definition 3.3) cannot rule out accidental representation.

Third, there may simply be nothing to be similar to because some representations represent no actual object [3.64, p. 26]. Some paintings represent elves and dragons, and some models represent phlogiston and the ether. None of these exist. As *Toon* points out, this is a problem in particular for the similarity view [3.49, pp. 246–247]: models without objects cannot represent what they seem to represent because in order for two things to be similar to each other both have to exist. If there is no ether, then an ether model cannot be similar to the ether.

It would seem that at least the second problem could be solved by adding the requirement that  $M$  denote  $T$  (as considered, but not endorsed, by *Goodman* [3.64, pp. 5–6]). Amending the previous definition accordingly yields:

#### **Definition 3.4 Similarity 3**

A scientific model  $M$  represents a target  $T$  iff  $M$  and  $T$  are similar in relevant respects and to the relevant degrees and  $M$  denotes  $T$ .

This account would also solve the problem with reflexivity (and symmetry), because denotation is directional in a way similarity is not. Unfortunately similarity 3 (Definition 3.4) still suffers from the first and the third problems. It would still lead to the conflation of misrepresentations with nonrepresentations because the first conjunct (similar in the relevant respects) would still be false. And a nonexistent system cannot be denoted and so we have to conclude that models of, say, the ether and phlogiston represent nothing. This seems an unfortunate consequence because there is a clear sense in which models without targets are about something. Maxwell’s writings on the ether provide a detailed and intelligible account of a number of properties of the

ether, and these properties are highlighted in the model. If ether existed then similarity 3 (Definition 3.4) could explain why these were important by appealing to them as being relevant for the similarity between an ether model and its target. But since ether does not, no such explanation is offered.

A different version of the similarity view sets aside the moves made in similarity 3 (Definition 3.4) and tries to improve on similarity 2 (Definition 3.3). The crucial move is to take the very act of *asserting* a specific similarity between a model and a target as constitutive of the scientific representation.

#### Definition 3.5 Similarity 4

A scientific model  $M$  represents a target system  $T$  if and only if a theoretical hypotheses  $H$  asserts that  $M$  and  $T$  are similar in certain respects and to certain degrees.

This comes close to the view *Giere* advocated in *Explaining Science* [3.71, p. 81] (something like this is also found in *Cartwright* ([3.73, pp. 192–193], [3.74, pp. 261–262]) who appeals to a “loose notion of resemblance”; her account of modeling is discussed in more detail in Sect. 3.6.3). This version of the similarity view avoids problems with misrepresentation because, being hypotheses, there is no expectation that the assertions made in  $H$  are true. If they are, then the representation is accurate (or the representation is accurate to the extent that they hold). If they are not, then the representation is a misrepresentation. It resolves the problem of mistargeting because hypotheses identify targets before asserting similarities with  $M$  (that is, the task of picking the right target is now placed in the court of the hypothesis and is no longer expected to be determined by the similarity relation). Finally it also resolves the issue with directionality because  $H$  can be understood as introducing a directionality that is not present in the similarity relation. However, it fails to resolve the problem with representation without a target. If there is no ether, no hypotheses can be asserted about it.

Let us set the issue of nonexistent targets aside for the moment and have a closer look at the notion of representation proposed in similarity 4 (Definition 3.5). A crucial point remains understated in similarity 4 (Definition 3.5). Hypotheses don’t assert themselves; hypotheses are put forward by those who work with representations, in the case of models, scientists. So the crucial ingredient – users – is left implicit in similarity 4 (Definition 3.5).

In a string of recent publications *Giere* made explicit the fact that “scientists are intentional agents with goals and purposes” [3.60, p. 743] and proposed to build this insight explicitly into an account of epistemic

representation. This involves adopting an agent-based notion of representation that focuses on “the activity of representing” [3.60, p. 743]. Analyzing epistemic representation in these terms amounts to analyzing schemes like “ $S$  uses  $X$  to represent  $W$  for purposes  $P$ ” [3.60, p. 743], or in more detail [3.51, p. 274]:

“Agents (1) intend; (2) to use model,  $M$ ; (3) to represent a part of the world  $W$ ; (4) for purposes,  $P$ . So agents specify which similarities are intended and for what purpose.”

This conception of representation had already been proposed half a century earlier by *Apostel* when he urged the following analysis of model-representation [3.75, p. 4]:

“Let then  $R(S, P, M, T)$  indicate the main variables of the modeling relationship. The subject  $S$  takes, in view of the purpose  $P$ , the entity  $M$  as a model for the prototype  $T$ .”

Including the intentions of model agents in the definition of scientific representation is now widely accepted, as we discuss in more detail in Sect. 3.4 (although *Rusanen* and *Lappi* disagree with this, and claim that “the semantics of models as scientific representations should be based on the mind-independent model-world relation” [3.76, p. 317]).

*Giere*’s proposal, in our own terminology comes down to:

#### Definition 3.6 Similarity 5

A scientific model  $M$  represents a target system  $T$  iff there is an agent  $A$  who uses  $M$  to represent a target system  $T$  by proposing a theoretical hypothesis  $H$  specifying a similarity (in certain respects and to certain degrees) between  $M$  and  $T$  for purpose  $P$ .

This definition inherits from similarity 4 (Definition 3.5) the resolutions of the problems of directionality, misrepresentation, and mistargeting; and for the sake of argument we assume that the problem with nonexistent targets can be resolved in one way or other.

A crucial thing to note about similarity 5 (Definition 3.6) is that, by invoking an active role for the purposes and actions of scientists in constituting epistemic representation, it marks a significant change in emphasis for similarity-based accounts. *Suárez* [3.23, pp. 226–227], drawing on *van Fraassen* [3.77] and *Putnam* [3.78], defines *naturalistic* accounts of representation as ones where “whether or not representation obtains depends on facts about the world and does not in any way answer to the personal purposes, views or interests of enquirers”. By building the purposes of model

users directly into an answer to the ER-problem, similarity 5 (Definition 3.6) is explicitly not a naturalistic account (in contrast, for example, to similarity 1 (Definition 3.2)). As noted in Sect. 3.2 we do not demand a naturalistic account of model-representation (and as we will see later, many of the more developed answers to the ER-problem are also not naturalistic accounts).

Does this suggest that similarity 5 (Definition 3.6) is a successful similarity-based solution to the ER-problem? Unfortunately not. A closer look at similarity 5 (Definition 3.6) reveals that the role of similarity has shifted. As far as offering a solution to the ER-problem is concerned, all the heavy lifting in similarity 5 (Definition 3.6) is done by the appeal to agents and similarity has in fact become an idle wheel. *Giere* implicitly admits this when he writes [3.60, p. 747]:

“How do scientists use models to represent aspects of the world? What is it about models that makes it possible to use them in this way? One way, perhaps the most important way, but probably not the only way, is by exploiting similarities between a model and that aspect of the world it is being used to represent. Note that I am not saying that the model itself represents an aspect of the world because it is similar to that aspect. There is no such representational relationship. [footnote omitted] Anything is similar to anything else in countless respects, but not anything represents anything else. It is not the model that is doing the representing; it is the scientist using the model who is doing the representing.”

But if similarity is not the only way in which a model can be used as a representation, and if it is the use by a scientist that turns a model into a representation (rather than any mind-independent relationship the model bears to the target), then similarity has become otiose in a reply to the ER-problem. A scientist could invoke any relation between  $M$  and  $T$  and  $M$  would still represent  $T$ . Being similar in the relevant respects to the relevant degrees now plays the role either of a representational style, or of a normative criterion for accurate representation, rather than of a grounding of representation. We assess in the next section whether similarity offers a cogent reply to the issues of style and accuracy.

A further problem is that there seems to be a hidden circularity in the analysis. As *Toon* [3.49, pp. 251–252] points out, having a scientist form a theoretical hypothesis about the similarity relation between two objects  $A$  and  $B$  and exploit this similarity for a certain purpose  $P$  is not sufficient for representation.  $A$  and  $B$  could be two cars in a showroom and an engineer inspects car  $A$  and then use her knowledge about similarities to make assertions about  $B$  (for instance if both cars are of the same brand she can infer something about  $B$ 's quality

of manufacturing). This, *Toon* submits, is not a case of representation: neither car is representational. Yet, if we delete the expression *to represent* on the right hand side of the biconditional in similarity 5 (Definition 3.6), the resulting condition provides an accurate description of what happens in the showroom. So the only difference between the nonrepresentational activity of comparing cars and representing  $B$  by  $A$  is that in one case  $A$  is *used to represent* and in the other it's only *used*. So representation is explained in terms of *to represent*, which is circular. So similarity 5 (Definition 3.6) does not provide nontrivial conditions for something to be used *as a representation*.

One way around the problem would be to replace *to represent* by *to denote*. This, however, would bring the account close to similarity 3 (Definition 3.4), and it would suffer from the same problems.

*Mäki* [3.79] suggested an extension of similarity 5 (Definition 3.6), which he explicitly brands as “a (more or less explicit) version” of *Giere*'s. *Mäki* adds two conditions to *Giere*'s: the agent uses the model to address an audience  $E$  and adds a commentary  $C$  [3.79, p. 57]. The role of the commentary is to specify the nature of the similarity. This is needed because [3.79, p. 57]:

“representation does not require that all parts of the model resemble the target in all or just any arbitrary respects, or that the issue of resemblance legitimately arises in regard to all parts. The relevant model parts and the relevant respects and degrees of resemblance must be delimited.”

What these relevant respects and degrees of resemblance are depends on the purposes of the scientific representation in question. These are not determined *in the model* as it were, but are pragmatic elements. From this it transpires that in effect  $C$  plays the same role as that played by theoretical hypotheses in *Giere*'s account. Certain aspects of  $M$  are chosen as those relevant to the representational relationship between  $M$  and  $T$ .

The addition of an audience, however, is problematic. While models are often shared publicly, this does not seem to be a necessary condition for the representational use of a model. There is nothing that precludes a lone scientist from coining a model  $M$  and using it representationally. That some models are easier to grasp, and therefore serve as more effective tools to drive home a point in certain public settings, is an indisputable fact, but one that has no bearing on a model's status as a representation. The pragmatics of communication and the semantics of modeling are separate issues.

The conclusion we draw from this discussion is that similarity does not offer a viable answer to the ER-problem.

### 3.3.2 Accuracy and Style

Accounting for the possibility of misrepresentation resulted in a shift of the division of labor for the more developed similarity-based accounts. Rather than being the relation that grounds representation, similarity should be considered as setting a standard of accuracy or as providing an answer to the question of style (or both). The former is motivated by the observation that a proposed similarity between  $M$  and  $T$  could be wrong, and hence if the model user's proposal does in fact hold (and  $M$  and  $T$  are in fact similar in the specified way) then  $M$  is an accurate representation of  $T$ . The latter transpires from the simple observation that a judgment of accuracy in fact presupposes a choice of respects in which  $M$  and  $T$  are claimed to be similar. Simply proposing that they are similar in some unspecified respect is vacuous. But delineating relevant properties could potentially provide an answer to the problem of style. For example, if  $M$  and  $T$  are proposed to be similar with respect to their causal structure, then we might have a style of causal modeling; if  $M$  and  $T$  are proposed to be similar with respect to structural properties, then we might have a style of structural modeling; and so on and so forth. So the idea is that if  $M$  representing  $T$  involves the claim that  $M$  and  $T$  are similar in a certain respect, the respect chosen specifies the style of the representation; and if  $M$  and  $T$  are in fact similar in that respect (and to the specified degree), then  $M$  accurately represents  $T$  within that style.

In this section we investigate both options. But before delving into the details, let us briefly step back and reflect on possible constraints on viable answers. Taking his cue from Lopes' [3.59] discussion of pictures, Downes [3.80, pp. 421–422] proposes two constraints on allowable notions of similarity. The first, which he calls the *independence challenge*, requires that a user must be able to specify the relevant representation-grounding similarity *before* engaging in a comparison between  $M$  and  $T$ . Similarities that are recognizable only with hindsight are an unsound foundation of a representation. We agree with this requirement, which in fact is also a consequence of the surrogative reasoning condition: a model can generate novel hypotheses only if (at least some of the) similarity claims are not known only *ex post facto*.

Downes' second constraint, the *diversity constraint*, is the requirement that the relevant notion of similarity has to be identical in all kinds of representation and across all representational styles. So all models must bear the same similarity relations to their targets. Whatever its merits in the case of pictorial representation, this observation does not hold water in the case

of scientific representation. Both Giere and Teller have insisted – rightly, in our view – that there need not be a substantive sense of similarity uniting all representations (see also Callender and Cohen [3.26, p. 77] for a discussion). A proponent of the similarity view is free to propose different kinds of similarity for different representations and is under no obligation to also show that they are special cases of some overarching conception of similarity.

We now turn to the issue of style. A first step in the direction of an understanding of styles is the explicit analysis of the notion of similarity. Unfortunately the philosophical literature contains surprisingly little explicit discussion about what it means for something to be similar to something else. In many cases similarity is taken to be primitive, possible worlds semantics being a prime example. The problem is then compounded by the fact that the focus is on comparative overall similarity instead rather than on similarity in respect and degrees; for a critical discussion see [3.81]. Where the issue is discussed explicitly, the standard way of cashing out what it means for an object to be similar to another object is to require that they co-instantiate properties. This is the idea that Quine [3.82, pp. 117–118] and Goodman [3.83, p. 443] had in mind in their influential critiques of the notion. They note that if all that is required for two things to be similar is that they co-instantiate *some* property, then everything is similar to everything else, since any pair of objects have at least one property in common.

The issue of similarity seems to have attracted more attention in psychology. In fact, the psychological literature provides formal accounts to capture it directly in more fully worked out accounts. The two most prominent suggestions are the *geometric* and *contrast* accounts (see [3.84] for an up-to-date discussion). The former, associated with Shepard [3.85], assigns objects a place in a multidimensional space based on values assigned to their properties. This space is then equipped with a metric and the degree of similarity between two objects is a function of the distance between the points representing the two objects in that space.

This account is based on the strong assumptions that values can be assigned to all features relevant to similarity judgments, which is deemed unrealistic. This problem is supposed to be overcome in Tversky's *contrast account* [3.86]. This account defines a graded notion of similarity based on a weighted comparison of properties. Weisberg ([3.33, Chap. 8], [3.87]) has recently introduced this account into the philosophy of science where it serves as the starting point for his so-called *weighted feature matching account of model world-relations*. This account is our primary interest here.

The account introduces a set  $\Delta$  of relevant properties. Let then  $\Delta_M \subseteq \Delta$  be the set of properties from  $\Delta$  that are instantiated by the model  $M$ ; likewise  $\Delta_T$  is the set of properties from  $\Delta$  instantiated by the target system. Furthermore let  $f$  be a ranking function assigning a real number to every subset of  $\Delta$ . The simplest version of a ranking function is one that assigns to each set the number of properties in the set, but rankings can be more complex, for instance by giving important properties more weight. The level of similarity between  $M$  and  $T$  is then given by the following equation [3.87, p. 788] (the notation is slightly amended)

$$S(M, T) = \theta f(\Delta_M \cap \Delta_T) - \alpha f(\Delta_M - \Delta_T) - \beta f(\Delta_T - \Delta_M),$$

where  $\alpha$ ,  $\beta$  and  $\theta$  are weights, which can in principle take any value. This equation provides “a similarity score that can be used in comparative judgments of similarity” [3.87, p. 788]. The score is determined by weighing the properties the model and target have in common against those they do not. (Thus we note that this account could be seen as a quantitative version of *Hesse’s* [3.88] theory of analogy in which properties that  $M$  and  $T$  share are the *positive analogy* and ones they don’t share are the *negative analogy*.) In the above formulation the similarity score  $S$  can in principle vary between any two values (depending on the choice of the ranking function and the value of the weights). One can then use standard mathematical techniques to renormalize  $S$  so that it takes values in the unit interval  $[0, 1]$  (these technical moves need not occupy us here and we refer the reader to *Weisberg* for details [3.33, Chap. 8]).

The obvious question at this point is how the various blanks in the account can be filled. First in line is the specification of a property set  $\Delta$ . *Weisberg* is explicit that there are no general rules to rely on and that “the elements of  $\Delta$  come from a combination of context, conceptualization of the target, and theoretical goals of the scientist” [3.33, p. 149]. Likewise, the ranking function as well as the values of weighting parameters depend on the goals of the investigation, the context, and the theoretical framework in which the scientists operate. *Weisberg* further divides the elements of  $\Delta$  into *attributes* and *mechanisms*. The former are the “the properties and patterns of a system” while the latter are the “underlying mechanism[s] that generates these properties” [3.33, p. 145]. This distinction is helpful in the application to concrete cases, but for the purpose of our conceptual discussion it can be set aside.

Irrespective of these choices, the similarity score  $S$  has a number of interesting features. First, it is asymmetrical for  $\alpha \neq \beta$ , which makes room for the pos-

sibility of  $M$  being similar to  $T$  to a different degree than  $T$  is similar to  $M$ . So  $S$  provides the asymmetrical notion of similarity mentioned in Sect. 3.3.1. Second,  $S$  has a property called *maximality*: everything is maximally similar to itself and every other nonidentical object is equally or less similar. Formally:  $S(A, A) \geq S(A, B)$  for all objects  $A$  and  $B$  as long as  $A \neq B$  [3.33, p. 154].

What does this account contribute to a response to the question of style? The answer, we think, is that it has heuristic value but does not provide substantive account. In fact, stylistic questions stand outside the proposed framework. The framework can be useful in bringing questions into focus, but eventually the substantive stylistic questions concern inclusion criteria for  $\Delta$  (what properties do we focus on?), the weight given by  $f$  to properties (what is the relative importance of properties?) and the value of the parameters (how significant are disagreements between the properties of  $M$  and  $T$ ?). These questions have to be answered outside the account. The account is a framework in which questions can be asked but which does not itself provide answers, and hence no classification of representational styles emerges from it.

Some will say that this is old news. *Goodman* denounced similarity as “a pretender, an impostor, a quack” [3.83, p. 437] not least because he thought that it merely put a label to something unknown without analyzing it. And even some proponents of the similarity view have insisted that no general characterization of similarity was possible. Thus *Teller* submits that [3.52, p. 402]:

“[t]here can be no general account of similarity, but there is also no need for a general account because the details of any case will provide the information which will establish just what should count as relevant similarity in that case.”

This amounts to nothing less than the admission that no analysis of similarity (or even different kinds of similarity) is possible and that we have to deal with each case in its own right.

Assume now, for the sake of argument, that the stylistic issues have been resolved and full specifications of relevant properties and their relative weights are available. It would then seem plausible to say that  $S(M, T)$  provides a degree of accuracy. This reading is supported by the fact that *Weisberg* paraphrases the role of  $S(M, T)$  as providing “standards of fidelity” [3.33, p. 147]. Indeed, in response to *Parker* [3.89], *Weisberg* claims that his weighted feature matching account is supposed to answer the ER-problem and provide standards of accuracy.

As we have seen above,  $S(M, T)$  is maximal if  $M$  is a perfect replica of  $T$  (with respect to the properties

in  $\Delta$ ), and the fewer properties  $M$  and  $T$  share, the less accurate the representation becomes. This lack of accuracy is then reflected in a lower similarity score. This is plausible and Weisberg's account is indeed a step forward in the direction of quantifying accuracy.

Weisberg's account is an elaborate version of the co-instantiation account of similarity. It improves significantly on simple versions, but it cannot overcome that account's basic limitations. Niiniluoto distinguishes between two different kinds of similarities [3.90, pp. 272–274]: partial identity and likeness (which also feature in Hesse's discussion of analogies, see, for instance [3.88, pp. 66–67]). Assume  $M$  instantiates the relevant properties  $P_1, \dots, P_n$  and  $T$  instantiates the relevant properties  $Q_1, \dots, Q_n$ . If these properties are identical, i. e., if  $P_i = Q_i$  for all  $i = 1, \dots, n$ , then  $M$  and  $T$  are similar in the sense of being *partially identical*. Partial identity contrasts with what Niiniluoto calls *likeness*.  $M$  and  $T$  are similar in the sense of likeness if the properties are not identical but similar themselves:  $P_i$  is similar to  $Q_i$  for all  $i = 1, \dots, n$ . So in likeness the similarity is located at the level of the properties themselves. For example, a red post box and a red London bus are similar with respect to their color, even if they do not instantiate the exact same shade of red. As Parker [3.89, p. 273] notes, Weisberg's account (like all co-instantiation accounts) deals well with partial identity, but has no systematic place for likeness. To deal with likeness Weisberg would in effect have to reduce likeness to partial identity by introducing *imprecise* properties which encompass the  $P_i$  and the  $Q_i$ . Parker [3.89] suggests that this can be done by introducing intervals in the feature set, for instance of the form “the value of feature  $X$  lies in the interval  $[x - \varepsilon, x + \varepsilon]$ ” where  $\varepsilon$  is a parameter specifying the precision of overlap. To illustrate she uses Weisberg's example of the San Francisco bay model and claims that in order to account for the similarity between the model and the actual bay with respect to their Froude number Weisberg has to claim something like [3.89, p. 273]:

“The Bay model and the real Bay share the property of having a Froude number that is within 0.1 of the real Bay's number. It is more natural to say that the Bay model and the real Bay have *similar* Froude numbers – similar in the sense that their values differ by at most 0.1.”

In his response Weisberg accepts this and argues that he is trying to provide a reductive account of similarity that bottoms out in properties shared and those not shared [3.91, p. 302]. But such interval-valued properties have to be part of  $\Delta$  in order for the formal account to capture them. This means that another important decision regarding whether or not  $M$  and  $T$  are

similar occurs outside of the formal account itself. The inclusion criteria on what goes into  $\Delta$  now not only has to delineate relevant properties, but, at least for the quantitative ones, also has to provide an interval defining when they qualify as similar. Furthermore, it remains unclear how to account for  $M$  and  $T$  to be alike with respect to their qualitative properties. The similarity between genuinely qualitative properties cannot be accounted for in terms of numerical intervals. This is a particularly pressing problem for Weisberg, because he takes the ability to compare models and their targets with respect to their qualitative properties as a central desideratum for any account of similarity between the two [3.33, p. 136].

### 3.3.3 Problems of Ontology

Another problem facing similarity-based approaches concerns their treatment of the ontology of models. If models are supposed to be similar to their targets in the ways specified by theoretical hypotheses or commentaries, then they must be the *kind* of things that can be so similar.

Some models are homely physical objects. The Army Corps of Engineers' model of the San Francisco bay is a water basin equipped with pumps to simulate the action of tidal flows [3.33]; ball and stick models of molecules are made of metal or wood [3.92]; the Phillips–Newlyn model of an economy is system of pipes and reservoirs [3.93]; and model organisms in biology are animals like worms and mice [3.46]. For models of this kind similarity is straightforward (at least in principle) because they are of the same ontological kind as their respective targets: they are material objects.

But many interesting scientific models are not like this. Two perfect spheres with a homogeneous mass distribution that interact only with each other (the Newtonian model of the Sun–Earth system) or a single-species population isolated from its environment and reproducing at fixed rate at equidistant time steps (the logistic growth model of a population) are what *Hacking* aptly describes as “something you hold in your head rather than your hands” [3.44, p. 216]. Following Thomson–Jones [3.94] we call such models *nonconcrete models*. The question then is what kind of objects nonconcrete models are. Giere submits that they are abstract objects ([3.60, p. 747], cf. [3.51, p. 270], [3.71, p. 81]):

“Models in advanced sciences such as physics and biology should be abstract objects constructed in conformity with appropriate general principles and specific conditions.”

The appeal to abstract entities brings a number of difficulties with it. The first is that the class of abstract

objects is rather large. Numbers and other objects of pure mathematics, classes, propositions, concepts, the letter *A*, and Dante's *Inferno* are abstract objects [3.95], and *Hale* [3.96, pp. 86–87] lists no less than 12 different possible characterizations of abstract objects. At the very least this list shows that there is great variety in abstract objects and classifying models as abstract objects adds little specificity to an account of what models are. *Giere* could counter that he limits attention to those abstract objects that possess “all and only the characteristics specified in the principles” [3.60, p. 745], where principles are general rules like Newton's laws of motion. He further specifies that he takes “abstract entities to be human constructions” and that “abstract models are definitely not to be identified with linguistic entities such as words or equations” [3.60, p. 747]. While this narrows down the choices somehow, it still leaves many options and ultimately the ontological status of models in a similarity account remains unclear.

*Giere* fails to expand on this ontological issue for a reason: he dismisses the problem as one that philosophers of science can set aside without loss. He voices skepticism about the view that philosophers of science “need a deeper understanding of imaginative processes and of the objects produced by these process” [3.97, p. 250] or that “we need say much more [...] to get on with the job of investigating the functions of models in science” [3.97].

We remain unconvinced about this skepticism, not least because there is an obvious yet fundamental issue with abstract objects. No matter how the above issues are resolved (and irrespective of whether they are resolved at all), at the minimum it is clear that models are *abstract* in the sense that they have no spatiotemporal location. *Teller* [3.52, p. 399] and *Thomson-Jones* [3.98] supply arguments suggesting that this alone causes serious problems for the similarity account. The similarity account demands that models can instantiate properties and relations, since this is a necessary condition on them being similar to their targets. In particular, it requires that models can instantiate the properties and relations mentioned in theoretical hypotheses or commentaries. But such properties and relations are typically *physical*. And if models have no spatiotemporal location, then they do not instantiate any such properties or relations. *Thomson-Jones'* example of the idealized pendulum model makes this clear. If the idealized pendulum is abstract then it is difficult to see how to make sense of the idea that it has a length, or a mass, or an oscillation period of any particular time.

An alternative suggestion due to *Teller* [3.52] is that we should instead say that whilst “concrete objects HAVE properties [...] properties are PARTS of models” [3.52, p. 399] (original capitalization). It is not

entirely clear what *Teller* means by this, but our guess is that he would regard models as bundles of properties. Target systems, as concrete objects, are the sorts of things that can instantiate properties delineated by theoretical hypotheses. Models, since they are abstract, cannot. But rather than being objects instantiating properties, a model can be seen as a bundle of properties. A collection of properties is an abstract entity that is the sort of thing that can contain the properties specified by theoretical hypotheses as parts. The similarity relation between models and their targets shifts from the co-instantiation of properties, to the idea that targets instantiate (relevant) properties that are parts of the model. With respect to what it means for a model to be a bundle of properties *Teller* claims that the “[d]etails will vary with ones account of instantiation, of properties and other abstract objects, and of the way properties enter into models” [3.52].

But as *Thompson-Jones* [3.98, pp. 294–295] notes, it is not obvious that this suggestion is an improvement on *Giere's* abstract objects. A bundle view incurs certain metaphysical commitments, chiefly the existence of properties and their abstractness, and a bundle view of objects, concrete or abstract, faces a number of serious problems [3.99]. One might speculate that addressing these issues would push *Teller* either towards the kind of more robust account of abstract objects that he endeavored to avoid, or towards a fictionalist understanding of models.

The latter option has been discussed by *Giere*, who points out that a natural response to *Teller's* and *Thomson-Jones'* problem is to regard models as akin to *imaginary* or *fictional* systems of the sort presented in novels and films. It seems true to say that *Sherlock* is a smoker, despite the fact that *Sherlock* an imaginary detective, and smoking is a physical property. At times, *Giere* seems sympathetic to this view. He says [3.97, p. 249]:

“it is widely assumed that a work of fiction is a creation of human imagination [...] the same is true of scientific models. So, ontologically, scientific models and works of fiction are on a par. They are both imaginary constructs.”

And he observes that [3.51, p. 278]:

“novels are commonly regarded as works of imagination. That, ontologically, is how we should think of abstract scientific models. They are creations of scientists imaginations. They have no ontological status beyond that.”

However, these seem to be occasional slips and he recently positioned himself as an outspoken opponent of any approach to models that likens them to literary

fiction. We discuss these approaches as well as Giere's criticisms of them in Sect. 3.6.

### 3.4 The Structuralist Conception

The structuralist conception of model-representation originated in the so-called semantic view of theories that came to prominence in the second half of the 20th century (*Suppes* [3.100], *van Fraassen* [3.101], and *Da Costa and French* [3.102] provide classical statements of the view; *Byerly* [3.103], *Chakravartty* [3.104], *Klein* [3.105] and *Portides* [3.106, 107] provide critical discussions). The semantic view was originally proposed as an account of theory structure rather than model-representation. The driving idea behind the position is that scientific theories are best thought of as collections of models. This invites the questions: What are these models, and how do they represent their target systems? Defenders of the semantic view of theories take models to be structures, which represent their target systems in virtue of there being some kind of *mapping* (isomorphism, partial isomorphism, homomorphism, ...) between the two. (It is worth noting that Giere, whose account of scientific representation we discussed in the previous section, is also associated with the semantic view, despite not subscribing to either of these positions.)

This conception has two *prima facie* advantages. The first advantage is that it offers a straightforward answer to the ER-problem, and one that accounts for surrogative reasoning: the mappings between the model and the target allow scientists to convert truths found in the model into claims about the target system. The second advantage concerns the applicability of mathematics. There is time-honored position in the philosophy of mathematics that sees mathematics as the study of structures; see, for instance, *Resnik* [3.108] and *Shapiro* [3.109]. It is a natural move for the scientific structuralist to adopt this point of view, which, without further ado, provides a neat explanation of how mathematics is used in scientific modeling.

#### 3.4.1 Structures and the Problem of Ontology

Almost anything from a concert hall to a kinship system can be referred to as a *structure*. So the first task for a structuralist account of representation is to articulate what notion of structure it employs. A number of different notions of structure have been discussed in the literature (for a review see *Thomson-Jones* [3.110]), but by far the most common and widely used is the notion

In sum, the similarity view is yet to be equipped with a satisfactory account of the ontology of models.

of structure one finds in set theory and mathematical logic. A structure  $S$  in that sense (sometimes *mathematical structure* or *set-theoretic structure*) is a composite entity consisting of the following: a nonempty set  $U$  of objects called the domain (or universe) of the structure and a nonempty indexed set  $R$  of relations on  $U$ . With the exception of the caveat below regarding interpretation functions, this definition of structure is widely used in mathematics and logic; see for instance *Machover* [3.111, p. 149], *Hodges* [3.112, p. 2], and *Rickart* [3.113, p. 17]. It is convenient to write these as  $S = \langle U, R \rangle$ , where  $\langle \cdot, \cdot \rangle$  denotes an ordered tuple. Sometimes operations are also included in the definition of a structure. While convenient in some applications, operations are redundant because operations reduce to relations (see *Boolos and Jeffrey* [3.114, pp. 98–99]).

It is important to be clear on what we mean by *object* and *relation* in this context. As *Russell* [3.115, p. 60] points out, in defining the domain of a structure it is irrelevant what the objects are. All that matters from a structuralist point of view is that there are so and so many of them. Whether the object is a desk or a planet is irrelevant. All we need are dummies or placeholders whose *only* property is *objecthood*. Similarly, when defining relations one disregards completely what the relation is *in itself*. Whether we talk about *being the mother of* or *standing to the left of* is of no concern in the context of a structure; all that matters is between which objects it holds. For this reason, a relation is specified purely extensionally: as a class of ordered  $n$ -tuples. The relation literally is nothing over and above this class. So a structure consists of dummy objects between which purely extensionally defined relations hold.

Let us illustrate this with an example. Consider the structure with the domain  $U = \{a, b, c\}$  and the following two relations:  $r_1 = \{a\}$  and  $r_2 = \{\langle a, b \rangle, \langle b, c \rangle, \langle a, c \rangle\}$ . Hence  $R$  consists of  $r_1$  and  $r_2$ , and the structure itself is  $S = \langle U, R \rangle$ . This is a structure with a three-object domain endowed with a monadic property and a transitive relation. Whether the objects are books or iron rods is of no relevance to the structure; they could be literally anything one can think of. Likewise  $r_1$  could be literally any monadic property (being green, being waterproof, etc.) and  $r_2$  could be any (irreflexive) transitive relation (larger than, hotter than, more expensive than, etc.).

It is worth pointing out that this use of *structure* differs from the use one sometimes finds in logic, where linguistic elements are considered part of the model as well. Specifically, over and above  $S = \langle U, R \rangle$ , a structure is also taken to include a language (sometimes called a *signature*)  $L$ , and an interpretation function ([3.112, Chap. 1] and [3.116, pp. 80–81]). But in the context of the accounts discussed in this section, a structure is the ordered pair  $S = \langle U, R \rangle$  as introduced above and so we disregard this alternative use of *structure*.

The first basic posit of the structuralist theory of representation is that models are structures in the above sense (the second is that models represent their targets by being suitably morphic to them; we discuss morphisms in the next subsection). *Suppes* has articulated this stance clearly when he declared that “the meaning of the concept of model is the same in mathematics and the empirical sciences” [3.117, p. 12]. Likewise, *van Fraassen* posits that a “scientific theory gives us a family of models to represent the phenomena”, that “[t]hese models are mathematical entities, so all they have is structure [...]” [3.118, pp. 528–529] and that therefore [3.118, p. 516]

“[s]cience is [...] interpreted as saying that the entities stand in relations which are transitive, reflexive, etc. but as giving no further clue as to what those relations are.”

*Redhead* submits that “it is this abstract structure associated with physical reality that science aims, and to some extent succeeds, to uncover [...]” [3.119, p. 75]. Finally, *French* and *Ladyman* affirm that “the specific material of the models is irrelevant; rather it is the structural representation [...] which is important” [3.120, p. 109]. Further explicit statements of this view are offered by: *Da Costa* and *French* [3.121, p. 249], *Suppes* ([3.122, p. 24], [3.123, Chap. 2]) and *van Fraassen* ([3.101, pp. 43, 64], [3.118, pp. 516, 522], [3.124, p. 483], [3.125, p. 6]).

These structuralist accounts have typically been proposed in the framework of the so-called semantic view of theories. There are differences between them, and formulations vary from author to author. However, as *Da Costa* and *French* [3.126] point out, all these accounts share a commitment to analyzing models as structures. So we are presented with a clear answer to the problem of ontology: models are structures. The remaining issue is what structures themselves are. Are they platonic entities, equivalence classes, modal constructs, or yet something else? This is a hotly debated issue in the philosophy of logic and mathematics; for different positions see for instance *Dummett* [3.127, 295ff.], *Hellman* [3.128, 129], *Redhead* [3.119], *Resnik* [3.108], and *Shapiro* [3.109].

But philosophers of science need not resolve this issue and can pass off the burden of explanation to philosophers of mathematics. This is what usually happens, and hence we don’t pursue this matter further.

An extension of the standard conception of structure is the so-called partial structures approach (for instance, *Da Costa* and *French* [3.102] and *Bueno* et al. [3.130]). Above we defined relations by specifying between which tuples it holds. This naturally allows a sorting of all tuples into two classes: ones that belong to the relation and ones that don’t. The leading idea of partial structures is to introduce a third option: for some tuples it is indeterminate whether or not they belong to the relation. Such a relation is a *partial relation*. A structure with a set  $R$  containing partial relations is a *partial structure* (formal definitions can be found in references given above). Partial structures make room for a process of scientific investigation where one begins not knowing whether a tuple falls under the relation and then learns whether or not it does.

Proponents of that approach are more guarded as regards the ontology of models. *Bueno* and *French* emphasize that “advocates of the semantic account need not be committed to the ontological claim that models *are* structures” [3.53, p. 890] (original emphasis). This claim is motivated by the idea that the task for philosophers of science is to represent scientific theories and models, rather than to reason about them directly. *French* [3.131] makes it explicit that according to his account of the semantic view of theories, a scientific theory is *represented* as a class of models, but should not be identified with that class. Moreover, a class of models is just one way of representing a theory; we can also use an intrinsic characterization and represent the same theory as a set of sentences in order to account for how they can be objects of our epistemic attitudes [3.132].

He therefore adopts a quietist position with respect to what a theory or a model *is*, declining to answer the question [3.131, 133]. There are thus two important notions of representation at play: representation of targets by models, which is the job of scientists, and representation of theories and models by structures, which is the job of philosophers of science. The question for this approach then becomes whether or not the structuralist representation of models and epistemic representation – as partial structures and morphisms that hold between them – is an accurate or useful one. And the concerns raised below remain when translated into this context as well.

There is an additional question regarding the correct formal framework for thinking about models in the structuralist position. *Landry* [3.134] argues that in certain contexts group, rather than set, theory should

be used when talking about structures and morphisms between them, and Halvorson [3.135, 136] argues that theories should be identified with categories rather than classes or sets. Although these discussions highlight important questions regarding the nature of scientific theories, the question of how individual models represent remains unchanged. Halvorson still takes individual models to be set-theoretic structures. And Landry's paper is not an attempt to reframe the representational relationship between models and their targets (see [3.137] for her skepticism regarding how structuralism deals with this question). Thus, for reasons of simplicity we will focus on the structuralist view that identifies models with set-theoretic structures throughout the rest of this section.

### 3.4.2 Structuralism and the ER-Problem

The most basic structuralist conception of scientific representation asserts that scientific models, understood as structures, represent their target systems in virtue of being isomorphic to them. Two structures  $S_a = \langle U_a, R_a \rangle$  and  $S_b = \langle U_b, R_b \rangle$  are isomorphic iff there is a mapping  $f: U_a \rightarrow U_b$  such that (i)  $f$  is one-to-one (bijective) and (ii)  $f$  preserves the system of relations in the following sense: The members  $a_1, \dots, a_n$  of  $U_a$  satisfy the relation  $r_a$  of  $R_a$  iff the corresponding members  $b_1 = f(a_1), \dots, b_n = f(a_n)$  of  $U_b$  satisfy the relation  $r_b$  of  $R_b$ , where  $r_b$  is the relation corresponding to  $r_a$  (for difficulties in how to cash out this notion of correspondence without reference to an interpretation function see Halvorson [3.135] and Glymour [3.138]).

Assume now that the target system  $T$  exhibits the structure  $S_T = \langle U_T, R_T \rangle$  and the model is the structure  $S_M = \langle U_M, R_M \rangle$ . Then the model represents the target iff it is isomorphic to the target:

#### **Definition 3.7 Structuralism 1**

A scientific model  $M$  represents its target  $T$  iff  $S_M$  is isomorphic to  $S_T$ .

This view is articulated explicitly by Ubbink, who posits that [3.139, p. 302]

“a model represents an object or matter of fact in virtue of this structure; so an object is a model [...] of matters of fact if, and only if, their structures are isomorphic.”

Views similar to Ubbink's seem operable in many versions of the semantic view. In fairness to proponents of the semantic view it ought to be pointed out, though, that for a long time representation was not the focus of attention in the view and the attribution of (something like) structuralism 1 (Definition 3.7) to the

semantic view is an extrapolation. Representation became a much-debated topic in the first decade of the 21st century, and many proponents of the semantic view then either moved away from structuralism 1 (Definition 3.7), or pointed out that they never held such a view. We turn to more advanced positions shortly, but to understand what motivates such positions it is helpful to understand why structuralism 1 (Definition 3.7) fails.

An immediate question concerns the target end structure  $S_T$ . At least *prima facie* target systems aren't structures; they are physical objects like planets, molecules, bacteria, tectonic plates, and populations of organisms. An early recognition that the relation between targets and structures is not straightforward can be found in Byerly, who emphasizes that structures are abstracted from objects [3.103, pp. 135–138]. The relation between structures and physical targets is indeed a serious question and we will return to it in Sect. 3.4.4. In this subsection we grant the structuralist the assumption that target systems are (or at least have) structures.

The first and most obvious problem is the same as with the similarity view: isomorphism is symmetrical, reflexive, and transitive, but epistemic representation isn't. This problem could be addressed by replacing isomorphism with an alternative mapping. Bartels [3.140], Lloyd [3.141], and Mundy [3.142] suggest homomorphism; van Fraassen [3.36, 101, 118] and Redhead isomorphic embeddings [3.119]; advocates of the partial structures approach prefer partial isomorphisms [3.102, 120, 121, 143–145]; and Swoyer [3.25] introduces what he calls  $\Delta/\Psi$ -morphisms. We refer to these collectively as *morphisms*.

This solves some, but not all problems. While many of these mappings are asymmetrical, they are all still reflexive, and at least some of them are also transitive. But even if these formal issues could be resolved in one way or another, a view based on structural mappings would still face other serious problems. For ease of presentation we discuss these problems in the context of the isomorphism view; *mutatis mutandis* other formal mappings suffer from the same difficulties (For detailed discussions of homomorphism and partial isomorphism see Suárez [3.23, pp. 239–241] and Pero and Suárez [3.146]; Mundy [3.142] discusses general constraints one may want to impose on morphisms.)

Like similarity, isomorphism is too inclusive: not all things that are isomorphic represent each other. In the case of similarity this case was brought home by Putnam's thought experiment with the ant crawling on the beach; in the case of isomorphism a look at the history of science will do the job. Many mathematical structures have been discovered and discussed long before they have been used in science. Non-Euclidean geometries were studied by mathematicians long before

Einstein used them in the context of spacetime theories, and Hilbert spaces were studied by mathematicians prior to their use in quantum theory. If representation was nothing over and above isomorphism, then we would have to conclude that Riemann discovered general relativity or that Hilbert invented quantum mechanics. This is obviously wrong. Isomorphism on its own does not establish representation [3.20, p. 10].

Isomorphism is more restrictive than similarity: not everything is isomorphic to everything else. But isomorphism is still too abundant to correctly identify the extension of a representation (i.e., the class of systems it represents), which gives rise to a version of the mistargeting problem. The root of the difficulties is that the same structures can be instantiated in different target systems. The  $1/r^2$  law of Newtonian gravity is also the *mathematical skeleton* of Coulomb's law of electrostatic attraction and the weakening of sound or light as a function of the distance to the source. The mathematical structure of the pendulum is also the structure of an electric circuit with condenser and solenoid (a detailed discussion of this case is provided by Kroes [3.147]). Linear equations are ubiquitous in physics, economics and psychology. Certain geometrical structures are instantiated by many different systems; just think about how many spherical things we find in the world. This shows that the same structure can be exhibited by more than one target system. Borrowing a term from the philosophy of mind, one can say that structures are *multiply realizable*. If representation is explicated solely in terms of isomorphism, then we have to conclude that, say, a model of a pendulum also represents an electric circuit. But this seems wrong. Hence isomorphism is too inclusive to correctly identify a representation's extension.

One might try to dismiss this point as an artifact of a misidentification of the target. Van Fraassen [3.101, p. 66], mentions a similar problem under the heading of "unintended realizations" and then expresses confidence that it will "disappear when we look at larger observable parts of the world". Even if there are multiply realizable structures to begin with, they vanish as science progresses and considers more complex systems because these systems are unlikely to have the same structure. Once we focus on a sufficiently large part of the world, no two phenomena will have the same structure. There is a problem with this counter, however. To appeal to *future science* to explain how models work *today* seems unconvincing. It is a matter of fact that we *currently* have models that represent electric circuits and sound waves, and we do not have to await future science providing us with more detailed accounts of a phenomenon to make our models represent what they actually already do represent.

As we have seen in the last section, a misrepresentation is one that portrays its target as having features it doesn't have. In the case of an isomorphism account of representation this presumably means that the model portrays the target as having structural properties that it doesn't have. However, isomorphism demands identity of structure: the structural properties of the model and the target must correspond to one another exactly. A misrepresentation won't be isomorphic to the target. By the lights of structuralism 1 (Definition 3.7) it is therefore is not a representation at all. Like simple similarity accounts, structuralism 1 (Definition 3.7) conflates misrepresentation with nonrepresentation.

Muller [3.148, p. 112] suggests that this problem can be overcome in a two-stage process: one first identifies a submodel of the model, which in fact is isomorphic to at least a part of the target. This *reduced* isomorphism establishes representation. One then constructs "a tailor-made morphism on a case by case basis" [3.148, p. 112] to account for accurate representation. Muller is explicit that this suggestion presupposes that there is "at least one resemblance" [3.148, p. 112] between model and target because "otherwise one would never be called a representation of the other" [3.148, p. 112]. While this may work in some cases, it is not a general solution. It is not clear whether all misrepresentations have isomorphic submodels. Models that are gross distortions of their targets (such as the liquid drop model of the nucleus or the logistic model of a population) may well not have such submodels. More generally, as Muller admits, his solution "precludes total misrepresentation" [3.148, p. 112]. So in effect it just limits the view that representation coincides with correct representation to a submodel. However, this is too restrictive a view of representation. Total misrepresentations may be useless, but they are representations nevertheless.

Another response refers to the partial structures approach and emphasizes that partial structures are in fact constructed to accommodate a mismatch between model and target and are therefore not open to this objection [3.53, p. 888]. It is true that the partial structures framework has a degree of flexibility that the standard view does not. However, we doubt that this flexibility stretches far enough. While the partial structure approach deals successfully with incomplete representations, it does not seem to deal well with distortive representations (we come back to this point in the next subsection). So the partial structures approach, while enjoying an advantage over the standard approach, is nevertheless not yet home and dry.

Like the similarity account, structuralism 1 (Definition 3.7) has a problem with nonexistent targets because no model can be isomorphic to something that doesn't

exist. If there is no ether, a model can't be isomorphic to it. Hence models without target cannot represent what they seem to represent.

Most of these problems can be resolved by making moves similar to the ones that lead to similarity 5 (Definition 3.6): introduce agents and hypothetical reasoning into the account of representation. Going through the motions one finds:

#### **Definition 3.8 Structuralism 2**

A scientific model  $M$  represents a target system  $T$  iff there is an agent  $A$  who uses  $M$  to represent a target system  $T$  by proposing a theoretical hypothesis  $H$  specifying an isomorphism between  $S_M$  and  $S_T$ .

Something similar to this was suggested by Adams [3.149, p. 259] who appeals to the idea that physical systems are the *intended* models of a theory in order to differentiate them from purely mathematical models of a theory. This suggestion is also in line with van Fraassen's recent pronouncements on representation. He offers the following as the *Hauptstatz* of a theory of representation: "there is no representation except in the sense that some things are used, made, or taken, to represent things as thus and so" [3.36, p. 23]. Likewise, Bueno submits that "representation is an *intentional* act relating two objects" [3.150, p. 94] (original emphasis), and Bueno and French point out that using one thing to represent another thing is not only a function of (partial) isomorphism but also depends on *pragmatic* factors "having to do with the use to which we put the relevant models" [3.53, p. 885]. This, of course, gives up on the idea of an account that reduces representation to intrinsic features of models and their targets. At least one extra element, the model user, also features in whatever relation is supposed to constitute the representational relationship between  $M$  and  $T$ . In a world with no agents, there would be no scientific representation.

This seems to be the right move. Like similarity 5 (Definition 3.6), structuralism 2 (Definition 3.8) accounts for the directionality of representation and has no problem with misrepresentation. But, again as in the case of similarity 5 (Definition 3.6), this is a Pyrrhic victory as the role of isomorphism has shifted. The crucial ingredient is the agent's intention and isomorphism has in fact become either a representational style or normative criterion for accurate representation. Let us now assess how well isomorphism fares as a response to these problems.

### **3.4.3 Accuracy, Style and Demarcation**

The problem of style is to identify representational styles and characterize them. Isomorphism offers an

obvious response to this challenge: one can represent a system by coming up with a model that is structurally isomorphic to it. We call this the isomorphism-style. This style also offers a clear-cut condition of accuracy: the representation is accurate if the hypothesized isomorphism holds; it is inaccurate if it doesn't.

This is a neat answer. The question is what status it has vis-à-vis the problem of style. Is the isomorphism-style merely one style among many other styles which are yet to be identified, or is it in some sense privileged? The former is uncontentious. However, the emphasis many structuralists place on isomorphism suggests that they do not regard isomorphism as merely one way among others to represent something. What they seem to have in mind is the stronger claim that a representation *must* be of that sort, or that the isomorphism-style is the only acceptable style.

This claim seems to conflict with scientific practice. Many representations are inaccurate in some way. As we have seen above, partial structures are well equipped to deal with incomplete representations. However, not all inaccuracies are due to something being left out. Some models distort, deform and twist properties of the target in ways that seem to undercut isomorphism. Some models in statistical mechanics have an infinite number of particles and the Newtonian model of the solar system represents the sun as perfect sphere where it in reality is fiery ball with no well-defined surface at all. It is at best unclear how isomorphism, partial or otherwise, can account for these kinds of idealizations. From an isomorphism perspective all one can say about such idealizations is that they are failed isomorphism representations (or isomorphism misrepresentations). This is rather uninformative. One might try to characterize these idealizations by looking at *how* they fail to be isomorphic to their targets, but we doubt that this is going very far. Understanding how distortive idealizations work requires a positive characterization of them, and we cannot see how such a characterization could be given within the isomorphism framework. So one has to recognize styles of representation other than isomorphism.

This raises that question of whether other mappings such as homomorphisms or embeddings would fit the bill. They would, we think, make valuable additions to the list of styles, but they would not fill all gaps. Like isomorphism, these mappings are not designed to accommodate distortive idealizations, and hence a list of styles that includes them still remains incomplete.

Structuralism's stand on the demarcation problem is by and large an open question. Unlike similarity, which has been widely discussed across different domains, isomorphism is tied closely to the formal framework of set theory, and it has been discussed only sparingly outside the context of the mathematized sciences. An ex-

ception is *French*, who discusses isomorphism accounts in the context of pictorial representation [3.35]. He discusses in detail *Budd's* [3.151] account of pictorial representation and points out that it is based on the notion of a structural isomorphism between the structure of the surface of the painting and the structure of the relevant visual field. Therefore representation is the perceived isomorphism of structure [3.35, pp. 1475–1476] (this point is reaffirmed by *Bueno* and *French* [3.53, pp. 864–865]; see *Downes* [3.80, pp. 423–425] for a critical discussion). In a similar vein, *Bueno* claims that the partial structures approach offers a framework in which different representations – among them “outputs of various instruments, micrographs, templates, diagrams, and a variety of other items” [3.150, p. 94] – can be accommodated. This would suggest that an isomorphism account of representation at least has a claim to being a universal account covering representations across different domains.

This approach faces a number of questions. First, neither a visual field nor a painting is a structure, and the notion of there being an isomorphism in the set theoretic sense between the two at the very least needs unpacking. The theory is committed to the claim that paintings and visual fields have structures, but, as we will see in the next subsection, this claim faces serious issues. Second, *Budd's* theory is only one among many theories of pictorial representation, and most alternatives do not invoke isomorphism. So there is question whether a universal claim can be built on *Budd's* theory. In fact, there is even a question about isomorphism's universality within scientific representation. Nonmathematized sciences work with models that aren't structures. *Godfrey-Smith* [3.152], for instance, argues that models in many parts of biology are imagined concrete objects. There is a question whether isomorphism can explain how models of that kind represent.

This points to a larger issue. The structuralist view is a rational reconstruction of scientific modeling, and as such it has some distance from the actual practice. Some philosophers have worried that this distance is too large and that the view is too far removed from the actual practice of science to be able to capture what matters to the practice of modeling (this is the thrust of many contributions to [3.11]; see also [3.73]). Although some models used by scientists may be best thought of as set theoretic structures, there are many where this seems to contradict how scientists actually talk about, and reason with, their models. Obvious examples include physical models like the San Francisco bay model [3.33], but also systems such as the idealized pendulum or imaginary populations of interbreeding animals. Such models have the strange property of being *concrete-if-real* and scientists talk about them as if they were real systems,

despite the fact that they are obviously not. *Thomson-Jones* [3.98] dubs this *face value practice*, and there is a question whether structuralism can account for that practice.

### 3.4.4 The Structure of Target Systems

Target systems are physical objects: atoms, planets, populations of rabbits, economic agents, etc. Isomorphism is a relation that holds between two structures and claiming that a set theoretic structure is isomorphic to a piece of the physical world is *prima facie* a category mistake. By definition, all of the mappings suggested – isomorphism, partial isomorphism, homomorphism, or isomorphic embedding – only hold between two structures. If we are to make sense of the claim that the model is isomorphic to its target we have to assume that the target somehow exhibits a certain structure  $S_T = \langle U_T, R_T \rangle$ . But what does it mean for a target system – a part of the physical world – to possess a structure, and where in the target system is the structure located?

The two prominent suggestions in the literature are that data models are the target end structures represented by models, and that structures are, in some sense, instantiated in target systems. The latter option comes in three versions. The first version is that a structure is ascribed to a system; the second version is that systems instantiate structural universals; and the third version claims that target systems simply are structures. We consider all suggestions in turn.

What are data models? Data are what we gather in experiments. When observing the motion of the moon, for instance, we choose a coordinate system and observe the position of the moon in this coordinate system at consecutive instants of time. We then write down these observations. The data thus gathered are called the *raw* data. The raw data then undergo a process of cleansing, rectification and regimentation: we throw away data points that are obviously faulty, take into consideration what the measurement errors are, take averages, and usually idealize the data, for instance by replacing discrete data points by a continuous function. Often, although not always, the result is a smooth curve through the data points that satisfies certain theoretical desiderata (*Harris* [3.153] and *van Fraassen* [3.36, pp. 166–168] elaborate on this process). These resulting data models can be treated as set theoretic structures. In many cases the data points are numeric and the data model is a smooth curve through these points. Such a curve is a relation over  $\mathbb{R}^n$  (for some  $n$ ), or subsets thereof, and hence it is structure in the requisite sense.

*Suppes* [3.122] was the first to suggest that data models are the targets of scientific models: models don't represent parts of the world; they represent data

structures. This approach has then been adopted by *van Fraassen*, when he declares that “[t]he whole point of having theoretical models is that they should fit the phenomena, that is, fit the models of data” [3.154, p. 667]. He has defended this position numerous times over the years ([3.77, p. 164], [3.101, p. 64], [3.118, p. 524], [3.155, p. 229] and [3.156, p. 271]) including in his most recent book on representation [3.36, pp. 246, 252]. So models don’t represent planets, atoms or populations; they represent data that are gathered when performing measurements on planets, atoms or populations.

This revisionary point of view has met with stiff resistance. *Muller* articulates the unease about this position as follows [3.148, p. 98]:

“the best one could say is that a data structure  $\mathcal{D}$  seems to act as *simulacrum* of the concrete actual being  $B$  [...] But this is not good enough. We don’t want simulacra. We want the real thing. Come on.”

*Muller*’s point is that science aims (or at least has to aim) to represent real systems in the world and not data structures. *Van Fraassen* calls this the “loss of reality objection” [3.36, p. 258] and accepts that the structuralist must ensure that models represent target systems, rather than finishing the story at the level of data. In his [3.36] he addresses this issue in detail and offers a solution. We discuss his solution below, but before doing so we want to articulate the objection in more detail. To this end we briefly revisit the discussion about phenomena and data which took place in the 1980s and 1990s.

*Bogen* and *Woodward* [3.157], *Woodward* [3.158], and more recently (and in a somewhat different guise) *Teller* [3.159], introduced the distinction between phenomena and data and argue that models represent phenomena, not data. The difference is best introduced with an example: the discovery of weak neutral currents [3.157, pp. 315–318]. What the model at stake consists of is particles: neutrinos, nucleons, and the  $Z^0$  particle, along with the reactions that take place between them. (The model we are talking about here is not the so-called standard model of elementary particles as a whole. Rather, what we have in mind is one specific model about the interaction of certain particles of the kind one would find in a theoretical paper on this experiment.) Nothing of that, however, shows in the relevant data. CERN (Conseil Européen pour la Recherche Nucléaire) in Geneva produced 290 000 bubble chamber photographs of which roughly 100 were considered to provide evidence for the existence of neutral currents. The notable point in this story is that there is no part of the model (provided by quantum field theory) that could be claimed to be isomorphic to these pho-

tographs. Weak neutral currents are the phenomenon under investigation; the photographs taken at CERN are the raw data, and any summary one might construct of the content of these photographs would be a data model. But it’s weak neutral currents that occur in the model; not any sort of data we gather in an experiment.

This is not to say that these data have nothing to do with the model. The model posits a certain number of particles and informs us about the way in which they interact both with each other and with their environment. Using this knowledge we can place them in a certain experimental context. The data we then gather in an experiment are the product of the elements of the model and of the way in which they operate in that context. Characteristically this context is one that we are able to control and about which we have reliable knowledge (knowledge about detectors, accelerators, photographic plates and so on). Using this and the model we can derive predictions about what the outcomes of an experiment will be. But, and this is the salient point, these predictions involve the entire experimental setup and not only the model and there is nothing in the model itself with which one could compare the data. Hence, data are highly contextual and there is a big gap between observable outcomes of experiments and anything one might call a substructure of a model of neutral currents.

To underwrite this claim *Bogen* and *Woodward* notice that parallel to the research at CERN, the National Accelerator Laboratory (NAL) in Chicago also performed an experiment to detect weak neutral currents, but the data obtained in that experiment were quite different. They consisted of records of patterns of discharge in electronic particle detectors. Though the experiments at CERN and at NAL were totally different and as a consequence the data gathered had nothing in common, they were meant to provide evidence for the same theoretical model. But the model, to reiterate the point, does not contain any of these contextual factors. It posits certain particles and their interaction with other particles, not how detectors work or what readings they show. That is, the model is not idiosyncratic to a special experimental context in the way the data are and therefore it is not surprising that they do not contain a substructure that is isomorphic to the data. For this reason, models represent phenomena, not data.

It is difficult to give a general characterization of phenomena because they do not belong to one of the traditional ontological categories [3.157, p. 321]. In fact, phenomena fall into many different established categories, including particular objects, features, events, processes, states, states of affairs, or they defy classification in these terms altogether. This, however, does not detract from the usefulness of the concept of a phe-

nomenon because specifying one particular ontological category to which all phenomena belong is inessential to the purpose of this section. What matters to the problem at hand is the distinctive role they play in connection with representation.

What then is the significance of data, if they are not the kind of things that models represent? The answer to this question is that data perform an evidential function. That is, data play the role of evidence for the presence of certain phenomena. The fact that we find a certain pattern in a bubble chamber photograph is evidence for the existence of neutral currents. Thus construed, we do not denigrate the importance of data in science, but we do not have to require that data have to be embeddable into the model at stake.

Those who want to establish data models as targets can reply to this in three ways. The first reply is an appeal to radical empiricism. By postulating phenomena over and above data we leave the firm ground of observable things and started engaging in transempirical speculation. But science has to restrict its claims to observables and remain silent (or at least agnostic) about the rest. Therefore, so the objection goes, phenomena are chimeras that cannot be part of any serious account of science. It is, however, doubtful that this helps the data model theorist. Firstly, note that it even rules out representing *observable phenomena*. To borrow *van Fraassen's* example on this story, a population model of deer reproduction would represent data, rather than deer [3.36, pp. 254–260]. Traditionally, empiricists would readily accept that deer, and the rates at which they reproduce, are observable phenomena. Denying that they are represented, by replacing them with data models, seems to be an implausible move. Secondly, irrespective of whether one understands phenomena realistically [3.157] or antirealistically [3.160], it is phenomena that models portray and not data. To deny the reality of phenomena just won't make a theoretical model *represent* data. Whether we regard neutral currents as real or not, it is neutral currents that are portrayed in a field-theoretical model, not bubble chamber photographs. Of course, one can suspend belief about the reality of these currents, but that is a different matter.

The second reply is to invoke a chain of representational relationships. *Brading* and *Landry* [3.137] point out that the connection between a model and the world can be broken down in two parts: the connection between a model and a data model, and the connection between a data model and the world [3.137, p. 575]. So the structuralist could claim that scientific models represent data models in virtue of an isomorphism between the two and additionally claim that data models in turn represent phenomena. But the key questions that

need to be addressed here are: (a) What establishes the representational relationship between data models and phenomena? and (b) Why if a scientific model represented some data model, which in turn represented some phenomenon, would that establish a representational relationship between the model and the phenomenon itself? With respect to the first question, *Brading* and *Landry* argue that it cannot be captured within the structuralist framework [3.137, p. 575]. The question has just been pushed back: rather than asking how a scientific model qua mathematical structure represents a phenomenon, we now ask how a data model qua mathematical structure represents a phenomenon. With respect to the second question, although representation is not intransitive, it is not transitive [3.20, pp. 11–12]. So more needs to be said regarding how a scientific model representing a data model, which in turn represents the phenomenon from which data are gathered, establishes a representational relationship between the first and last element in the representational chain.

The third reply is due to *van Fraassen* [3.36]. His *Wittgensteinian* solution is to diffuse the loss of reality objection. Once we pay sufficient attention to the pragmatic features of the contexts in which scientific and data models are used, *van Fraassen* claims, there actually is no difference between representing data and representing a target (or a phenomenon in Bogen and Woodward's sense) [3.36, p. 259]:

“in a context in which a given [data] model is *someone's* representation of a phenomenon, there is *for that person* no difference between the question *whether a theory* [theoretical model] *fits that representation* and the question *whether that theory fits the phenomenon.*”

*Van Fraassen's* argument for this claim is long and difficult and we cannot fully investigate it here; we restrict attention to one crucial ingredient and refer the reader to *Nguyen* [3.161] for a detailed discussion of the argument.

Moore's paradox is that we cannot assert sentences of the form *p and I don't believe that p*, where *p* is an arbitrary proposition. For instance, someone cannot assert that Napoleon was defeated in the battle of Waterloo and assert, at the same time, that she doesn't believe that Napoleon was defeated in the battle of Waterloo. *Van Fraassen's* treatment of Moore's paradox is that speakers cannot assert such sentences because the pragmatic commitments incurred by asserting the first conjunct include that the speaker believe that *p*. This commitment is then contradicted by the assertion of the second conjunct. So instances of Moore's paradox are pragmatic contradictions. *Van Fraassen* then draws an analogy between this paradox and the scientific representation. He

submits that a user simply cannot, on pain of pragmatic contradiction, assert that a data model of a target system be embeddable within a theoretical model without thereby accepting that the theoretical model represents the target.

However, *Nguyen* [3.161] argues that in the case of using a data model as a representation of a phenomenon, no such pragmatic commitment is incurred, and therefore no such contradiction follows when accompanied by doubt that the theoretical model also represents the phenomenon. To see why this is the case, consider a more mundane example of representation: a caricaturist can represent Margaret Thatcher as draconian without thereby committing himself to the belief that Margaret Thatcher really is draconian. Pragmatically speaking, acts of representation are weaker than acts of assertion: they do not incur the doxastic commitments required for van Fraassen's analogy to go through. So it seems van Fraassen doesn't succeed in dispelling the loss of reality objection. How target systems enter the picture in the structuralist account of scientific representation remains therefore a question that structuralists who invoke data models as providing the target-end structures must address. Without such an account the structuralist account of representation remains at the level of data, a position that seems implausible, and contrary to actual scientific practice.

We now turn to the second response: that a structure is instantiated in the system. As mentioned above, this response comes in three versions. The first is metaphysically more parsimonious and builds on the systems' constituents. Although target systems are not structures, they are composed of parts that instantiate physical properties and relations. The parts can be used to define the domain of individuals, and by considering the physical properties and relations purely extensionally, we arrive at a class of extensional relations defined over that domain (see for instance *Suppes'* discussion of the solar system [3.100, p. 22]). This supplies the required notion of structure. We might then say that physical systems instantiate a certain structure, and it is this structure that models are isomorphic to.

As an example consider the methane molecule. The molecule consists of a carbon atom and four hydrogen atoms grouped around it, forming a tetrahedron. Between each hydrogen atom and the carbon atom there is a covalent bond. One can then regard the atoms as objects and the bonds are relations. Denoting the carbon atom by  $a$ , and the four hydrogen atoms by  $b$ ,  $c$ ,  $d$ , and  $e$ , we obtain a structure  $S$  with the domain  $U = \{a, b, c, d, e\}$  and the relation  $r = \{\langle a, b \rangle, \langle b, a \rangle, \langle a, c \rangle, \langle c, a \rangle, \langle a, d \rangle, \langle d, a \rangle, \langle a, e \rangle, \langle e, a \rangle\}$ , which can be interpreted as *being connected by a covalent bond*.

The main problem facing this approach is the underdetermination of target-end structure. Underdetermination threatens in two distinct ways. Firstly, in order to identify the structure determined by a target system, a domain of objects is required. What counts as an object in a given target system is a substantial question [3.21]. One could just as well choose bonds as objects and consider the relation *sharing a node with another bond*. Denoting the bonds by  $a'$ ,  $b'$ ,  $c'$  and  $d'$ , we obtain a structure  $S'$  with the domain  $U' = \{a', b', c', d'\}$  and the relation  $r' = \{\langle a', b' \rangle, \langle b', a' \rangle, \langle a', c' \rangle, \langle c', a' \rangle, \langle a', d' \rangle, \langle d', a' \rangle, \langle b', c' \rangle, \langle c', b' \rangle, \langle b', d' \rangle, \langle d', b' \rangle, \langle c', d' \rangle, \langle d', c' \rangle\}$ . Obviously  $S$  and  $S'$  are not isomorphic. So which structure is picked out depends on how the system is described. Depending on which parts one regards as individuals and what relation one chooses, very different structures can emerge. And it takes little ingenuity to come up with further descriptions of the methane molecule, which lead to yet other structures.

There is nothing special about the methane molecule, and any target system can be presented under alternative descriptions, which ground different structures. So the lesson learned generalizes: there is no such thing as *the* structure of a target system. Systems only have a structure under a particular description, and there are many nonequivalent descriptions. This renders talk about a model being isomorphic to target system *simpliciter* meaningless. Structural claims do not *stand on their own* in that their truth rests on the truth of a more concrete description of the target system. As a consequence, descriptions are an integral part of an analysis of scientific representation.

In passing we note that *Frigg* [3.21, pp. 55–56] also provides another argument that pulls in the same direction: structural claims are abstract and are true only relative to a more concrete nonstructural description. For a critical discussion of this argument see *Frisch* [3.162, pp. 289–294] and *Portides*, Chap. 2.

How much of a problem this is depends on how austere one's conception of models is. The semantic view of theories was in many ways the result of an antilinguistic turn in the philosophy of science. Many proponents of the view aimed to exorcise language from an analysis of theories, and they emphasized that the model-world relationship ought to be understood as a *purely* structural relation. *Van Fraassen*, for instance, submits that “no concept which is essentially language dependent has any philosophical importance at all” [3.101, p. 56] and observes that “[t]he semantic view of theories makes language largely irrelevant” [3.155, p. 222]. And other proponents of the view, while less vocal about the irrelevance of language, have not assigned language a systematic place in their analysis of theories.

For someone of that provenance the above argument is bad news. However, a more attenuated position could integrate descriptions in the package of modeling, but this would involve abandoning the idea that representation can be cashed out solely in structural terms. *Bueno* and *French* have recently endorsed such a position. They accept the point that different descriptions lead to different structures and explain that such descriptions would involve “at the very least some minimal mathematics and certain physical assumptions” [3.53, p. 887]. Likewise, Munich structuralists explicitly acknowledge the need for a concrete description of the target system [3.163, pp. 37–38], and they consider these *informal descriptions* to be *internal* to the theory. This is a plausible move, but those endorsing this solution have to concede that there is more to epistemic representation than structures and morphisms.

The second way in which structural indeterminacy can surface is via Newman’s theorem. The theorem essentially says that any system instantiates any structure, the only constraint being cardinality (a practically identical conclusion is reached in Putnam’s so called model-theoretic argument; see *Demopoulos* [3.164] for a discussion). Hence, any structure of cardinality  $C$  is isomorphic to a target of cardinality  $C$  because the target instantiates any structure of cardinality  $C$  (see *Ketland* [3.165] and *Frigg* and *Votsis* [3.166] for discussions). This problem is not unsolvable, but all solutions require that among all structures formally instantiated by a target system one is singled out as being the true or natural structure of the system. How to do this in the structuralist tradition remains unclear (*Ainsworth* [3.167] provides a useful summary of the different solutions).

Newman’s theorem is both stronger and weaker than the argument from multiple descriptions. It’s stronger in that it provides more alternative structures than multiple descriptions. It’s weaker in that many of the structures it provides are *unphysical* because they are purely set theoretical combinations of elements. By contrast, descriptions pick out structures that a system can reasonably be seen as possessing.

The second version of the second response emerges from the literature on the applicability of mathematics. Structural platonists like *Resnik* [3.108] and *Shapiro* [3.41, 109, 168] take structures to be *ante rem* universals. In this view, structures exist independently of physical systems, yet they can be instantiated in physical systems. In this view systems instantiate structures and models are isomorphic to these instantiated structures.

This view raises all kind of metaphysical issues about the ontology of structures and the instantiation relation. Let us set aside these issues and assume that they

can be resolved in one way or another. This would still leave us with serious epistemic and semantic questions. How do we know a certain structure is instantiated in a system and how do we refer to it? Objects do not come with labels on their sleeves specifying which structures they instantiate, and proponents of structural universals face a serious problem in providing an account of *how we access* the structures instantiated by target systems. Even if – as a brute metaphysical fact – target systems only instantiate a small number of structures, and therefore there is a substantial question regarding whether or not scientific models represent them, this does not help us understand how we could ever come to know whether or not the isomorphism holds. It seems that individuating a domain of objects and identifying relations between them is the only way for us to access a structure. But then we are back to the first version of the response, and we are again faced with all the problems that it raises.

The third version of the second response is more radical. One might take target systems themselves to be structures. If this is the case then there is no problem with the idea that they can be isomorphic to a scientific model. One might expect ontic structural realists to take this position. If the world fundamentally is a structure, then there is nothing mysterious about the notion of an isomorphism between a model and the world. Surprisingly, some ontic structuralists have been hesitant to adopt such a view (see *French* and *Ladyman* [3.120, p. 113] and *French* [3.169, p. 195]). Others, however, seem to endorse it. *Tegmark* [3.170], for instance, offers an explicit defense of the idea that the world simply is a mathematical structure. He defines a seemingly moderate form of realism – what he calls the *external reality hypothesis* (ERH) – as the claim that “there exists an external physical reality completely independent of us humans” [3.170, p. 102] and argues that this entails that the world is a mathematical structure (his “mathematical universe hypothesis”) [3.170, p. 102]. His argument for this is based on the idea that a so-called *theory of everything* must be expressible in a form that is devoid of human-centric *baggage* (by the ERH), and the only theories that are devoid of such baggage are mathematical, which, strictly speaking, describe mathematical structures. Thus, since a complete theory of everything describes an external reality independent of humans, and since it describes a mathematical structure, the external reality itself *is* a mathematical structure.

This approach stands or falls on the strengths of its premise that a complete theory of everything will be formulated purely mathematically, without any human baggage, which in turn relies on a strict reductionist account of scientific knowledge [3.170, pp. 103–104]. Discussing this in any detail goes beyond our current

purposes. But it is worth noting that Tegmark’s discussion is focused on the claim that *fundamentally* the world is a mathematical structure. Even if this were the case, it seems irrelevant for many of our current scientific models, whose targets aren’t at this level. When modeling an airplane wing we don’t refer to the funda-

mental super-string structure of the bits of matter that make up the wing, and we don’t construct wing models that are isomorphic to such fundamental structures. So Tegmark’s account offers no answer to the question about where structures are to be found at the level of nonfundamental target systems.

## 3.5 The Inferential Conception

In this section we discuss accounts of scientific representation that analyze representation in terms of the inferential role of scientific models. On the previous accounts discussed, a model’s inferential capacity dropped out of whatever it was that was supposed to answer the ER-problem: proposed morphisms or similarity relations between models and their targets for example. The accounts discussed in this section build the notion of surrogative reasoning directly into the conditions on epistemic representation.

### 3.5.1 Deflationary Inferentialism

Suárez argues that we should adopt a “deflationary or minimalist attitude and strategy” [3.32, p. 770] when addressing the problem of epistemic representation. We will discuss deflationism in some detail below, but in order to formulate and discuss Suárez’s theory of representation we need at least a preliminary idea of what is meant by a deflationary attitude. In fact two different notions of deflationism are in operation in his account. The first is [3.32, p. 771]:

“abandoning the aim of a substantive theory to seek universal necessary and sufficient conditions that are met in each and every concrete real instance of scientific representation [...] necessary conditions will certainly be good enough.”

We call the view that a theory of representation should provide only necessary conditions *n*-deflationism (*n* for *necessary*). The second notion is that we should seek “no deeper features to representation other than its surface features” [3.32, p. 771] or “platitudes” [3.171, p. 40], and that we should deny that an analysis of a concept “is the kind of analysis that will shed explanatory light on our use of the concept” [3.172, p. 39]. We call this position *s*-deflationism (*s* for *surface feature*). As far as we can tell, Suárez intends his account of representation to be deflationary in both senses.

Suárez dubs the account that satisfies these criteria *inferentialism* [3.32, p. 773]:

#### Definition 3.9 Inferentialism 1

A scientific model *M* represents a target *T* only if (i) the representational force of *M* points towards *T*, and (ii) *M* allows competent and informed agents to draw specific inferences regarding *T*.

Notice that this condition is not an instantiation of the ER-scheme: in keeping with *n*-deflationism it features a material conditional rather than a biconditional and hence provides necessary (but not sufficient) conditions for *M* to represent *T*. We now discuss each condition in turn, trying to explicate in what way they satisfy *s*-deflationism.

The first condition is designed to make sure that *M* and *T* indeed enter into a representational relationship, and Suárez stresses that representational force is “necessary for any kind of representation” [3.32, p. 776]. But explaining representation in terms of representational force seems to shed little light on the matter as long as no analysis of representational force is offered. Suárez addresses this point by submitting that the first condition can be “satisfied by mere stipulation of a target for any source” [3.32, p. 771]. This might look like denotation as in Sect. 3.2. But Suárez stresses that this is not what he intends for two reasons. Firstly, he takes denotation to be a substantive relation between a model and its target, and the introduction of such a relation would violate the requirement of *s*-deflationism [3.172, p. 41]. Secondly, *M* can denote *T* only if *T* exists. Thus including denotation as a necessary condition on scientific representation “would rule out fictional representation, that is, representation of nonexistent entities” [3.32, p. 772], and “any adequate account of scientific representation must accommodate representations with fictional or imaginary targets” [3.172, p. 44].

The second issue is one that besets other accounts of representation too, in particular similarity and isomorphism accounts. The first reason, however, goes right to the heart of Suárez’s account: it makes good on the *s*-deflationary condition that nothing other than surface features can be included in an account of representation.

At a surface level one cannot explicate *representational force* at all and any attempt to specify what representational force consists in is a violation of *s*-deflationism.

The second necessary condition, that models allow competent and informed agents to draw specific inferences about their targets, is in fact just the *surrogative reasoning condition* we introduced in Sect. 3.1, now taken as a necessary condition on epistemic representation. The sorts of inferences that models allow are not constrained. Suárez points out that the condition “does not require that [*M*] allow deductive reasoning and inference; any type of reasoning inductive, analogical, abductive – is in principle allowed” [3.32, p. 773]. (The insistence on inference makes Suárez’s account an instance of what Chakravarty [3.173] calls a *functional conception* of representation.)

A problem for this approach is that we are left with no account of how these inferential rules are generated: what is it about models that allows them to license inferences about their targets, or what leads them to license some inferences and not others? Contessa makes this point most stridently when he argues that [3.29, p. 61]:

“On the inferential conception, the user’s ability to perform inferences from a vehicle [model] to a target seems to be a brute fact, which has no deeper explanation. This makes the connection between epistemic representation and valid surrogative reasoning needlessly obscure and the performance of valid surrogative inferences an activity as mysterious and unfathomable as soothsaying or divination.”

This seems correct, but Suárez can dismiss this complaint by appeal to *s*-deflationism. Since inferential capacity is supposed to be a surface-level feature of scientific representation, we are not supposed to ask for any elucidation about what makes an agent competent and well informed and how inferences are drawn.

For these reasons Suárez’s account is deflationary both in the sense of *n*-deflationism and of *s*-deflationism. His position provides us with a concept of epistemic representation that is cashed out in terms of an inexplicable notion of representational force and of an inexplicable capacity to ground inferences. This is very little indeed. It is the adoption of a deflationary attitude that allows him to block any attempt to further unpack these conditions and so the crucial question is: why should one adopt deflationism?

We turn to this question shortly. Before doing so we want to briefly outline how the above account fares with respect to the other problems introduced in Sect. 3.1. The account provides a neat explanation of the possibility of misrepresentation [3.32, p. 776]:

“part (ii) of this conception accounts for inaccuracy since it demands that we correctly draw inferences from the source about the target, but it does not demand that the conclusions of these inferences be all true, nor that all truths about the target may be inferred.”

Models represent their targets only if they license inferences about them. They represent them accurately to the extent that the conclusions of these inferences are true.

With respect to the representational demarcation problem, Suárez illustrates his account with a large range of representations, including diagrams, equations, scientific models, and nonscientific representations such as artistic portraits. He explicitly states that “if the inferential conception is right, scientific representation is in several respects very close to iconic modes of representation like painting” [3.32, p. 777] and he mentions the example of Velázquez’s portrait of Innocent X [3.32]. It is clear that the conditions of inferentialism 1 (Definition 3.9) are met by nonscientific as well as scientific epistemic representations. So, at least without sufficient conditions, there is no clear way of demarcating between the different kinds of epistemic representation.

Given the wide variety of types of representation that this account applies to, it’s unsurprising that Suárez has little to say about the ontological problem. The only constraint that inferentialism 1 (Definition 3.9) places on the ontology of models is that “[i]t requires [*M*] to have the internal structure that allows informed agents to correctly draw inferences about [*T*]” [3.32, p. 774]. And relatedly, since the account is supposed to apply to a wide variety of entities, including equations and mathematical structures, the account implies that mathematics is successfully applied in the sciences, but in keeping with the spirit of deflationism no explanation is offered about how this is possible.

Suárez does not directly address the problem of style, but a minimalist answer emerges from what he says about representation. On the one hand he explicitly acknowledges that many different kinds of inferences are allowed by the second condition in inferentialism 1 (Definition 3.9). In the passage quoted above he mentions inductive, analogical and abductive inferences. This could be interpreted as the beginning of classification of representational styles. On the other hand, Suárez remains silent about what these kinds are and about how they can be analyzed. This is unsurprising because spelling out what these inferences are, and what features of the model ground them, would amount to giving a substantial account, which is something Suárez wants to avoid.

Let us now return to the question about the motivation for deflationism. As we have seen, a commitment to deflationism about the concept is central to Suárez's approach to scientific representation. But deflationism comes in different guises, which Suárez illustrates by analogy with deflationism with respect to truth. Suárez [3.172] distinguishes between the *redundancy* theory (associated with Frank Ramsey and also referred to as the *no theory* view), *abstract minimalism* (associated with Crispin Wright) and the *use theory* (associated with Paul Horwich). What all three are claimed to have in common is that they accept the disquotational schema – i. e., instances of the form:  $P$  is true iff  $P$ . Moreover they [3.172, p. 37]

“either do not provide an analysis in terms of necessary and sufficient conditions, or if they do provide such conditions, they claim them to have no explanatory purchase.”

He claims that the redundancy theory of truth is characterized by the idea that [3.172, p. 39]:

“the terms *truth* and *falsity* do not admit a theoretical elucidation or analysis. But that, since they can be eliminated in principle – if not in practice – by disquotation, they do not in fact require such an analysis.”

So, as Suárez characterizes the position, the redundancy theory denies that any necessary and sufficient conditions for application of the truth predicate case be given. He argues that [3.172]:

“the generalization of this *no-theory theory* for any given putative concept  $X$  is the thought that  $X$  neither possesses nor requires necessary and sufficient conditions because it is not in fact a *genuine*, explanatory or substantive concept.”

This motivates  $n$ -deflationism (although one might ask why such a position would allow even necessary conditions. Suárez doesn't discuss this).

This approach faces a number of challenges. First, the argument is based on the premise that if deflationism is good for truth it must be good for representation. This premise is assumed tacitly. There is, however, a question whether the analogy between truth and representation is sufficiently robust to justify subjecting them to the same theoretical treatment. Surprisingly, Suárez offers little by way of explicit argument in favor of any sort of deflationary account of epistemic representation. In fact, the natural analogue of the linguistic notion of truth is accurate epistemic representation, rather than epistemic representation itself, which may be more appropriately compared with linguistic meaning. Second, the argument insinuates that deflationism is the cor-

rect analysis of truth. This, however, is far from an established fact. Different positions are available in the debate and whether deflationism (or any specific version of it) is superior to other proposals remains a matter of controversy (see, for instance, Kühne [3.174]). But as long as it's not clear that deflationism about truth is a superior position, it's hard to see how one can muster support for deflationism about representation by appealing to deflationism about truth.

Moreover, a position that allows only necessary conditions on epistemic representation faces a serious problem. While such an account allows us to *rule out* certain scenarios as instances of epistemic representation (for example a proper name doesn't allow for a competent and well informed language user to draw any specific inferences about its bearer and Callender and Cohen's salt shaker doesn't allow a user to draw any specific inferences about Madagascar), the lack of sufficient conditions doesn't allow us to *rule in* any scenario as an instance of epistemic representation. So on the basis of inferentialism 1 (Definition 3.9) we are never in position to assert that a particular model actually is a representation, which is an unsatisfactory situation.

The other two deflationary positions in the debate over truth are abstract minimalism and the use theory. Suárez characterizes the use theory as being based on the idea that “truth is nominally a property, although not a substantive or explanatory one, which is essentially defined by the platitudes of its use of the predicate in practice” [3.172, p. 40]. Abstract minimalism is presented as the view that while truth is [3.172, p. 40]:

“legitimately a property, which is abstractly characterized by the platitudes, it is a property that cannot explain anything, in particular it fails to explain the norms that govern its very use in practice.”

Both positions imply that necessary and sufficient conditions for truth *can* be given [3.172]. But on either account, such conditions only capture nonexplanatory surface features. This motivates  $s$ -deflationism.

Since  $s$ -deflationism explicitly allows for necessary and sufficient conditions, inferentialism 1 (Definition 3.9) can be extended to an instance of the ER-scheme, providing necessary and sufficient conditions (which also seems to be in line with Suárez and Solé [3.171, p. 41] who provide a formulation of inferentialism with a biconditional):

#### **Definition 3.10 Inferentialism 2**

A scientific model  $M$  represents a target  $T$  iff (i) the representational force of  $M$  points towards  $T$ , and (ii)  $M$  allows competent and informed agents to draw specific inferences regarding  $T$ .

If one takes conditions (i) and (ii) to refer to “features of activates within a normative practice, [that] do not stand for relations between sources and targets” [3.172, p. 46], then we arrive at a *use-based* account of epistemic representation. In order to understand a particular instance of a model  $M$  representing a target  $T$  we have to understand how scientists go about establishing that  $M$ 's representational force points towards  $T$ , and the inferential rules, and particular inferences from  $M$  to  $T$ , they use and make.

Plausibly, such a focus on practice amounts to looking at the inferential rules employed in each instance, or type of instance, of epistemic representation. This, however, raises a question about the status of any such analysis vis-à-vis the general theory of representation as given in inferentialism 2 (Definition 3.10). There seem to be two options. The first is to affirm inferentialism 2's (Definition 3.10) status as an exhaustive theory of representation. This, however, would imply that any analysis of the workings of a particular model would fall outside the scope of a theory of representation because any attempt to address Contessa's objection would push the investigation outside the territory delineated by *s*-deflationism. Such an approach seems to be overly purist. The second option is to understand inferentialism 2 (Definition 3.10) as providing abstract conditions that require concretization in each instance of epistemic representation (abstraction can here be understood, for instance, in *Cartwright's* [3.74] sense). Studying the concrete realizations of the abstract conditions is then an integral part of the theory. This approach seems plausible, but it renders deflationism obsolete. Thus understood, the view becomes indistinguishable from a theory that accepts the *surrogate reasoning condition* and the *requirement of directionality* as conditions of adequacy and analyzes them in pluralist spirit, that is, under the assumption that these conditions can have different concrete realizers in different contexts. But this program can be carried out without ever mentioning deflationism.

One might reply that the first option unfairly stacks the deck against inferentialism and point out that different inferential practices *can* be studied within the inferentialist framework. One way of making good on this idea would be to submit that the inferences from models to their targets should be taken as conceptually basic, denying that they need to be explained; in particular, denying that they need to be grounded by any (possibly varying) relation(s) that might hold between models and their targets. Such an approach is inspired by Brandom's inferentialism in the philosophy of language where the central idea is to reverse the order of explanation from representational notions – like truth and reference – to inferential notions – such as the va-

lidity of argument [3.175, 176]. Instead, we are urged to begin from the inferential role of sentences (or propositions, or concepts, and so on) – that is the role that they play in providing reasons for other sentences (or propositions etc.), and having such reasons provided for them – and from this reconstruct their representational aspects.

Such an approach is developed by *de Donato Rodríguez* and *Zamora Bonilla* [3.177] and seems like a fruitful route for future research, but for want of space we will not discuss it in detail here. There is no evidence that Suárez would endorse such an approach. And, more worrying for inferentialism 2 (Definition 3.10), it is not clear whether such an approach would satisfy *s*-deflationism. Each investigation into the inferential rules utilized in each instance, or type of instance of epistemic representation will likely be a substantial (possibly sociological or anthropological) project. Thus the *s*-deflationary credentials of the approach – at least if they are taken to require that nothing substantial can be said about scientific representation in each instance, as well as in general – are called into question.

Finally, if the conditions in inferentialism 2 (Definition 3.10) are taken to be abstract platitudes then we arrive at an abstract minimalism. Although inferentialism 2 (Definition 3.10) defines the concept of epistemic representation, the definition does not suffice to explain the use of any particular instance of epistemic representation for ([3.172, p. 48], cf. [3.171]):

“on the abstract minimalism here considered, to apply this notion to any given concrete case of representation requires that some additional relation obtains between  $[M]$  and  $[T]$ , or a property of  $[M]$  or  $[T]$ , or some other application condition.”

Hence, according to this approach representational force and inferential capacity are taken to be abstract platitudes that suffice to define the concept of scientific representation. However, because of their level of generality, they fail to explain any particular instance of it. To do this requires reference to additional features that vary from case to case. These other conditions can be “isomorphism or similarity” and they “would need to obtain in each concrete case of representation” ([3.171, p. 45], [3.32, p. 773], [3.172, p. 43]). These extra conditions are called the *means* of representation, the relations that scientists exploit in order to draw inferences about targets from their models, and are to be distinguished from conditions (i) and (ii), the *constituents* of representation, that define the concept ([3.23, p. 230], [3.171, p. 43], [3.172, p. 46], [3.178, pp. 93–94]). We are told that the means cannot be reduced to the constituents but that [3.171, p. 43]:

“all representational means (such as isomorphism and similarity) are concrete instantiations, or realizations, of one of the basic platitudes that constitute representation”

and that “there can be no application of representation without the simultaneous instantiation of a particular set of properties of  $[M]$  and  $[T]$ , and their relation” [3.171, p. 44].

Such an approach amounts to using conditions (i) and (ii) to answer the ER-problem, but again with the caveat that they are abstract conditions that require concretization in each instance of epistemic representation. In this sense it is immune to Contessa’s objection about the mysterious capacity that models have to license about their targets. They do so in virtue of more concrete relations that hold between models and their targets, albeit relations that vary from case to case. The key question facing this account is to fill in the details about what sort of relations concretize the abstract conditions. But we are now facing a similar problem as the above. Even if *s*-deflationism applies to epistemic representation in general, an investigation into each specific instance of will involve uncovering substantial relations that hold between models and their targets, which again conflicts with Suárez’s adherence to a deflationist approach.

### 3.5.2 Inflating Inferentialism: Interpretation

In response to difficulties like the above Contessa claims that “it is not clear why we should adopt a deflationary attitude *from the start*” [3.29, p. 50] and provides a “interpretational account” of scientific representation that is still, at least to some extent, inspired by Suárez’s account, but without being deflationary. Contessa claims [3.29, p. 48]:

“[t]he main difference between the interpretational conception [...] and Suárez’s inferential conception is that the interpretational account is a substantial account – interpretation is not just a ‘symptom’ of representation; it is what makes something an epistemic representation of a something else.”

To explain in virtue of what the inferences can be drawn, Contessa introduces the notion of an *interpretation* of a model, in terms of its target system as a necessary and sufficient condition on epistemic representation ([3.29, p. 57], [3.179, pp. 126–127]):

#### **Definition 3.11 Interpretation**

A scientific model  $M$  is an epistemic representation of a certain target  $T$  (for a certain user) if and only if the user adopts an interpretation of  $M$  in terms of  $T$ .

Contessa offers a detailed formal characterization of an interpretation, which we cannot repeat here for want of space (see [3.29, pp. 57–62] for details). The leading idea is that the model user first identifies a set of relevant objects in the model, and a set of properties and relations these objects instantiate, along with a set of relevant objects in the target and a set of properties and relations these objects instantiate. The user then:

1. Takes  $M$  to denote  $T$ .
2. Takes every identified object in the model to denote exactly one object in the target (and every relevant object in the target has to be so denoted and as a result there is a one-to-one correspondence between relevant objects in the model and relevant objects in the target).
3. Takes every property and relation in the model to denote a property or relation of the same arity in the target (and, again, and every property and relation in the target has to be so denoted and as a result there will be one-to-one correspondence between relevant properties and relations in the model and target).

A formal rendering of these conditions is what Contessa calls an *analytic interpretation* (he also includes an additional condition pertaining to functions in the model and target, which we suppress for brevity). The relationship between interpretations and the surrogative reasoning mentioned above is that it is in virtue of the user adopting an analytic interpretation that a model licenses inferences about its target.

At first sight Contessa’s interpretation may appear to be equivalent to setting up an isomorphism between model and target. This impression is correct in as far as an interpretation requires that there be a one-to-one correspondence between relevant elements and relations in the model and the target. However, unlike the isomorphism view, Contessa’s interpretations are not committed to models being structures, and relations can be interpreted as full-fledged relations rather than purely extensionally specified sets of tuples.

Interpretation (Definition 3.11) is a nondeflationary account of scientific representation: most (if not all) instances of scientific representation involve a model user adopting an analytic interpretation towards a target. The capacity for surrogative reasoning is then seen as a symptom of the more fundamental notion of a model user adopting an interpretation of a model in terms of its target. For this reason the adoption of an analytical interpretation is a substantial sufficient condition on establishing the representational relationship. Contessa focuses on the sufficiency of analytic interpretations rather than their necessity and adds that he does [3.29, p. 58]

“not mean to imply that all interpretation of vehicles [models] in terms of the target are necessarily analytic. Epistemic representations whose standard interpretations are not analytic are at least conceivable.”

Even with this in mind, it is clear that he intends that *some* interpretation is a necessary condition on epistemic representation.

Let’s now turn to how interpretation fares with respect to our questions for an account of epistemic representation as set out in Sect. 3.2. Modulo the caveat about nonanalytical interpretations, interpretation (Definition 3.11) provides necessary and sufficient conditions on epistemic representation and hence answers the ER-problem. Furthermore, it does so in a way that explains the directionality of representation: interpreting a model in terms of a target does not entail interpreting a target in terms of a model.

Contessa does not comment on the applicability of mathematics but since his account shares with the structuralist account an emphasis on relations and one-to-one model-target correspondence, Contessa can appeal to the same account of the applicability of mathematics as structuralist.

With respect to the demarcation problem, *Contessa* is explicit that “[p]ortraits, photographs, maps, graphs, and a large number of other representational devices” perform inferential functions [3.29, p. 54]. Since nothing in the notion of an interpretation seems restricted to scientific models, it is plausible to regard interpretation (Definition 3.11) as a universal theory of epistemic representation (a conclusion that is also supported by the fact that *Contessa* [3.29] uses the example of the London Underground map to motivate his account; see also [3.179]). As such, interpretation (Definition 3.11) seems to deny the existence of a substantial distinction between scientific and nonscientific epistemic representations (at least in terms of their representational properties). It remains unclear how interpretation (Definition 3.11) addresses the problem of style. As we have seen earlier, in particular visual representations fall into different categories. It is a question for future research how these can be classified within the interpretational framework.

With respect to the question of ontology, interpretation (Definition 3.11) itself places few constraints on what scientific models are, ontologically speaking. All it requires is that they consist of objects, properties, relations, and functions. For this reason our discussion in Sect. 3.3.3 above rears its head again here. As before, how to apply interpretation (Definition 3.11) to physical models can be understood relatively easily. But how to apply it to nonphysical models is less straightforward.

*Contessa* [3.180] distinguishes between mathematical models and fictional models, where fictional models are taken to be fictional objects. We briefly return to his ontological views in Sect. 3.6.

In order to deal with the possibility of misrepresentation, *Contessa* notes that “a user does not need to believe that every object in the model denotes some object in the system in order to interpret the model in terms of the system” [3.29, p. 59]. He illustrates this claim with an example of contemporary scientists using the Aristotelian model of the cosmos to represent the universe, pointing out that “in order to interpret the model in terms of the universe, we do not need to assume that the sphere of fixed stars itself [...] denotes anything in the universe” [3.29].

From this example it is clear that the relevant sets of objects, properties and functions isolated in the construction of the analytic interpretation do not need to exhaust the objects, properties, relations, and functions of either the model or the target. The model user can identify a relevant *proper* subset in each instance. This allows interpretation (Definition 3.11) to capture the common practice of abstraction in scientific models: a model need only represent some features of its target, and moreover, the model may have the sort of *surplus* features are not taken to represent anything in the target, i. e., that not all of a model’s features need to play a direct representational role.

This suggestion bears some resemblance to partial structures, and it suffers from the same problem too. In particular distortive idealisations are a source of problems for interpretation (Definition 3.11), as several commentators have observed (see *Shech* [3.181] and *Bolinska* [3.28]). *Contessa* is aware of this problem and illustrates it with the example of a massless string. His response to the problem is to appeal to a user’s corrective abilities [3.29, p. 60]:

“since models often misrepresent some aspect of the system or other, it is usually up to the user’s competence, judgment, and background knowledge to use the model successfully in spite of the fact that the model misrepresents certain aspects of the system.”

This is undoubtedly true, but it is unclear how such a view relates, or even derives from, interpretation (Definition 3.11). An appeal to the competence of users seems to be an ad hoc move that has no systematic grounding in the idea of an interpretation, and it is an open question how the notion of an interpretation could be amended to give distortive idealizations a systematic place.

*Ducheyne* [3.182] provides a variant of interpretation (Definition 3.11) that one might think could be used

to accommodate these distortive idealizations. The details of the account, which we won't state precisely here for want of space, can be found in [3.182, pp. 83–86]. The central idea is that each relevant relation specified in the interpretation holds precisely in the model, and corresponds to the same relation that holds only approximately (with respect to a given purpose) in the target. For example, the low mass of an actual pendulum's string approximates the masslessness of the string in the model. The one-to-one correspondence between (relevant) objects and relations in the model and target is retained, but the notion of a user taking relations in the model to denote relations in the target is replaced with the idea that the relations in the target are approximations of the ones they correspond to. Ducheyne calls this the *pragmatic limiting case* account of scientific representation (the pragmatic element comes from the fact that the level of approximation required is determined by the purpose of the model user).

However, if this account is to succeed in explaining how distortive idealizations are scientific representations, then more needs to be said about how a target relation can *approximate* a model relation. Ducheyne implicitly relies on the fact that relations are such that “we can determine *the extent to which* [they hold] empirically” [3.182, p. 83] (emphasis added). This suggests that he has quantifiable relations in mind, and that what it means for a relation  $r$  in the target to approximate a relation  $r'$  in the model is a matter of comparing numerical values, where a model user's purpose determines how close they must be if the former is to count as an approximation of the latter. But whether this exhausts the ways in which relations can be approximations remains unclear. Hendry [3.183], Laymon [3.184], Liu [3.185], Norton [3.186], and Ramsey [3.187], among others, offer discussions of different kinds of idealizations and approximations, and Ducheyne would have to make it plausible that all these can be accommodated in his account.

More importantly, Ducheyne's account has problems dealing with misrepresentations. Although it is designed to capture models that misrepresent by being approximations of their targets, it remains unclear how it deals with models that are outright mistaken. For example, it seems a stretch to say that Thomson's model of the atom (now derogatively referred to as the *plum pudding model*) is an approximation of what the quantum mechanical shell model tells us about atoms, and it seems unlikely that there is a useful sense in which the relations that hold between electrons in Thomson's model *approximate* those that hold in reality. But this does not mean that it is not a scientific representation of the atom; it's just an incorrect one. It does not seem to

be the case that all cases of scientific misrepresentation are instances where the model is an approximation of the target (or even conversely, it is not clear whether all instances of approximation need to be considered cases of *misrepresentation* in the sense that they license falsehoods about their targets).

### 3.5.3 The Denotation, Demonstration, and Interpretation Account

Our final account is *Hughes' denotation, demonstration, and interpretation* (DDI) account of scientific representation [3.188] and [3.189, Chap. 5]. This account has inspired both the inferential (see Suárez [3.32, p. 770] and [3.172]) and the interpretational account (see Contessa [3.179, p. 126]) discussed in this section.

Quoting directly from Goodman [3.64, p. 5], Hughes takes a model of a physical system to “be a symbol for it, stand for it, refer to it” [3.188, p. 330]. Presumably the idea is that a model denotes its target in the same way that a proper name denotes its bearer, or, stretching the notion of denotation slightly, a predicate denote elements in its extension. (Hughes [3.188, p. 330] notes that there is an additional complication when the model has multiple targets but this is not specific to the DDI account and is discussed in more detail in Sect. 3.8). This is the first *D* in *DDI*. What makes models epistemic representations and thereby distinguishes them from proper names, are the demonstration and interpretation conditions.

The demonstration condition, the second *D* in *DDI*, relies on a model being “a secondary subject that has, so to speak, a life of its own. In other words, [a] representation has an internal dynamic whose effects we can examine” [3.188, p. 331] (that models have an *internal dynamic* is all that Hughes has to say about the problem of ontology). The two examples offered by Hughes are both models of what happens when light is passed through two nearby slits. One model is mathematical where the internal dynamics are “supplied by the deductive, resources of the mathematics they employ” [3.188], the other is a physical ripple chamber where they are supplied by “the natural processes involved in the propagation of water waves” [3.188, p. 332].

Such demonstrations, on either mathematical models or physical models are still primarily about the models themselves. The final aspect of Hughes' account – the *I* in *DDI* – is interpretation of what has been demonstrated in the model in terms of the target system. This yields the predictions of the model [3.188, p. 333]. Unfortunately Hughes has little to say about what it means to interpret a result of a demonstration on a model in terms of its target system, and so one has

to retreat to an intuitive (and unanalyzed) notion of carrying over results from models to targets.

Now Hughes is explicit that he is not attempting to answer the ER-problem, and that he does not even offer denotation, demonstration and interpretation as individually necessary and jointly sufficient conditions for scientific representation. He prefers the more [3.188, p. 339]

“modest suggestion that, if we examine a theoretical model with these three activities in mind, we shall achieve some insight into the kind of representation that it provides.”

We are not sure how to interpret Hughes’ position in light of this. On one reading, he can be seen as describing how we *use* models. As such, *DDI* functions as a diachronic account of what a model user does when using a model in an attempt to learn about a target system. We first stipulate that the model stands for the target, then prove what we want to know, and finally *transfer* the results obtained in the model back to the target. Details aside, this picture seems by and large correct. The problem with the *DDI* account is that it does not explain why and how this is possible. Under what conditions is it true that the model denotes the target? What kinds of things are models that they allow for demonstrations? How does interpretation work; that is, how can results obtained in the model be transferred to the target? These are questions an account of epistemic representation has to address, but which are left unanswered by the *DDI* account thus interpreted. Accordingly, *DDI* provides an answer to a question distinct from the ER-problem. Although a valuable answer to the question of how models are used, it does not help us too much here, since it presupposes the very representational relationship we are interested in between models and their targets.

An alternative reading of Hughes’ account emerges when we consider the developments of the structuralist and similarity conceptions discussed previously, and the discussion of deflationism in Sect. 3.5.1: perhaps the very act of using a model, with all the user intentions and practices that brings with it, constitutes the epistemic representation relationship itself. And as such, perhaps the *DDI* conditions could be taken as an answer to the ER-problem:

### 3.6 The Fiction View of Models

In this section we discuss a number of recent attempts to analyze scientific modeling by drawing an analogy with literary fiction. We begin by introducing the leading ideas and differentiating between different strands

#### Definition 3.12 *DDI-ER*

A scientific model  $M$  represents a target  $T$  iff  $M$  denotes  $T$ , an agent (or collection of thereof)  $S$  exploits the internal dynamic of  $M$  to make demonstrations  $D$ , which in turn are interpreted by the agent (or collection of thereof) to be about  $T$ .

This account comes very close to interpretation (Definition 3.11) as discussed in Sect. 3.5.2. And as such it serves to answer the questions we set out in Sect. 3.1 above in the same way. But in this instance, the notion of what it means to *exploit an internal dynamic* and *interpret the results* of this to be about  $T$  need further explication. If the notion of an interpretation is cashed out in the same way as Contessa’s analytic interpretation, then the account will be vulnerable to the same issues as those discussed previously. In another place *Hughes* endorses Giere’s semantic view of theories, which he characterizes as connecting models to the target with a theoretical hypothesis [3.190, p. 121]. This suggests that an interpretation is a theoretical hypothesis in this sense. If so, then Hughes’s account collapses into a version of Giere’s.

Given that *Hughes* describes his account as “designedly skeletal [and in need] to be supplemented on a case-by-case basis” [3.188, p. 335], one option available is to take the demonstration and interpretation conditions to be abstract (in the sense of abstract minimalism discussed above), which require filling in each instance, or type of instance, of epistemic representation. As *Hughes* notes, his examples of the internal dynamics of mathematical and physical models are radically different with the demonstrations of the former utilizing mathematics, and the latter physical properties such as the propagation of water waves. Similar remarks apply to the interpretation of these demonstrations, as well as to denotation. But as with Suárez’s account, the definition sheds little light on the problem at hand as long as no concrete realizations of the abstract conditions are discussed. Despite *Hughes*’ claims to the contrary, such an account could prove a viable answer the ER-problem, and it seems to capture much of what is valuable about both the abstract minimalist version of inferentialism 2 (Definition 3.10) as well as interpretation (Definition 3.11) discussed above.

of argument. We then examine a number of accounts that analyze epistemic representation against the backdrop of literary fiction. We finally discuss criticisms of the fiction view.

### 3.6.1 Models and Fiction

Scientific discourse is rife with passages that appear to be descriptions of systems in a particular discipline, and the pages of textbooks and journals are filled with discussions of the properties and the behavior of those systems. Students of mechanics investigate at length the dynamical properties of a system consisting of two or three spinning spheres with homogeneous mass distributions gravitationally interacting only with each other. Population biologists study the evolution of one species that reproduces at a constant rate in an unchanging environment. And when studying the exchange of goods, economists consider a situation in which there are only two goods, two perfectly rational agents, no restrictions on available information, no transaction costs, no money, and dealings are done immediately. Their surface structure notwithstanding, no one would mistake descriptions of such systems as descriptions of an *actual* system: we know very well that there are no such systems (of course some models are actual systems – a scale model of a car in a wind tunnel for example – but in this section we focus on models that are not of this kind). Scientists sometimes express this fact by saying that they talk about *model land* (for instance [3.191, p.135]).

*Thomson-Jones* [3.98, p. 284] refers to such a description as a “description of a missing system”. These descriptions are embedded in what he calls the “face value practice” [3.98, p. 285]: the practice of talking and thinking about these systems as if they were real. We observe that the amplitude of an ideal pendulum remains constant over time in much the same way in which we say that the Moon’s mass is approximately  $7.34 \times 10^{22}$  kg. Yet the former statement is about a point mass suspended from a massless string – and there is no such thing in the world.

The face value practice raises a number of questions. What account should be given of these descriptions and what sort of objects, if any, do they describe? How should we analyze the face value practice? Are we putting forward truth-evaluable claims when putting forward descriptions of missing systems? An answer to these questions emerges from the following passage by *Peter Godfrey-Smith* [3.152, p. 735]:

“[...] I take at face value the fact that modelers often *take* themselves to be describing imaginary biological populations, imaginary neural networks, or imaginary economies. [...] Although these imagined entities are puzzling, I suggest that at least much of the time they might be treated as similar to something that we are all familiar with, the imagined objects of literary fiction. Here I have in

mind entities like Sherlock Holmes’ London, and Tolkein’s Middle Earth. [...] the model systems of science often work similarly to these familiar fictions.”

This is the core of the fiction view of models: models are akin to places and characters in literary fiction. When modeling the solar system as consisting of ten perfectly spherical spinning tops physicists describe (and *take themselves* to describe) an imaginary physical system; when considering an ecosystem with only one species biologists describe an imaginary population; and when investigating an economy without money and transaction costs economists describe an imaginary economy. These imaginary scenarios are tellingly like the places and characters in works of fiction like *Madame Bovary* and *Sherlock Holmes*.

Although hardly at the center of attention, the parallels between certain aspects of science and literary fiction have not gone unnoticed. Maxwell discussed in great detail the motion of “a purely imaginary fluid” in order to understand the electromagnetic field [3.192, pp. 159–160]. The parallel between science and fiction occupied center stage in *Vaihinger’s* [3.193] philosophy of the *as if*. More recently, the parallel has also been drawn specifically between models and fiction. *Cartwright* observes that “a model is a work of fiction” [3.194, p. 153] and later suggests an analysis of models as fables [3.73, Chap. 2]. *McCloskey* [3.195] emphasises the importance of narratives and stories in economics. *Fine* notes that modeling natural phenomena in every area of science involves fictions in *Vaihinger’s* sense [3.196, p. 16], and *Sklar* highlights that describing systems *as if* they were systems of some other kind is a royal route to success [3.197, p. 71]. *Elgin* [3.198, Chap. 6] argues that science shares important epistemic practices with artistic fiction. *Hartmann* [3.199] and *Morgan* [3.200] emphasize that stories and narratives play an important role in models, and *Morgan* [3.201] stresses the importance of imagination in model building. *Sugden* [3.202] points out that economic models describe “counterfactual worlds” constructed by the modeler. *Frigg* [3.30, 203] suggests that models are imaginary objects, and *Grüne-Yanoff* and *Schweitzer* [3.204] emphasize the importance of stories in the application of game theory. *Toon* [3.48, 205] has formulated an account of representation based on a theory of literary fiction. *Contessa* [3.180] provides a fictional ontology of models and *Levy* [3.43, 206] discusses models as fictions.

But simply likening modeling to fiction does not solve philosophical problems. Fictional discourse and fictional entities face well-known philosophical questions, and hence explaining models in terms of fictional

characters seems to amount to little more than to explain *obscurum per obscurius*. The challenge for proponents of the fiction view is to show that drawing an analogy between models and fiction has heuristic value.

A first step towards making the analogy productive is to get clear on what the problem is that the appeal to fiction is supposed to solve. This issue divides proponents of the fiction view into two groups. Authors belonging to the first camp see the analogy with fiction as providing an answer to the problem of ontology. Models, in that view, are *ontologically* on par with literary fiction while there is no productive parallel between models and fiction as far as the ER-problem (or indeed any other problem of representation) is concerned. Authors belonging to the second group hold the opposite view. They see the analogy with fiction first and foremost as providing an answer to the ER-problem (although, as we have seen, this may place restrictions on the ontology of models). Scientific representation, in this view, has to be understood along the lines of how literary fiction relates to reality. Positions on ontology vary. Some authors in this group also adopt a fiction view of ontology; some remain agnostic about the analogy's contribution to the matters of ontology; and some reject the problem of ontology altogether.

This being a review of models and representation, we refer the reader to *Gelfert's* contribution to this book for an in-depth discussion of the ontology of models, Chap. 1, and focus on the fiction view's contribution to semantics. Let us just note that those who see fiction as providing an ontology of models are spoiled for choice. In principle every option available in the extensive literature on fiction is a candidate for an ontology of models; for reviews of these options see *Friend* [3.207] and *Salis* [3.208]. Different authors have made different choices, with proposals being offered by *Contessa* [3.180], *Ducheyne* [3.72], *Frigg* [3.203], *Godfrey-Smith* [3.209], *Levy* [3.43], and *Sugden* [3.210]. *Cat* [3.211], *Liu* [3.212, 213], *Pincock* [3.214, Chap. 12], *Thomson-Jones* [3.98] and *Toon* [3.205] offer critical discussions of some of these approaches.

Even if these ontological problems were settled in a satisfactory manner, we would not be home and dry yet. *Vorms* [3.215, 216] argues that what's more important than the entity itself is the format in which the entity is presented. A fiction view that predominantly focuses on understanding the fictional entities themselves (and, once this task is out of the way, their relation to the real-world targets), misses an important aspect, namely how agents draw inferences from models. This, *Vorms* submits, crucially depends on the format under which they are presented to scientists, and

different formats allow scientists to draw different inferences. This ties in with *Knuuttila's* insistence that we ought to pay more attention to the “medium of representation” when studying models [3.9, 217].

One last point stands in need of clarification: the meaning of the term *fiction*. Setting aside subtleties that are irrelevant to the current discussion, the different uses of *fiction* fall into two groups: fiction as falsity and fiction as imagination [3.218]. Even though not mutually exclusive, the senses should be kept separate. The first use of *fiction* characterizes something as deviating from reality. We brand Peter's account of events a fiction if he does not report truthfully how things have happened. In the second use, *fiction* refers to a kind of literature, *literary fiction*. Rife prejudice notwithstanding, the defining feature of literary fiction is not falsity. Neither is everything that is said in, say, a novel untrue (novels like *War and Peace* contain correct historical information); nor does every text containing false reports qualify as fiction (a wrong news report or a faulty documentary do not by that token turn into fiction – they remain what they are, namely wrong factual statements). What makes a text fictional is the attitude that the reader is expected to adopt towards it. When reading a novel we are not meant to take the sentences we read as reports of fact; rather we are supposed to imagine the events described.

It is obvious from what has been said so far that the fiction view of models invokes the second sense of *fiction*. Authors in this tradition do not primarily intend to brand models as false; they aim to emphasize that models are presented as something to ponder. This is not to say the first sense of fiction is irrelevant in science. Traditionally fictions in that sense have been used as calculational devices for generating predictions, and recently *Bokulich* [3.14] emphasized the explanatory function of fictions. The first sense of fiction is also at work in philosophy where antirealist positions are described as fictionalism. For instance, someone is a fictionalist about numbers if she thinks that numbers don't exist (see *Kalderon* [3.219] for a discussion of several fictionalisms of this kind). Scientific antirealists are fictionalists about many aspects of scientific theories, and hence *Fine* characterizes fictionalism as an “antirealist position in the debate over scientific realism” [3.196, 220, 221], a position echoed in *Winsberg* [3.222] and *Suárez* [3.223]. *Morrison* [3.224] and *Purves* [3.225] and offer critical discussions of this approach, which the latter calls fiction as “truth conducive falsehood” [3.225, p. 236]; *Woods* [3.226] offers a critical assessment of fictionalism in general. Although there are interesting discussions to be had about the role that this kind of fictions play in the philosophy of science, it is not our interest here.

### 3.6.2 Direct Representation

In this subsection and the next we discuss proposals that have used the analogy between models and fiction to elucidate representation.

Most theories of representation we have encountered so far posit that there are model systems and construe epistemic representation as a relation between two entities, the model system and the target system. *Toon* calls this the *indirect* view of representation [3.205, p. 43]; *Levy*, speaking specifically about the fiction view of models, refers to it as the *whole-cloth fiction* view [3.206, p. 741]. Indeed, *Weisberg* views this indirectness as the defining feature of modeling [3.227]. This view faces the problem of ontology because it has to say what kind of things model systems are. This view contrasts with what *Toon* [3.205, p. 43] and *Levy* [3.43, p. 790] call a *direct* view of representation (*Levy* [3.206, p. 741] earlier also referred to it as the *worldly fiction* view). This view does not recognize model systems and aims instead to explain epistemic representation as a form of direct description. Model descriptions (like the description of an ideal pendulum) provide an “imaginative description of real things” [3.206, p. 741] such as actual pendula, and there is no such thing as a model system of which the pendulum description is literally true [3.205, pp. 43–44]. In what follows we use *Toon*’s terminology and refer to this approach as *direct representation*.

*Toon* and *Levy* both reject the indirect approach because of metaphysical worries about fictional entities, and they both argue that the direct view has the considerable advantage that it does not have to deal with the vexed problem of the ontology of model systems and their comparison with real things at all. *Levy* [3.43, p. 790] sees his approach as “largely complimentary to *Toon*’s”. So we first discuss *Toon*’s approach and then turn to *Levy*’s.

*Toon* [3.48, 205, 228] takes as his point of departure *Walton*’s [3.229] theory of representation in the arts. At the heart of this theory is the notion of a game of make believe. The simplest examples of these games are children’s plays [3.229, p. 11]. In one such play we imagine that stumps are bears and if we spot a stump we imagine that we spot a bear. In *Walton*’s terminology the stumps are *props*, and the rule that we imagine a bear when we see a stump is a *principle of generation*. Together a prop and a principle of generation prescribe what is to be imagined. If a proposition is so prescribed to be imagined, then the proposition is *fictional* in the relevant game. The term *fictional* has nothing to do with falsity; on the contrary, it indicates that the proposition is *true in the game*. The set of propositions actually imagined by someone need not coincide with the set

of all fictional propositions in game. It could be the case that there is a stump somewhere that no one has seen and hence no one imagines that it’s a bear. Yet the proposition that the unseen stump is a bear is fictional in the game.

*Walton* considers a vast variety of different props. In the current context two kinds of props are particularly important. The first are objects like statues. Consider a statue showing Napoleon on horseback [3.205, p. 37]. The statue is the prop, and the games of make believe for it are governed by certain principles of generation that apply to statues of this kind. So when seeing the statue we are mandated to imagine, for instance, that Napoleon has a certain physiognomy and certain facial expressions. We are not mandated to imagine that Napoleon was made of bronze, or that he hasn’t moved for more than 100 years.

The second important kind of props are works of literary fiction. In this case the text is the prop, which together with principles of generation appropriate for literary fictions of a certain kind, generates fictional truths by prescribing readers to imagine certain things. For instance, when reading *The War of the Worlds* [3.205, p. 39] we are prescribed to imagine that the dome of St Paul’s Cathedral has been attacked by aliens and now has a gaping hole on its western side.

In *Walton*’s theory something is a *representation* if it has the social function of serving as a prop in a game of make believe, and something is an *object of a representation* if the representation prescribes us to imagine something about the object [3.229, pp. 35, 39]. In the above examples the statue and the written text are the props, and Napoleon and St Paul’s Cathedral, respectively, are the objects of the representations.

The crucial move now is to say that models are props in games of make believe. Specifically, material models – such as an architectural model of the Forth Road Bridge – are like the statue of Napoleon [3.205, p. 37]: the model is the prop and the bridge is the object of the representation. The same observation applies to theoretical models, such as a mechanical model of a bob bouncing on a spring. The model portrays the bob as a point mass and the spring as perfectly elastic. The model description represents the real ball and spring system in the same way in which a literary text represents its objects [3.205, pp. 39–40]: the model description prescribes imaginings about the real system – we are supposed to imagine the real spring as perfectly elastic and the bob as a point mass.

We now see why *Toon*’s account is a direct view of modeling. Theoretical model descriptions represent actual concrete objects: the Forth Road Bridge and the bob on a spring. There is no intermediary en-

tivity of which model descriptions are literally true and which are doing the representing. Models prescribe imaginings about a real world target, and that is what representation consists in.

This is an elegant account of representation, but it is not without problems. The first issue is that it does not offer an answer to the ER-problem. Imagining that the target has a certain feature does not tell us how the imagined feature relates to the properties the target actually has, and so there is no mechanism to transfer model results to the target. Imagining the pendulum bob to be a point mass tells us nothing about which, if any, claims about point masses are also true of the real bob. *Toon* mentions this problem briefly. His response is that [3.205, pp. 68–69]:

“Principles of generation often link properties of models to properties of the system they represent in a rather direct way. If the model has a certain property then we are to imagine that system does too. If the model is accurate, then the model and the system will be similar in this respect. [...] [But] not all principles of generation are so straightforward. [...] In some cases similarity seems to play no role at all.”

In as far as the transfer mechanism is similarity, the view moves close to the similarity view, which brings with it both some of the benefits and the problems we have discussed in Sect. 3.3. The cases in which similarity plays no role are left unresolved and it remains unclear how surrogative reasoning with such models is supposed to happen.

The next issue is that not all models have a target system, which is a serious problem for a view that analyzes representation in terms of imagining something *about* a target. *Toon* is well aware of this issue and calls them *models without objects* [3.205, p. 76]. Some of these are models of discredited entities like the ether and phlogiston, which were initially thought to have a target but then turned out not to have one [3.205, p. 76]. But not all models without objects are errors: architectural plans of buildings that are never built or models of experiments that are never carried out fall into the same category [3.205, p. 76].

*Toon* addresses this problem by drawing another analogy with fiction. He points out that not all novels are like *The War of the Worlds*, which has an object. Passages from *Dracula*, for instance, “do not represent any actual, concrete object but are instead about fictional characters” [3.205, p. 54]. Models without a target are like passages from *Dracula*. So the solution to the problem is to separate the two cases neatly. When a model has target then it represents that target

by prescribing imaginings about the target; if a model has no target it prescribes imaginings about a fictional character [3.205, p. 54].

*Toon* immediately admits that models without targets “give rise to all the usual problems with fictional characters” [3.205, p. 54]. However, he seems to think that this is a problem we can live with because the more important case is the one where models do have a target, and his account offers a neat solution there. He offers the following summative statement of his account [3.205, p. 62]:

#### **Definition 3.13 Direct Representation**

A scientific model  $M$  represents a target system  $T$  iff  $M$  functions as prop in game of make believe.

This definition takes it to be understood that the imaginings prescribed are about the target  $T$  if there is a target, and about a fictional character if there isn’t because there need not be any object that the model prescribes imaginings about [3.205, p. 81].

This bifurcation of imaginative activities raises questions. The first is whether the bifurcation squares with the face value practice. *Toon*’s presentation would suggest that the imaginative practices involved in models with targets are very different from the ones involved in models without them. Moreover, they require a different analysis because imagining something about an existing object is different from imagining something about a fictional entity. This, however, does not seem to sit well with scientific practice. In some cases we are mistaken: we think that the target exists but then find out that it doesn’t (as in the case of phlogiston). But does that make a difference to the imaginative engagement with a phlogiston model of combustion? Even today we can understand and use such models in much the same way as its original protagonists did, and knowing that there is no target seems to make little, if any, difference to our imaginative engagement with the model. Of course the presence or absence of a target matters to many other issues, most notably surrogative reasoning (there is nothing to reason about if there is no target!), but it seems to have little importance for how we imaginatively engage with the scenario presented to us in a model.

In other cases it is simply left open whether there is target when the model is developed. In elementary particle physics, for instance, a scenario is often proposed simply as a suggestion worth considering and only later, when all the details are worked out, the question is asked whether this scenario bears an interesting relation to what happens in nature, and if so what the relation is. So, again, the question of whether there is or isn’t a target seems to have little, if any, influence

on the imaginative engagement of physicists with scenarios in the research process. This does not preclude different philosophical analyses being given of modeling with and without a target, but any such analysis will have to make clear the commonalities between the two.

Let us now turn to a few other aspects of direct representation (Definition 3.13). The view successfully solves the problem of asymmetry. Even if it uses similarity in response to the ER-problem, the imaginative process is clearly directed towards the target. An appeal to imagination also solves the problem of misrepresentation because there is no expectation that our imaginations are correct when interpreted as statements about the target. Given its roots in a theory of representation in art, it's natural to renounce any attempts to demarcate scientific representation from other kinds of representation [3.205, p. 62]. The problem of ontology is dispelled for representations with an object, but it remains unresolved for representations without one. However, direct representation (Definition 3.13) offers at best a partial answer to the ER-problem, and nothing is said about either the problem of style and/or standards of accuracy. Similarly, Toon remains silent about the applicability of mathematics.

Levy also rejects an indirect view primarily because of the unwieldiness of its ontology and endorses a direct view of representation ([3.43, pp. 780–790], [3.206, pp. 744–747]). Like Toon, he develops his version of the direct view by appeal to Walton's notion of prop-oriented make believe. When, for instance, we're asked where in Italy the town of Crotona lies, we can be told that it's in the arch of the Italian boot. In doing so we are asked to imagine something about the shape of Italy and this imagination is used to convey geographical information. Levy then submits that "we treat models as games of prop-oriented make believe" [3.206, p. 791]. Hence modeling consists in imagining something directly about the target.

Levy pays careful attention to the ER-problem. In his [3.206, p. 744] he proposed that the problem be conceptualized in analogy with metaphors, but immediately added that this was only a beginning which requires substantial elaboration. In his [3.43, pp. 792–796] he takes a different route and appeals to Yablo's [3.230] theory of partial truth. The core idea of this view is that a statement is partially true "if it is true when evaluated only relative to a subset of the circumstances that make up its subject matter – the subset corresponding to the relevant content-part" [3.43, p. 792]. Levy submits that this will also work for a number of cases of modeling, but immediately adds that there are other sorts of cases that don't fit the mold [3.43, p. 794]. Such cases often are ones in which

distortive idealizations are crucial and cannot be set aside. These require a different treatment and it's an open question what this treatment would be.

Levy offers a radical solution to the problem of models without targets: there aren't any! He first broadens the notion of a target system, allowing for models that are only loosely connected to targets [3.43, pp. 796–797]. To this end he appeals to Godfrey-Smith's notion of *hub-and-spoke* cases: families of models where only some have a target (which makes them the hub models) and the others are connected to them via conceptual links (spokes) but don't have a specific target. Levy points out that such cases should be understood as having a *generalized target*. If something that looks like a model doesn't meet the requirement of having even a generalized target, then it's not a model at all. Levy mentions structures like the game of life and observes that they are "bits of mathematics" rather than models [3.43, p. 797]. This eliminates the need for fictional characters in the case of targetless models.

This is a heroic act of liberation, but questions about it remain. The direct view renders fictional entities otiose by positing that a model is nothing but an act of imagining something about a concrete actual thing. But generalized targets are not concrete actual things, and often not even classes of such things. There is a serious question whether one can still reap the (alleged) benefits of a view that analyzes modeling as imaginings about concrete things, if the things about which we imagine something are no longer concrete. Population growth or complex behavior are not concrete things like rabbits and stumps, and this would seem to pull the rug from underneath a direct approach to representation. Likewise, the claim that models without target are just mathematics stands in need of further elucidation. Looking back at Toon's examples of such models, a view that considers them just mathematics does not come out looking very natural.

### 3.6.3 Parables and Fables

Cartwright [3.231] focuses on highly idealized models such as Schelling's model of social segregation [3.232] and Pissarides' model of the labor market [3.233]. The problem with these models is that the objects and situations we find in such models are not at all like the things in the world that we are interested in. Cities aren't organized as checkerboards and people don't move according to simple algorithmic rules (as they do in Schelling's model), and there are no laborers who are solely interested in leisure and income (as is the case in Pissarides' model). Yet we are supposed to learn something about the real world from these models. The question is how.

*Cartwright* submits that an answer to this question emerges from a comparison of models with narratives, in particular fables and parables. An example of a fable is the following: “A marten eats the grouse; a fox throttles the marten; the tooth of the wolf, the fox. Moral: the weaker are always prey to the stronger” [3.231, p. 20]. The characters in the fable are highly idiosyncratic, and typically we aren’t interested in them per se – we don’t read fables to learn about foxes and martens. What we are interested in is the fable’s general and more abstract conclusion, in the above example that the weaker are always prey to the stronger. In the case of the fable the moral is typically built in the story and explicitly stated [3.231].

*Cartwright* then invites us to consider the parable of the laborers in the vineyard told in the Gospel of Matthew [3.231]. A man goes to the market to hire day laborers. He hires the first group early in the morning, and then returns several times during the day to hire more laborers, and he hires the last group shortly before dusk. Some worked all day, while some hardly started when the day ended. Yet he pays the same amount to all of them. Like in a fable, when engaging with a parable the reader takes no intrinsic interest in the actors and instead tries to extract a more general moral. But unlike in fables, in parables no moral appears as part of the parable itself [3.231, p. 29]. Hence parables need interpretation, and alternative interpretations are possible. The above fable is often interpreted as being about the entry to God’s kingdom, but, as *Cartwright* observes, it can just as well be interpreted as making the market-based capitalist point that you get what you contract for, and should not appeal to higher forms of justice [3.231, p. 21].

These are features models share with fables and parables: “like the characters in the fable, the objects in the model are highly special and do not in general resemble the ones we want to learn about” [3.231, p. 20] and the “lesson of the model is, properly, more abstract than what is seen to happen in the model” [3.231, p. 28]. This leaves the question whether models are fables or parables. Some models are like fables in that they have the conclusion explicitly stated in them. But most models are like parables [3.231, p. 29]: their lesson is not written in the models themselves [3.231, p. 21], and worse: “a variety of morals can be attributed to the models” [3.231, p. 21]. A model, just like a parable, is interpreted against a rich background of theory and observation, and the conclusion we draw depends to a large extent on the background [3.231, p. 30].

So far the focus was on deriving a conclusion about the model *itself*. *Cartwright* is clear that one more step is needed: “In many cases we want to use the results of these models to inform our conclusions about

a range of actually occurring (so-called *target*) situations” [3.231, p. 22] (original emphasis). In fact, making this transfer of model results to the real world is the ER-problem. Unfortunately she does not offer much by way of explaining this step and merely observes that “a description of what happens in the model that does not fit the target gets recast as one that can” [3.231, p. 20]. This gestures in the right direction, but more would have to be said about how exactly a model description is recast to allow for transfer of model results to target systems. In earlier work *Cartwright* observed that what underlies the relationship between models and their targets is a “loose notion of resemblance” [3.73, pp. 192–193] and [3.74, pp. 261–262]. This could be read as suggesting that she would endorse some kind of similarity view of representation. Such a view, however, is independent of an appeal to fables and parables.

In passing we would like to mention that the same kind of models is also discussed in *Sugden* [3.202, 210]. However, his interest is in induction rather than representation, and if reframed in representational terms then his account becomes a similarity account like *Giere*’s. See *Grüne-Yanoff* [3.234] and *Knuuttila* [3.235] for a discussion.

### 3.6.4 Against Fiction

The criticisms we have encountered above were intrinsic criticisms of particular versions of the fiction view, and as such they presuppose a constructive engagement with the view’s point of departure. Some critics think that any such engagement is misplaced because the view got started on the wrong foot entirely. There are five different lines of attack. The first criticism is driven by philosophical worries about fiction. Fictions, so the argument goes, are intrinsically dubious and are beset with so many serious problems that one should steer away from them whenever possible. So it could be claimed that assigning them a central role in science is a manifestation of philosophical masochism. This, however, overstates the problems with fictions. Sure enough, there is controversy about fictions. But the problems pertaining to fictions aren’t more devastating than those surrounding other items on the philosophical curriculum, and these problems surely don’t render fictions off limits.

The second criticism, offered for example by *Giere* [3.97, p. 257], is that the fiction view – involuntarily – plays into the hands of irrationalists. Creationists and other science skeptics will find great comfort, if not powerful rhetorical ammunition, in the fact that philosophers of science say that scientists produce fiction. This, so the argument goes, will be seen

as a justification of the view that religious dogma is on par with, or even superior to, scientific knowledge. Hence the fiction view of models undermines the authority of science and fosters the cause of those who wish to replace science with religious or other unscientific worldviews.

Needless to say, we share Giere's concerns about creationism. In order not to misidentify the problem it is important to point out that Giere's claim is not that the view itself – or its proponents – support creationism; his worry is that the view is a dangerous tool when it falls into the wrong hands. What follows from this, however, is not that the fiction view itself should be abandoned; but rather that some care is needed when dealing with the press office. As long as the fiction view of models is discussed in informed circles, and, when popularized, is presented carefully and with the necessary qualifications, it is no more dangerous than other ideas, which, when taken out of context, can be put to uses that would (probably) send shivers down the spines of their progenitors (think, for instance, of the use of Darwinism to justify eugenics).

The third objection, also due to *Giere*, has it that the fiction view misidentifies the aims of models. Giere agrees that from an *ontological* point of view scientific models and works of fictions are on par, but emphasizes that “[i]t is their differing function in practice that makes it inappropriate to regard scientific models as works of fiction” [3.97, p. 249]. *Giere* identifies three functional differences [3.97, pp. 249–252]. First, while fictions are the product of a single author's individual endeavors, scientific models are the result of a public effort because scientists discuss their creations with their colleagues and subject them to public scrutiny. Second, there is a clear distinction between fiction and nonfiction books, and even when a book classified as nonfiction is found to contain false claims, it is not reclassified as fiction. Third, unlike works of fiction, whose prime purpose is to entertain (although some works can also give insight into certain aspects of human life), scientific models are representations of certain aspects of the world.

These observations, although correct in themselves, have no force against the fiction view of models. First, whether a fiction is the product of an individual or a collective effort has no impact on its status as a fiction; a collectively produced fiction is just a different kind of fiction. Even if *War and Peace* (to take Giere's example) had been written in a collective effort by all established Russian writers of Tolstoy's time, it would still be a fiction. Vice versa, even if Newton had never discussed his model of the solar system with anybody before publishing it, it would still be science. The history of production is immaterial to the fictional status

of a work. Second, as we have seen in Sect. 3.6.1, falsity is not a defining feature of fiction. We agree with Giere that there is a clear distinction between texts of fiction and nonfiction, but we deny that this distinction is defined by truth or falsity; it is the attitude that we are supposed to adopt towards the text's content that makes the difference. Once this is realized, the problem fades away. Third, many proponents of the fiction view (those belonging to the first group mentioned in Sect. 3.6.1) are clear that problems of ontology should be kept separate from function and agree that it is one of the prime function of models to represent. This point has been stressed by *Godfrey-Smith* [3.209, pp. 108–111] and it is explicit in other views such as *Frigg's* [3.203].

The fourth objection is due to *Magnani*, who dismisses the fiction view for misconstruing the role of models in the process of scientific discovery. The fundamental role played by models, he emphasizes [3.236, p. 3]:

“is the one we find in the core conceptual discovery processes, and that these kinds of models cannot be indicated as fictional at all, because they are constitutive of new scientific frameworks and new empirical domains.”

This criticism seems to be based on an understanding of fiction as falsity because falsities can't play a constitutive role in the constitution of new empirical domains. We reiterate that the fiction view is not committed to the *fiction as falsity* account and hence is not open to this objection.

The fifth objection is that fictions are superfluous and hence should not be regarded as forming part of (let alone *being*) scientific models because we can give a systematic account of how scientific models work without invoking fictions. This point has been made in different ways by *Pincock* [3.214, Chap. 12] and *Weisberg* [3.33, Chap. 4] (for a discussion of *Weisberg's* arguments see *Odenbaugh* [3.237]). We cannot do justice to the details of their sophisticated arguments here, and will concern ourselves only with their main conclusion. They argue that scientific models are mathematical objects and that they relate to the world due to the fact that there is a relationship between the mathematical properties of the model and the properties found in the target system (in *Weisberg's* version similarity relations to a parametrized version of the target). In other words, models are mathematical structures and they represent due to there being certain mathematical relations between these structures and a mathematical rendering of the target system. (*Weisberg* includes fictions as convenient *folk ontology* that may serve as a crutch when thinking about the model, but takes them to be ultimately dispensable when it comes to explain-

ing how models relate to the world.) This, however, brings us back to a structuralist theory of representation, and this theory, as we have seen in Sect. 3.4, is

far from unproblematic. So it is at best an open question whether getting rid of fiction provides an obvious advantage.

## 3.7 Representation-as

In this section we discuss approaches that depart from *Goodman's* notion of *representation-as* [3.64]. In his account of aesthetic representation the idea is that a work of art does not just denote its subject, but moreover it represents it as being thus or so. *Elgin* [3.34] further developed this account and, crucially, suggested that it also applies to scientific representations. This is a vital insight and it provides the entry point to what we think of as the most promising account of epistemic representation.

In this section we present Goodman and Elgin's notion of *representation-as*, and outline how it is a complex type of reference involving a mixture of denotation and what they call exemplification. We introduce the term of art *representation-as* to indicate that we are talking about the specific concept that emerges from Goodman's and Elgin's writings. We then discuss how the account needs to be developed in the context of scientific representation. And finally we present our own answer to the ER-problem, and demonstrate how it answers the questions laid out in Sect. 3.1.

### 3.7.1 Exemplification and Representation-as

Many instances of epistemic representation are instances of representation-as. Caricatures are paradigmatic examples: Churchill is represented as a bulldog, Thatcher is represented as a boxer, and the Olympic Stadium is represented as a UFO. Using these caricatures we can attempt to learn about their targets: attempt to learn about a politician's personality or a building's appearance. The notion applies beyond caricatures. Holbein's *Portrait of Henry VIII* represents Henry as imposing and powerful and Stoddart's statue of David Hume represents him as thoughtful and wise. The leading idea is that scientific representation works in much the same way. A model of the solar system represents the sun as perfect sphere; the logistic model of growth represents the population as reproducing at fixed intervals of time; and so on. In each instance, models can be used to attempt to learn about their targets by determining what the former represent the latter as being. So representation-as relates, in a way to be made more specific below, to the surrogate reasoning condition discussed in Sect. 3.1.

The locution of representation-as functions in the following way: An object  $X$  (e.g., a picture, statue, or model) represents a subject  $Y$  (e.g., a person or target system) as being thus or so ( $Z$ ). The question then is what establishes this sort of representational relationship? The answer requires presenting some of the tools Goodman and Elgin use to develop their account of representation-as.

One of the central posits of *Goodman's* account is that denotation is "the core of representation" [3.64, p. 5]. Stoddart's statue of David Hume denotes Hume and a model of the solar system denotes the solar system. In that sense the statue and the model are representations of their respective targets. To distinguish representation of something from other notions of representation we introduce the technical term *representation-of*. Denotation is what establishes representation-of. (For a number of qualifications and caveats about denotation see our [3.238, Sect. 2]).

Not all representations are a representation-of. A picture showing a unicorn is not a representation-of a unicorn because things that don't exist can't be denoted. Yet there is a clear sense in which such a picture is a representation. *Goodman* and *Elgin's* solution to this is to distinguish between being a representation-of something and being a something-representation ([3.34, pp. 1–2], [3.64, pp. 21–26]). What makes a picture a something-representation (despite the fact it may fail to denote anything) is that it is the sort of symbol that denotes. *Elgin* argues [3.34, pp. 1–2]:

"A picture that portrays a griffin, a map that maps the route to Mordor [...] are all representations, although they do not represent anything. To be a representation, a symbol need not itself denote, but it needs to be the sort of symbol that denotes. Griffin pictures are representations then because they are animal pictures, and some animal pictures denote animals. Middle Earth maps are representations because they are maps and some maps denote real locations. [...] So whether a symbol is a representation is a question of what kind of symbol it is."

These representations can be classified into genres, in a way that does not depend on what they are

representations-of (since some may fail to denote), but instead on what they portray. In the case of pictures, this is fairly intuitive (how this is to be developed in the case of scientific models is discussed below). If a picture portrays a man, it is a man-representation, if it portrays a griffin it is a griffin-representation and so on. In general, a picture  $X$  is  $Z$ -representation if it portrays  $Z$ . The crucial point is that this does not presuppose that  $X$  be a representation-of  $Z$ ; indeed  $X$  can be  $Z$ -representation without denoting anything. A picture must denote a man to be a representation-of a man. But it need not denote anything to be a man-representation.

The next notion we need to introduce is *exemplification*. An item exemplifies a property if it at once instantiates the property and refers to it [3.64, p. 53]:

“Exemplification is possession plus reference. To have without symbolizing is merely to possess, while to symbolize without having is to refer in some other way than by exemplifying.”

Exemplification is a mode of reference that holds between items and properties. In the current context properties are to be understood in the widest possible sense. An item can exemplify one-place properties, multi-place properties (i.e., relations), higher order properties, structural properties, etc. Paradigmatic examples of exemplification are samples. A chip of paint on a manufacturer’s sample card both instantiates a certain color, and at the same time refers to that color [3.239, p. 71].

But although exemplification requires instantiation, not every property instantiated by an object is exemplified by it. The chip of paint does not, for example, exemplify its shape or its location on the card. In order to exemplify a property, an object must both instantiate the property and the property itself must be made epistemically salient. How saliency is established will be determined on a case-by-case basis, and we say more about this below.

We can now turn to the conditions under which  $X$  represents  $Y$  as  $Z$ . A first stab would be to say that  $X$  represents  $Y$  as  $Z$  if  $X$  is a  $Z$ -representation and denotes  $Y$ . This however, is not yet good enough. It is important that properties of  $Z$  are *transferred* to  $Y$ . *Elgin* makes this explicit [3.34, p. 10]:

“[ $X$ ] does not merely denote [ $Y$ ] and happen to be a [ $Z$ ]-representation. Rather in being a [ $Z$ ]-representation, [ $X$ ] exemplifies certain properties and imputes those properties or related ones to [ $Y$ ]. [...] The properties exemplified in the [ $Z$ ]-representation thus serve as a bridge that connects [ $X$ ] to [ $Y$ ].”

This gives a name to the crucial step: imputation. This step can be analyzed in terms of stipulation by a user of a representation. When someone uses  $X$  as a representation-as, she has to stipulate that certain properties that are exemplified in  $X$  be imputed to  $Y$ . We emphasize that imputation does not imply truth:  $Y$  may or may not have the properties imputed to it by  $X$ . So the representation can be seen as generating a claim about  $Y$  that can be true or false; it should not be understood as producing truisms.

Applied to scientific models, the account of epistemic representation that emerges from Goodman and Elgin’s discussion of representation can then be summarized as follows:

#### Definition 3.14 Representation-As

A scientific model  $M$  represents a target system  $T$  iff:

1.  $M$  denotes  $T$
2.  $M$  is a  $Z$ -representation exemplifying properties  $P_1, \dots, P_n$
3.  $P_1, \dots, P_n$ , or related properties, are imputed to  $T$ .

It should be added that the first condition can easily be extended to include part-part denotation. In a family portrait the entire portrait denotes the family; at the same time a part of the portrait can denote the mother and another part the father. This is obvious and unproblematic.

We think that this account is on the right track, but all three conditions need to be further developed to furnish a full-fledged account of epistemic representation (at least as applied to scientific models). The developments needed are of different kinds, though. The first condition needs more specificity. How is denotation characterized? What different ways of establishing denotation are there? And how is denotation established in particular cases? These are but some of the questions that a complete account of epistemic representation will have to answer. In many cases epistemic representation seems to borrow denotation from linguistic descriptions in which they are embellished and denotation is in effect borrowed from language. So the philosopher of science can turn to the philosophy of language to get a deeper understanding of denotation. This is an interesting project, but it is not one we can pursue here.

In contrast with denotation the other two conditions need to be reformulated because an account molded on visual representations is only an imperfect match for scientific representations. This is the task for the next section.

### 3.7.2 From Pictures to Models: The Denotation, Exemplification, Keying-up and Imputation Account

According to Goodman and Elgin, for a picture to be a *Z*-representation it has to be the kind of symbol that denotes. On the face of it, there is a mismatch between pictures and scientific models in this regard. The Schelling model represents social segregation with a checkerboard; billiard balls are used to represent molecules; the Phillips–Newlyn model uses a system of pipes and reservoirs to represent the flow of money through an economy; and the worm *Caenorhabditis elegans* is used as a model of other organisms. But neither checkerboards, billiard balls, pipes, or worms seem to belong to classes of objects that typically denote. The same observation applies to scientific fictions (frictionless planes, utility maximizing agents, and so on) and the mathematical objects used in science. In fact, matrices, curvilinear geometries, Hilbert spaces etc. were all studied as mathematical objects before they became important in the empirical sciences.

Rather than relying on the idea that scientific models belong to classes of objects that typically denote we propose directly introducing an agent and ground representation in this agent's actions. Specific checkerboards, systems of pipes, frictionless places and mathematical structures, are epistemic representations because they are used by an agent to represent a system. When an agent uses an object as a representation, we call it a *base*.

What allows us to classify bases into *Z*-representations is also less clear in the case of scientific representation. We approach this issue in two steps. The first is to recognize the importance of the intrinsic constitution of the base. Pictures are typically canvases covered with paint. They are classified as *Z*-representations because under appropriate circumstances the canvas is recognized as portraying a *Z*. Much can be said about the canvas' material constitution (the thickness or chemical constitution of the paint, etc.), but these are generally of little interest to understanding what the picture portrays. By contrast, the properties of a scientific model – qua material object – do matter. How water flows through the pipes in the Phillips–Newlyn model is crucial to how it represents the movement of money in an economy. That *Caenorhabditis elegans* is a biological organism is of vital importance for how it is used representationally. In fact, models are frequently classified according to what their material base is. We talk about a pipe model of the economy or worm model of cell division because their bases are pipes and worms. Here we introduce a term of art to recognize that scientific models are generally categorized according to their

material constitution. An *O*-object specifies the kind of object something is, qua physical object.

*O*-objects become representations when they are used as such. But how are they classified as *Z*-representations? How does the Phillips–Newlyn machine become an economy-representation, or how does a collection of billiard balls become a gas-representation? (Again, recall that this is not because they denote economies or gases.) We suggest, and this is the second step, that this requires an act of *interpretation* (notice that we do not use *interpretation* in the same sense as Contessa). In the case of pictures, the nature of this interpretation has been the center of attention for a good while: how one sees a canvas covered with paint as showing a cathedral is regarded by many as one of the important problems of aesthetics. Schier [3.240, p. 1] dubbed it the “enigma of depiction”, and an entire body of literature is concerned with it (*Kulvicki* [3.241] provides a useful review). In the case of scientific models we don't think a simple and universal account of how models are interpreted as *Z*-representations can be given. Interpreting an *O*-object as a *Z*-representation requires attributing properties of *Zs* to the object. How this is done will depend on disciplinary traditions, research interests, background theory and much more. In fact, *interpretation* is a blank to be filled, and it will be filled differently in different cases.

Some examples should help elucidate what we mean by this. In the case of scale models the interpretation is *close* to the *O*-object in that it interprets the object in its *own* terms. The small car is interpreted as a car-representation and the small ship is interpreted as a ship-representation. Likewise, in the case of the Army Corps' model of the San Francisco bay [3.33], parts of the model bay are interpreted in terms of the real bay. In cases like these, the same predicates that apply to the base (qua *O*-object) are applied to the object in order to make it into a *Z*-representation (here  $O = Z$ ). But this is not always the case. For example, the Phillips–Newlyn machine is a system of pipes and reservoirs, but it becomes an economy-representation only when the quantity and flow of water throughout the system are interpreted as the quantity and flow of money throughout an economy. The system is interpreted in terms of predicates that do not apply to the object (qua *O*-object), but turn it into a *Z*-representation (here *O* and *Z* come apart). In sum, an *O*-object that has been chosen as the base of a representation becomes a *Z*-representation if *O* is interpreted in terms of *Z*.

Next in line is exemplification. Much can be said about exemplification in general, but the points by and large carry over from the general discussion to the case of models without much ado. There is one difference,

though, in cases like the Phillips–Newlyn machine. Recall that exemplification was defined as the instantiation of a property  $P$  by an object in such a way that the object thereby refers to  $P$ . How can the Phillips–Newlyn machine exemplify economic properties when it does not, strictly speaking, instantiate them? The crucial point is that nothing in the current account depends on instantiation being literal instantiation. On this point we are in agreement with Goodman and Elgin, whose account relies on nonliteral instantiation. The portrait of Henry cannot, strictly speaking, instantiate the property of being male, even if it represents him as such. Goodman and Elgin call this metaphorical instantiation ([3.64, pp. 50–51], [3.239, p. 81]).

What matters is that properties are epistemically accessible and salient, and this can be achieved with what we call *instantiation-under-an-interpretation*  $I$ , *I-instantiation* for short. An economic interpretation of the Phillips–Newlyn machine interprets amounts of water as amounts of money. It does so by introducing a clearly circumscribed rule of proportionality:  $x$  liters of water correspond to  $y$  millions of the model-economy’s currency. This rule is applied without exception when the machine is interpreted as an economy-representation. So we say that under the economic interpretation  $I_e$  the machine  $I_e$ -instantiates money properties. With the notion of *I-instantiation* at hand, exemplification poses no problem.

The final issue to clear is the imputation of the model’s exemplified properties to the target system. In particular, which properties are so imputed? Elgin describes this as the imputation of the properties exemplified by  $M$  or *related ones*. The observation that the properties exemplified by a scientific model and the properties imputed to its target system need not be identical is correct. In fact, few, if any, models in science portray their targets as exhibiting exactly the same features as the model itself. The problem with invoking *related* properties is not its correctness, but its lack of specificity. Any property can be related to any other property in some way or other, and as long as no specific relation is specified it remains unclear which properties are imputed onto the system.

In the context of science, the relation between the properties exemplified and the ones ascribed to the system is sometimes described as one of simplification [3.198, p. 184], idealization [3.198, p. 184] and approximation [3.34, p. 11]. This could suggest that *related ones* means *idealized*, at least in the context of science (we are not attributing this claim to Elgin; we are merely considering the option), perhaps similar to the way in which Ducheyne’s account discussed above took target properties to be approximations of model properties. But shifting from *related* to *idealized* or

*approximated* (or any of their cognates) makes things worse, not better. For one, *idealization* can mean very different things in different contexts and hence describing the relation between two properties as *idealization* adds little specificity (see Jones [3.242] for a discussion of different kinds of idealization). For another, while the relationship between some representation-target properties may be characterized in terms of idealization, many cannot. A map of the world exemplifies a distance of 29 cm between the two points labeled *Paris* and *New York*; the distance between the two cities is 5800 km; but 29 cm is not an idealization of 5800 km. A scale model of a ship being towed through water is not an idealization of an actual ship, at least not in any obvious way. Or in standard representations of Mandelbrot sets the color of a point indicates the speed of divergence of an iterative function for certain parameter value associated with that point, but color is not an idealization of divergence speed.

For this reason it is preferable, in our view, to build a specification of the relationship between model properties and target properties directly into an account of epistemic representation. Let  $P_1, \dots, P_n$  be the properties exemplified by  $M$ , and let  $Q_1, \dots, Q_m$  be the *related* properties that  $M$  imputes to  $T$  (where  $n$  and  $m$  are positive natural numbers that can but need not be equal). Then the representation  $M$  must come with a key  $K$  that specifies how exactly  $P_1, \dots, P_n$  are converted into  $Q_1, \dots, Q_m$  [3.50]. Borrowing notation from algebra (somewhat loosely) we can write  $K((P_1, \dots, P_n)) = \langle Q_1, \dots, Q_m \rangle$ .  $K$  can, but need not be, the identity function; any rule that associates a unique set  $Q_1, \dots, Q_m$  with  $P_1, \dots, P_n$  is admissible. The relevant clause in the definition of representation-as then becomes:  $M$  exemplifies  $P_1, \dots, P_n$  and the representation imputes properties  $Q_1, \dots, Q_m$  to  $T$  where the two sets of properties are connected to each other by a key  $K$ .

The above examples help illustrate what we have in mind. Let us begin with the example of the map (in fact the idea of a key is motivated by a study of maps; for a discussion of maps see Galton [3.243] and Sismondo and Chrisman [3.244]).  $P$  is a measured distance on the map between the point labeled *New York* and the point labeled *Paris*;  $Q$  is the distance between New York and Paris in the world; and  $K$  is the scale of the map (in the above case,  $1 : 20000000$ ). So the key allows us to translate a property of the map (the 29 cm distance) into a property of the world (that New York and Paris are 5800 km apart). But the key involved in the scale model of the ship is more complicated. One of the  $P$ s in this instance is the resistance the model ship faces when moved through the water in a tank. But this doesn’t translate into the resistance faced by the actual ship in the same way in which distances in a map trans-

late into distances in reality. In fact, the relation between the resistance of the model and the resistance of the real ship stand in a complicated nonlinear relationship because smaller models encounter disproportionate effects due to the viscosity of the fluid. The exact form of the key is often highly nontrivial and emerges as the result of a thoroughgoing study of the situation; see Sterrett [3.245] for a discussion of fluid mechanics. In the representation of the Madelbrod set in [3.246, p. 660] a key is used that translates color into divergence speed [3.246, p. 695]. The square shown is a segment of the complex plane and each point represents a complex number. This number is used as parameter value for an iterative function. If the function converges for number  $c$ , then the point in the plane representing  $c$  is colored black. If the function diverges, then a shading from yellow over green to blue is used to indicate the speed of divergence, where yellow is slow, green is in the middle and blue is fast.

Neither of these keys is obvious or trivial. Determining how to move from properties exemplified by models to properties of their target systems can be a significant task, and should not go unrecognized in an account of scientific representation. In general  $K$  is a blank to be filled, and it depends on a number of factors: the scientific discipline, the context, the aims and purposes for which  $M$  is used, the theoretical backdrop against which  $M$  operates, etc. Building  $K$  into the definition of representation-as does not prejudice the nature of  $K$ , much less single out a particular key as the correct one. The requirement merely is that there must be *some* key for  $M$  to qualify as a representation-as.

With these modifications in place we can now formulate our own account of representation [3.238, 247]. Consider an agent who chooses an  $O$ -object as the base of representation and turns it into  $Z$ -representation by adopting an interpretation  $I$ . Let  $M$  refer to the package of the  $O$ -object together with the interpretation  $I$  that turns it into a  $Z$ -representation. Then:

#### Definition 3.15 DEKI

A scientific model  $M$  represents a target  $T$  iff:

1.  $M$  denotes  $T$  (and, possibly, parts of  $M$  denote parts of  $T$ )
2.  $M$  is a  $Z$ -representation exemplifying properties  $P_1, \dots, P_n$
3.  $M$  comes with a key,  $K$ , specifying how  $P_1, \dots, P_n$  are translated into a set of features  $Q_1, \dots, Q_m$ :  $K((P_1, \dots, P_n)) = (Q_1, \dots, Q_m)$
4. The model imputes at least one of the properties  $Q_1, \dots, Q_m$  onto  $T$ .

We call this the DEKI account of representation to highlight its key features: denotation, exemplification, keying-up and imputation.

Before highlighting some issues with this account, let us clarify how the account answers the questions we laid out in Sect. 3.1. Firstly, as an answer to the ER-problem, DEKI (Definition 3.15) provides an abstract framework in which to think about epistemic representation. In general, what concretizes each of the conditions needs to be investigated on a case-by-case basis. But far from being a defect, this degree of abstractness is an advantage. *Epistemic representation*, and even the narrower *model-representation*, are umbrella terms covering a vast array of different activities in different fields, and a view that sees representations in fields as diverse as elementary particle physics, evolutionary biology, hydrology and rational choice theory work in exactly the same way is either mistaken or too coarse to make important features visible. DEKI (Definition 3.15) occupies the right middle ground: it is general enough to cover a large array of cases and yet it highlights what all instances of scientific representation have in common. At the same time the account offers an elegant solution to the problem of models without targets: a model that apparently represents  $Z$  while there is no  $Z$  is a  $Z$ -representation but not representation of a  $Z$ .

It should be clear how we can use models to perform surrogative reasoning about their targets according to DEKI (Definition 3.15). The account requires that we investigate the properties that are exhibited by the model. These are then translated into a set of properties that are imputed onto the target. This act of imputation supplies a hypothesis about the target system: does it, or does it not, have those properties? This hypothesis does not have to be true, and as such DEKI (Definition 3.15) allows for the possibility of misrepresentation in a straightforward manner.

DEKI's (Definition 3.15) abstract character also allows us to talk about different styles of representation. Style, on the DEKI (Definition 3.15) account, is not a monolithic concept; instead it has several dimensions. Firstly, different  $O$ -objects can be chosen. In this way we may speak, say, of the *checkerboard style* and of the *cellular automaton style*. In each case a specific kind of object has been chosen for various modeling purposes. Secondly, the notion of an interpretation allows us to talk about how closely connected the properties of the model are to those that the object  $I$ -instantiates. Thirdly, different types of keys could be used to characterize different styles. In some instances the key might be the identity key, which would amount to a style of modeling that aims to construct replicas of target systems; in other cases the key incorporates different kinds of ideal-

izations or abstractions, which gives rise to idealization and abstraction keys. But different keys may be associated with entirely different representational styles.

Similarly, DEKI (Definition 3.15) suggests that there is no significant difference between scientific representations and other kinds of epistemic representation, at least at the general level. However, this is not to say that the two cannot be demarcated whatsoever. The sorts of interpretations under which pictures portray *Zs* seem to be different to the sorts of interpretations that are adopted in the scientific framework. Whether or not this can be cashed of more specifically is an interesting question that we cannot investigate here.

Many details in DEKI (Definition 3.15) still need to be spelled out. But the most significant difficulty, perhaps, arises in connection with the problem of ontology. It is not by accident that we have illustrated the account with a physical model, the Phillips–Newlyn machine. Exemplification requires instantiation, which is easily understood for material models, but is highly problematic in the context of nonconcrete models. One option is to view models as fictional entities as discussed in Sect. 3.6. But whether, and if so how, fictional entities instantiate properties is controversially discussed and more philosophical work is needed to make sense of such a notion. It is therefore an open question how this account works for nonconcrete models; for a discussion and a proposal see *Frigg and Nguyen* [3.248].

Finally, the account provides us with resources with which to think about the applicability of mathematics.

### 3.8 Envoi

We reviewed theories of epistemic representation. That each approach faces a number of challenges and that there is no consensus on the matter will not have come as a surprise to anybody. We hope, however, that we managed to map the lay of the land and to uncover the fault lines, and thereby aid future discussions.

Like the problem of style, various options are available. Firstly, mathematical structures themselves can be taken to be *O*-objects and feature as bases of representation. They can be interpreted on their own terms and therefore exemplify strictly mathematical properties. If one were of a structuralist bent, then the appropriate mathematical properties could be *structural*, which could then be imputed onto the target system (although notice that this approach faces a similar problem to the question of target-end structure discussed in Sect. 3.4.4). Alternatively, the key could provide a translation of these mathematical properties into ones more readily applicable to physical systems. A third alternative would be to take scientific models to be fictional objects, and then adopt an interpretation towards them under which they exemplify mathematical properties. Again, these could be imputed directly onto the target system, or translated into an alternative set of properties. Finally, these fictional models could themselves exemplify physical properties, but in doing so exemplify structural ones as well. Whenever a physical property is exemplified, this provides an extensional relation defined over the objects that instantiate it. The pros and cons of each of these approaches demands further research, but for the purposes of this chapter we simply note that DEKI (Definition 3.15) puts all of these options on the table. Using the framework of *O*-objects, interpretations, exemplification, keys, and imputation provides a novel way in which to think about the applicability of mathematics.

**Acknowledgments.** The authors are listed alphabetically; the chapter is fully collaborative. We would like to thank Demetris Portides and Fiora Salis for helpful comments on an earlier draft.

# Models and Explanation

## 4. Models and Explanation

Alisa Bokulich

Detailed examinations of scientific practice have revealed that the use of idealized models in the sciences is pervasive. These models play a central role in not only the investigation and prediction of phenomena, but also in their received scientific explanations. This has led philosophers of science to begin revising the traditional philosophical accounts of scientific explanation in order to make sense of this practice. These new model-based accounts of scientific explanation, however, raise a number of key questions: Can the fictions and falsehoods inherent in the modeling practice do real explanatory work? Do some highly abstract and mathematical models exhibit a non-causal form of scientific explanation? How can one distinguish an exploratory *how-possibly* model explanation from a genuine *how-actually* model explanation? Do modelers face tradeoffs such that a model that is optimized for yielding explanatory insight, for example, might fail to be the most predictively accurate, and vice versa? This chapter explores the various answers that have been given to these questions.

Explanation is one of the central aims of science, and the attempt to understand the nature of scientific explanation is at the heart of the philosophy of science. An explanation can be analyzed as consisting of two parts, a phenomenon or event to be explained, known as the *explanandum*, and that which does the job of explaining, the *explanans*. On the traditional approach, to explain a phenomenon is either to deduce the explanandum phenomenon from the relevant laws of nature and initial conditions, such as on the deductive-nomological (DN) account [4.1], or to trace the detailed causal chain leading up to that event, such as on the causal-mechanical account [4.2]. Underlying this traditional approach are the assumptions that, in order to genuinely explain, the explanans must be entirely true, and that the more complete and detailed the explanans is, the better the scientific explanation.

As philosophers of science have turned to more careful examinations of actual scientific practice, however, there have been three key observations that have challenged this traditional approach: first, many of the phenomena scientists seek to explain are incredibly complex; second, the laws of nature supposedly needed for explanation are either few and far between or entirely absent in many of the sciences; and third, a detailed causal description of the chain of events and interactions leading up to a phenomenon are often either beyond our grasp or not in fact what is most important for a scientific understanding of the phenomenon.

More generally, there has been a growing recognition that much of science is a model-based activity. (For an overview of many different types of models in science, and some of the philosophical issues regarding the nature and use of such models, refer to [4.3]).

Models are by definition incomplete and idealized descriptions of the systems they describe. This practice raises all sorts of epistemological questions, such as how can it be that false models lead to true insights?

And most relevant to our discussion here, how might the extensive use of models in science lead us to revise our philosophical account of scientific explanation?

## 4.1 The Explanatory Function of Models

Model-based explanations (or model explanations, for short) are explanations in which the explanans appeal to certain properties or behaviors observed in an idealized model or computer simulation as part of an explanation for why the (typically real-world) explanandum phenomenon exhibits the features that it does. For example, one might explain why sparrows of a certain species vary in their feather coloration from pale to dark by appealing to a particular game theory model: although coloration is unrelated to fitness, such a polymorphism can be a badge of status that allows the sparrows to avoid unnecessary conflicts over resources; dark birds are dominant and displace the pale birds from food sources. The model demonstrates that such a strategy is stable and successful, and hence can be used as part of the explanation for why we find this polymorphism among sparrows (see [4.4, 5] for further discussion).

There are, of course, many perils in assuming that just because we see a phenomenon or pattern exhibited in a model that it therefore explains why we see it in the real world: the same pattern or phenomenon could be produced in multiple, very different ways, and hence it might be only a phenomenological model at best, useful for prediction, but not a genuine explanation. Explanation and the concomitant notion of understanding are what we call success terms: if the purported explanation is not, in fact, right (right in some sense that will need to be spelled out) and the understanding is only illusory, then it is not, in fact, a genuine explanation. Determining what the success conditions are for a genuine explanation is the central philosophical problem in scientific explanation.

Those who have defended the explanatory power of models have typically argued that further conditions must be met in order for a model's exhibiting of a salient pattern or phenomenon to count as part of a genuine explanation of its real-world counterpart. Not all models are explanatory, and an adequate account of model explanation must provide grounds for making such discriminations. As we will see, however, different approaches have filled in these further requirements in different ways.

One of the earliest defenses of the view that models can explain is McMullin's [4.6] *hypothetico-structural* HS account of model explanations. In an HS explanation, one explains a complex phenomenon by pos-

tulating an underlying structural model whose features are causally responsible for the phenomenon to be explained. McMullin notes that such models are often tentative or metaphorical, but that a good model explanation will lay out a research program for the further refinement of the model. On his account, the justification of the model as genuinely explanatory involves a process known as de-idealization, where features that were left out are added back or a more realistic representation of those processes is given. More specifically he requires that one be able to give a theoretical justification for this de-idealization process, so that it is not merely an ad hoc fitting of the model to the data. He writes [4.7, p. 261]:

“If techniques for which no theoretical justification can be given have to be utilized to correct a formal idealization, this is taken to count against the explanatory propriety of that idealization. The model itself in such a case is suspect, no matter how good the predictive results it may produce.”

He further notes that a theoretical justification for the de-idealization process will only succeed if the original model has successfully captured the real structure of the phenomenon of interest.

As an example, McMullin [4.8] describes the fertility of the continental drift model in explaining why the continents seem to fit together like pieces of a puzzle and why similar fossils are found at distant locations. The continental drift model involved all sorts of idealizations and gaps: most notably, the chief proponent of this approach, Alfred Wegener, could offer no account of the forces or mechanisms by which the massive continents could move. Strictly speaking, we now know that the continental drift model is false, and has been supplanted by plate tectonics. But as McMullin notes, the continental drift model nonetheless captures key features of the real structure of the phenomenon of interest, and, hence, succeeds in giving genuine explanatory insight.

While McMullin's account of HS model explanations fits in many cases, there are other examples of model explanations in the sciences that do not seem to fit his account. First, there seem to be examples of model explanations where the idealizations are ineliminable, and, hence, they cannot be justified through

anything like the de-idealization analysis that McMullin describes [4.9]. Second, not all models are related to their target phenomena via an idealization: some models represent through a fictionalization [4.10]. Third, insofar as McMullin's HS model explanations are a subspecies of causal explanations, they do not account for noncausal model explanations. These sort of cases will be discussed more fully in subsequent sections.

Another early account of the explanatory power of models is Cartwright's [4.11] *simulacrum* account of explanation, which she introduces as an alternative to the DN account of explanation and elaborates in her book *How the Laws of Physics Lie*. Drawing on Duhem's [4.12] theory of explanation, she argues [4.11, p. 152]:

“To explain a phenomenon is to find a model that fits it into the basic framework of the theory and that thus allows us to derive analogues for the messy and complicated phenomenological laws which are true of it.”

According to Cartwright, the laws of physics do not describe our real messy world, only the idealized world we construct in our models. She gives the example of the harmonic oscillator model, which is used in quantum mechanics to describe a wide variety of systems. One describes a real-world helium-neon laser as if it were a van der Pol oscillator; this is how the phenomenon becomes tractable and we are able to make use of the mathematical framework of our theory. The laws of quantum mechanics are true in this model, but this model is just a simulacrum of the real-world phenomenon. By *model*, Cartwright means “an especially prepared, usually fictional description of the system under study” [4.11, p. 158]. She notes that while some of the properties ascribed to the objects in the models are idealizations, there are other properties that are pure fictions; hence, one should not think of models in terms of idealizations alone.

Although Cartwright's simulacrum account is highly suggestive, it leaves unanswered many key questions, such as when a model should or should not be counted as explanatory. Elgin and Sober [4.13] offer a possible emendation to Cartwright's account that they argue discriminates which sorts of idealized causal models can explain. The key, according to their approach, is to determine whether or not the idealizations in the model are what they call *harmless*. A harmless idealization is one that if corrected “wouldn't make much difference in the predicted value of the effect variable” [4.13, p. 448]. They illustrate this approach using the example of optimality models in evolutionary biology. Optimality models are models that determine what value of a trait maximizes fitness (is optimal) for

an organism given certain constraints (e.g., the optimal length of a bear's fur, given the benefits of longer fur and the costs of growing it, or the optimal height at which crows should drop walnuts in order to crack open the shells, given the costs of flying higher, etc.). If organisms are indeed fitter the closer a trait is to the optimal value, and if natural selection is the only force operating, then the optimal value for that trait will evolve in the population. Thus, optimality models are used to explain why organisms have trait values at or near the optimal value (e.g., why crows drop walnuts from an average of 3 m high [4.14]).

As Elgin and Sober note, optimality models contain all sorts of idealizations: “they describe evolutionary trajectories of populations that are infinitely large in which reproduction is asexual with offspring always resembling their parents, etc.” [4.13, p. 447]. Nonetheless, they argue that these models are genuinely explanatory when it can be shown that the value described in the explanandum is close to the value predicted by the idealized model; when this happens we can conclude that the idealizations in the model are harmless [4.13, p. 448]. Apart from this concession about *harmless* idealizations, Elgin and Sober's account of explanation remains close to the traditional DN account in that they further require:

1. The explanans must cite the cause of the explanandum
2. The explanans must cite a law
3. All of the explanans propositions must be true [4.13, p. 446]

though their condition 3 might better be stated as all the explanans propositions are *either true or harmlessly false*.

As a general account of model explanations, however, one might argue that the approaches of Cartwright, Elgin, and Sober are too restrictive. As noted before, this approach still depends on there being laws of nature from which the phenomenon is to be derived, and such laws just might not be available. Moreover, it is not clear that explanatory models will contain only harmless idealizations. There may very well be cases in which the idealizations make a difference (are not harmless) and yet are essential to the explanation (e.g., [4.15, 16]).

While the simulacrum approach of Cartwright, especially as further developed by Elgin and Sober, largely draws its inspiration from the traditional DN approach to explanation, there are other approaches to model explanation that are tied more closely to the traditional causal-mechanical approach to explanation. Craver [4.17], for example, has argued that models are explanatory when they describe mechanisms. He writes “[...] the distinction between explanatory and nonex-

planatory models is that the [former], and not the [latter] describe mechanisms” [4.17, p. 367]. The central notion of mechanism, here, can be understood as consisting of the various components or parts of the phenomenon of interest, the activities of those components, and how they are organized in relation to each other.

Craver imposes rather strict conditions on when such mechanistic models can be counted as explanatory; he writes, “To characterize the phenomenon correctly and completely is the first restrictive step in turning a model into an acceptable mechanistic explanation” [4.17, p. 369]. (Some have argued that if one has a complete and accurate description of the system or phenomenon of interest, then it is not clear that one has a model [4.18]). Craver analyzes the example of the Hodgkin–Huxley mathematical model of the action potential in an axon (nerve fiber). Despite the fact that this model allowed Hodgkin and Huxley to derive many electrical features of neurons, and the fact that it was based on a number of fundamental laws of physics and chemistry, Craver argues that it was not in fact an explanatory model. He describes it instead as merely a phenomenological model because it failed to accurately describe the details of the underlying mechanism.

A similar mechanistic approach to model explanation has been developed by Kaplan [4.19], who introduces what he calls the mechanism–model–mapping (or 3M) constraint. He defines the 3M constraint as follows [4.19, p. 347]:

“A model of a target phenomenon explains that phenomenon to the extent that (a) the variables in the model correspond to identifiable components, activities, and organizational features of the target mechanism that produces, maintains, or underlies the phenomenon, and (b) the (perhaps mathematical) variables in the model correspond to causal relations among the components of the target mechanism.”

Kaplan takes this 3M constraint to provide a demarcation line between explanatory and nonexplanatory models. He further notes that [4.19, p. 347]

“3M aligns with the highly plausible assumption that the more accurate and detailed the model is for a target system or phenomenon the better it explains that phenomenon.”

Models that do not comply with 3M are rejected as nonexplanatory, being at best phenomenological models, useful for prediction, but giving no explanatory insight. In requiring that, explanatory models describe the *real* components and activities in the mechanism

that are *in fact* responsible for producing the phenomenon ([4.17, p. 361], [4.19, p. 353]). Craver and Kaplan rule out the possibility that fictional, metaphorical, or strongly idealized models can be explanatory.

One of the most comprehensive defenses of the explanatory power of models is given by Bokulich [4.18, 20–22], who argues that model explanations such as the three discussed previously (McMullin, Cartwright–Elgin–Sober, and Craver–Kaplan), can be seen as special cases of a more general account of the explanatory power of models. Bokulich’s approach draws on Woodward’s counterfactual account of explanation, in which [4.23, p. 11]

“the explanation must enable us to see what sort of difference it would have made for the explanandum if the factors cited in the explanans had been different in various possible ways.”

She argues that model explanations typically share the following three features: first, the explanans makes essential reference to a scientific model, which, as is the case with all models, will be an idealized, abstracted, or fictionalized representation of the target system. Second, the model explains the explanandum by showing how the elements of the model correctly capture the patterns of counterfactual dependence in the target system, enabling one to answer a wide range of what Woodward calls *what-if-things-had-been-different* questions. Finally, there must be what Bokulich calls a *justificatory step*, specifying the domain of applicability of the model and showing where and to what extent the model can be trusted as an adequate representation of the target for the purpose(s) in question [4.18, p. 39]; see also [4.22, p. 730]. She notes that this justificatory step can proceed bottom-up through something like a de-idealization analysis (as McMullin, Elgin, and Sober describe), top-down through an overarching theory (such as in the semiclassical mechanics examples Bokulich [4.20, 21] discusses), or through some combination.

Arguably one of the advantages of Bokulich’s approach is that it is not tied to one particular conception of scientific explanation, such as the DN or mechanistic accounts. By relaxing Woodward’s manipulationist construal of the counterfactual condition, Bokulich’s approach can even be extended to highly abstract, structural, or mathematical model explanations. She argues that the various *subspecies* of model explanation can be distinguished by noting what she calls the *origin* or ground of the counterfactual dependence. She explains, it could be either [4.18, p. 40]

“the elements represented in the model *causally producing* the explanandum (in the case of causal

model explanations), the elements of the model *being the mechanistic parts which make up the explanandum-system whole* (in the case of mechanistic model explanations), or the explanandum being a consequence of the laws cited in the model (in the case of covering law model explanations)."

She goes on to identify a fourth type of model explanation, which she calls structural model explanation, in which the counterfactual dependence is grounded in the typically mathematical structure of the theory, which limits the sorts of objects, properties, states, or behaviors that are admissible within the framework of that theory [4.18, p. 40]. Bokulich's approach can be thought of as one way to flesh out Morrison's suggestive, but unelaborated, remark that "the reason models are explanatory is that in representing these systems, they exhibit certain kinds of structural dependencies" [4.24, p. 63].

More recently, Rice [4.25] has drawn on Bokulich's account to develop a similar approach to the explanatory power of models that likewise uses Woodward's counterfactual approach without the manipulation condition. He writes [4.25, p. 20]:

"The requirement that these counterfactuals must enable one to, in principle, *intervene* in the system restricts Woodward's account to specifically causal explanations. However, I think it is a mistake to require that all scientific explanations must be causal. Indeed, if one looks at many of the explanations offered by scientific modelers, causes are not mentioned."

Compare this to Bokulich's statement [4.18, p. 39]:

"I think it is a mistake to construe all scientific explanation as a species of causal explanation, and more to the point here, it is certainly not the case that all model explanations should be understood as causal explanations. Thus while I shall adopt Woodward's account of explanation as the exhibiting of a pattern of counterfactual dependence, I will not construe this dependence narrowly in terms of the possible causal manipulations of the system"

Rice rightly notes that the question of causation is conceptually distinct from the question of what explains. He further requires on this approach that model explanations provide two kinds of counterfactual information, namely both what the phenomenon depends on and what sorts of changes are irrelevant to that phenomenon. Following Batterman [4.9, 15, 26], he notes that for explanations of phenomena that exhibit a kind of universality, an important part of the explanation is understanding that the particular causal details or processes are irrelevant – the same phenomenon would have been reproduced even if the causal details had been different in certain ways.

As an illustration, Rice discusses the case of optimality modeling in biology. He notes that optimality models are not only highly idealized, but also can be understood as a type of equilibrium explanation, where "most of the explanatory work in these models is done by *synchronic mathematical representations of structural features of the system*" [4.25, p. 8]. He connects this to the counterfactual account of model explanation as follows [4.25, p. 17]:

"Optimality models primarily focus on noncausal counterfactual relations between structural features and the system's equilibrium point. Moreover, these features can sometimes explain the target phenomenon without requiring any additional causal claims about the relationships represented in the model."

These causal details are irrelevant because the structural features cited in the model are multiply realizable; indeed, this is what allows optimality models to be used in explaining a wide variety of features across a diversity of biological systems.

In the approaches to model explanations discussed here, two controversial issues have arisen that merit closer scrutiny: first, whether the fictions or falsehoods in models can themselves do real explanatory work (i. e., even when they are neither harmless, deidealizable, nor eliminable), and second, whether many model explanations illustrate an important, but often overlooked, noncausal form of explanation. These issues will be taken up in turn in the next two sections.

## 4.2 Explanatory Fictions: Can Falsehoods Explain?

Models contain all sorts of falsehoods, from omissions, abstractions, and idealizations to outright fictions. One of the most controversial issues in model explanations is whether these falsehoods, which are inherent in the modeling practice, are compatible with the explanatory aims of science. *Reiss* in the context of explanatory models in economics has called this tension the *explanation paradox*: he writes [4.27, p. 43]:

“Three mutually inconsistent hypotheses concerning models and explanation are widely held: (1) economic models are false; (2) economic models are nevertheless explanatory; and (3) only true accounts explain. Commentators have typically resolved the paradox by rejecting either one of these hypotheses. I will argue that none of the proposed resolutions work and conclude that therefore the paradox is genuine and likely to stay.”

(This paradox, and some criticisms to *Reiss*’s approach (such as [4.28] are explored in a special issue of the *Journal of Economic Methodology* (volume 20, issue 3).)

The field has largely split into two camps on this issue: those who think it is only the true parts of models that do explanatory work and those who think the falsehoods play an essential role in the model explanation. Those in the former camp rely on things like de-idealization and harmless analyses to show that the falsehoods do not get in the way of the true parts of the model that do the real explanatory work. Those in the latter camp have the challenging task of showing that some idealizations are essential and some fictions yield true insights.

The *received view* is that the false parts of models only concern those things that are explanatorily irrelevant. Defenders of the received view include *Strevens*, who in his book detailing his kairetic account of scientific explanation (*Strevens* takes the term kairetic from the ancient Greek word *kairos*, meaning crucial moment [4.29, p. 477].), writes, “No causal account of explanation – certainly not the kairetic account – allows nonveridical models to explain” [4.29, p. 297]. He spells out more carefully how such a view is to be reconciled with the widespread use of idealized models to explain phenomena in nature, by drawing the following distinction [4.29, p. 318]:

“The content of an idealized model, then, can be divided into two parts. The first part contains the difference-makers for the explanatory target. [...] The second part is all idealization; its overt claims are false but its role is to point to parts of the actual

world that do not make a difference to the explanatory target.”

In other words, it is only the true parts of the model that do any explanatory work. The false parts are harmless, and hence should be able to be de-idealized away without affecting the explanation.

On the other side, a number of scholars have argued for the counterintuitive conclusion that sometimes it is in part *because* of their falsehoods – not despite them – that models explain. *Batterman* [4.9, 15, 26], for example, has argued that some idealizations are explanatorily ineliminable, that is, the idealizations or falsehoods themselves do real explanatory work. *Batterman* considers continuum model explanations of phenomena such as shocks (e.g., compressions traveling through a gas in a tube) and breaking drops (e.g., the shape of water as it drips from a faucet). In order to explain such phenomena, scientists make the idealization that the gas or fluid is a continuum (rather than describing it veridically as a collection of discrete gas or water molecules). These false continuum assumptions are essential for obtaining the desired explanation. In the breaking drop case, it turns out that different fluids of different viscosities dripping from faucets of different widths will all exhibit the same shape upon breakup. The explanation depends on a singularity that exists only in the (false) continuum model; such an explanation does not exist on the de-idealized molecular dynamics approach [4.15, pp. 442–443]). Hence, he concludes [4.15, p. 427],

“continuum idealizations are explanatorily ineliminable and [...] a full understanding of certain physical phenomena cannot be obtained through completely detailed, nonidealized representations.”

If such analyses are right, then they show that not all idealizations can be de-idealized, and, moreover, those falsehoods can play an essential role in the explanation.

*Bokulich* [4.10, 20–22] has similarly defended the view that it is not just the true parts of models that can do explanatory work, arguing that in some cases even fictions can be explanatory. She writes, “some fictions can give us genuine insight into the way the world is, and hence be genuinely explanatory and yield real understanding” [4.10, p. 94]. She argues that some fictions are able to do this by capturing in their fictional representation real patterns of structural dependencies in the world. As an example, she discusses semiclassical models whereby fictional electron orbits are used to explain peculiar features of quantum spectra. Although, according to quantum mechanics, electrons do not follow definite trajectories or orbits (i. e., such orbits are

fictions), physicists recognized that puzzling peaks in the recurrence spectrum of atoms in strong magnetic fields have a one-to-one correspondence with particular closed classical orbits [4.30, pp. 2789–2790] (quoted in [4.10, p. 99]):

“The resonances [...] form a series of strikingly simple and regular organization, not previously anticipated or predicted. [...] The regular type resonances can be physically rationalized and explained by classical periodic orbits of the electron on closed trajectories starting at and returning to the proton as origin.”

As she explains, at no point are these physicists challenging the status of quantum mechanics as the true, fundamental ontological theory; rather, they are deploying the fiction with the express recognition that it is indeed a literally false representation (interestingly this was one of the *Vaihinger*’s criteria for a *scientific* fiction [4.31, p. 98]). Nonetheless, it is a representation that is able to yield true physical insight and understanding by carefully capturing in its fictional representation the appropriate patterns of counterfactual dependence of the target phenomenon.

*Bokulich* [4.10, 20–22] offers several such examples of explanatory fictional models from semiclassical mechanics, where the received explanation of quantum phenomena appeals to classical structures, such as the Lyapunov (stability) exponents of classical trajectories, that have no clear quantum counterpart. Moreover, she notes that these semiclassical models with their fictional assumption of classical trajectories are valued not primarily as calculation tools (often they require calculations that are just as complicated), but rather are valued as models that provide an unparalleled level of physical insight into the structure of the quantum phenomena. Bokulich is careful to note that not just any fiction can do this kind of explanatory work; indeed, most fictions cannot. She shows more specifically how these semiclassical examples meet the three criteria of her account of model-based explanation, discussed earlier (e.g., [4.10, p. 106]).

A more pedestrian example of an explanatory fiction, and one that brings out some of the objections to such claims, is the case of light rays postulated by the ray (or geometrical) theory of optics. Strictly speaking, light rays are a fiction. The currently accepted fundamental theory of wave optics denies that they exist. Yet, light rays seem to play a central role in the scientific explanation of lots of phenomena, such as shadows and rainbows. The physicists *Kleppner* and *Delos*, for example, note [4.32, p. 610]:

“When one sees the sharp shadows of buildings in a city, it seems difficult to insist that light-rays are merely calculational tools that provide approximations to the full solution of the wave equation.”

Similarly, *Batterman*, argues [4.33, pp. 154–155]:

“One cannot explain various features of the rainbow (in particular, the universal patterns of intensities and fringe spacings) without ultimately having to appeal to the structural stability of ray theoretic structures called caustics – focal properties of families of rays.”

*Batterman* is quite explicit that he does not think that an explanatory appeal to these ray-theoretic structures requires reifying the rays; they are indeed fictions.

Some, such as *Belot*, want to dismiss ray-optics models as nothing but a mathematical device devoid of any physical content outside of the fundamental (wave) theory. He writes [4.34, p. 151]:

“The mathematics of the less fundamental theory is definable in terms of that of the more fundamental theory; so the requisite mathematical results can be proved by someone whose repertoire of interpreted physical theories included only the latter.”

The point is roughly this: it looks like in *Batterman*’s examples that one is making an explanatory appeal to fictional entities from a *less fundamental* theory that has been superseded (e.g., ray optics or classical mechanics). However, all one needs from that superseded theory is the mathematics – one does not need to give those bits of mathematics a physical interpretation in terms of the fictional entities or structures. Moreover, that mathematics appears to be definable in terms of the mathematics of the true *fundamental* theory. Hence, those fictional entities are not, in fact, playing an explanatory role.

*Batterman* has responded to these objections, arguing that in order to have an explanation, one does, in fact, need the fictional physical interpretation of that mathematics, and hence the explanatory resources of the nonfundamental theory. He explains [4.33, p. 159]:

“Without the physical interpretation to begin with, we would not know *what* boundary conditions to join to the differential equation. Neither, would we know *how* to join those boundary conditions to the equation. Put another way, we must examine the physical details of the *boundaries* (the shape, reflective and refractive details of the drops, etc.) in order to set up the *boundary conditions* required for the mathematical solution to the equation.”

In other words, without appealing to the fictional rays, we would not have the relevant information we need to appropriately set up and solve the mathematical model that is needed for the explanation.

In a paper with *Jansson*, Belot has raised similar objections against Bokulich's arguments that classical structures can play a role in explaining quantum phenomena. They write [4.35, p. 82]:

“Bokulich and others see explanations that draw on semiclassical considerations as involving elements of classical physics as well as of quantum physics. [...] But there is an alternative way of thinking of semiclassical mechanics: [...] starting with the formalism of quantum mechanics one proves theorems about approximate solutions – theorems that happen to involve some of the mathematical apparatus of classical mechanics. But this need not tempt us to think that there is [classical] physics in our explanations.”

Once again, we see the objection that it is just the bare mathematics, not the mathematics with its physical interpretation that is involved in the explanation. On Bokulich's view, however, it is precisely by connecting that *mathematical apparatus* to its physical interpretation in terms of classical mechanics, that one gains a deeper physical insight into the system one is studying. On her view, explanation is importantly about advancing understanding, and for this the physical interpretation is important. (*Potochnik* [4.5, Chap. 5] has also argued for a tight connection between explanation and understanding, responding to some of the traditional objections against this association. More broadly, she emphasizes the communicative function of explanation over the ontological approach to explanation, which makes more room for nonveridical model explanations than the traditional approach.) Even though classical mechanics is not the true fundamental theory, there are important respects in which it gets things right, and hence reasoning with fictional classical structures within the well-established confines of semiclassical mechanics, can yield explanatory insight and deepen our understanding.

As we have seen, these claims that fictions can explain (in special cases such as ray optics and classical structures) remain controversial and involve subtle issues. These debates are not entirely new, however, and they have some interesting historical antecedents, for example, in the works of Niels Bohr and James Clerk Maxwell. More specifically, when Bohr is articulating his widely misunderstood *correspondence principle*, (for an accessible discussion see [4.36]) he argues that one can explain why only certain quantum transitions between stationary states in atoms are allowed by ap-

pealing to which harmonic components appear in the Fourier decomposition of the electron's classical orbit (see [4.20, Sect. 4.2] and references therein). He does this even long after he has conceded to the new quantum theory that classical electron trajectories in the atom are impossible (i. e., they are a fiction). Although *Heisenberg* used this formulation of the correspondence principle to construct his matrix mechanics, he argued that “it must be emphasized that this correspondence is a purely formal result” [4.37, p. 83], and should not be thought of as involving any physical content from the other theory. Bohr, by contrast, was dissatisfied with this interpretation of the correspondence principle as pure mathematics, arguing instead that it revealed a deep *physical* connection between classical and quantum mechanics. Even earlier, we can see some of these issues arising in the work of *Maxwell*, who, in exploiting the utility of fictional models and physical analogies between disparate fields, argued ([4.38, p. 187]; for a discussion, see [4.39]):

“My aim has been to present the mathematical ideas to the mind in an embodied form [...] not as mere symbols, which convey neither the same ideas, nor readily adapt themselves to the phenomena to be explained.”

Three other challenges have been raised against the explanatory power of fictional models. First, there is a kind of slippery-slope worry that, once we admit some fictional models as explanatory, we will not have any grounds on which to dismiss other fictional models as nonexplanatory. *Bokulich* [4.22] introduces a framework for addressing this problem. Second, *Schindler* [4.40] has raised what he sees as a tension in Bokulich's account. He claims that on one hand she says semiclassical explanations of quantum phenomena are autonomous in the sense that they provide more insight than the quantum mechanical ones. Yet, on the other hand, she notes that semiclassical models are justified through semiclassical theory, which connects these representations as a kind of approximation to the full quantum mechanics. Hence, they cannot be autonomous. This objection seems to trade on an equivocation of the term *autonomous*: in the first case, *autonomous* is used to mean “a representation of the phenomenon that yields more physical insight” and in the second case *autonomous* is used to mean “cannot be mathematical justified through various approximation methods”. These seem to be two entirely different concepts, and, hence, not really in tension with each other. Moreover, Bokulich never uses the term *autonomous* to describe either, so this seems to be a misleading reading of her view.

Schindler also rehearses the objection, raised by *Belot* and *Jansson* [4.35], that by eliminating the interventionist condition in Woodward's counterfactual approach to explanation she loses what he calls "the asymmetry-individuating function", by which he means her account seems susceptible to the traditional problem of asymmetry that plagued the DN account of explanation (e.g., that falling barometers could be used to explain impending storms or shadows could be used to explain the height of flag poles, to recall Sylvain Bromberger's well-known examples). This problem was taken to be solved by the causal approach to explanation, whereby one secures the explanatory asymmetry simply by appealing to the asymmetry of causation. It is important to note, however, that this is not an objection specifically to Bokulich's account of structural model explanation, but rather is a challenge for any noncausal account of explanation (*Bokulich* outlines a solution to the problem of asymmetry for her account in [4.22]). Since many examples of explanatory models purport to be noncausal explanations, we will examine this topic more fully in the next section.

Another context in which this issue about the explanatory power of fictional models arises is in connection with cognitive models in psychology and cognitive neuroscience. *Weiskopf*, for example, discusses how psychological capacities are often understood in terms of cognitive models that functionally abstract from the underlying real system. More specifically, he notes [4.41, p. 328]:

"In attempting to understand the high level dynamics of complex systems like brains, modelers have recourse to many techniques for constructing such indirect accounts [...] *reification, functional abstraction, and fictionalization.*"

By reification, he means "positing something with the characteristics of a more or less stable and enduring object, where in fact no such thing exists" [4.41, p. 328]. He gives as an example the positing of symbolic representations in classical computational systems, even though he notes that nothing in the brain seems to *stand still* or be manipulable in the way symbols do. Functional abstraction, he argues occurs when we [4.41, p. 329]

"decompose a modeled system into subsystems and other components on the basis of what they do, rather than their correspondence with organizations and groupings in the target system."

He notes that this occurs when there are cross-cutting functional groupings that do not map onto the structural or anatomical divisions of the brain. He notes that this strategy emphasizes *networks, not locations* in

relating cognition to neural structures. Finally, there is also fictionalization, which, as he describes [4.41, p. 331],

"involves putting components into a model that are known not to correspond to any element of the modeled system, but which serve an essential role in getting the models to operate correctly."

He gives as an example of a fiction in cognitive modeling what are called *fast enabling links* (FELs), which are independent of the channels by which cells actually communicate and are assumed to have functionally infinite propagation speeds, allowing two cells to fire in synchrony [4.41, p. 331]. Despite being false in these ways, some modelers take these fictions to be essential to the operation of the model and not likely to be eliminated in future versions.

*Weiskopf* concludes that models involving reifications, functional abstractions, and fictions, can nonetheless in some cases succeed in "meeting the general normative constraints on explanatory models perfectly well" [4.41, p. 332], and hence such models can be counted as genuinely explanatory. Although *Weiskopf* recognizes the many great successes of mechanistic explanations in biological and neural systems, he wants to resist an *imperialism* that attempts to reduce all cases of model explanations in these fields to mechanistic model explanations.

More recently, *Buckner* [4.42] has criticized *Weiskopf's* arguments that functionalist models involving fictions, abstractions, and reification can be explanatory and defended the mechanist's maxim (e.g., as articulated by Craver and Kaplan) that only mechanistic models can genuinely explain. *Buckner* employs two strategies in arguing against *Weiskopf*: first, in cases where the models do explain, he argues that they are really just mechanism sketches, and where they cannot be reconstructed mechanistically, he dismisses them as impoverished explanations. He writes [4.42, p. 3]:

"Concerning fictionalization and reification, I concede that models featuring such components cannot be interpreted as mechanism sketches, but argue that interpreting their nonlocalizable components as natural kinds comes with clear costs in terms of those models' counterfactual power. [...] Functional abstraction, on the other hand, can be considered a legitimate source of kinds, but only on the condition that the functionally abstract models be interpreted as sketches that could be elaborated into a more complete mechanistic model."

An essential feature of mechanistic models seems to be that their components are localizable. *Weiskopf* argues, however, that his functional kinds are multi-

ply realizable, that is, they apply to many different kinds of underlying mechanisms, and that in some cases, they are distributed in the sense that they ascribe to a given model component capacities that are distributed amongst distinct parts of the physical system. Hence, without localization, such models cannot be reconstructed as mechanistic models.

What of Buckner's claim that fictional models will be impoverished with regard to their counterfactual power? Consider again Weiskopf's example of the fictional FELs, which are posited in the model to allow the cells to achieve synchrony. Buckner argues explanations involving models with FELs are impoverished in that if one had a true account of synchrony, that model explanation would support *more* counterfactual knowledge. It is not clear, however, that this objection undermines the explanatory power of models involving FELs per se; rather it seems only to suggest that if we knew more and had the true account of syn-

chrony we might have a *deeper* explanation (at least on the assumption that this true account of synchrony would allow us to answer a wider range of what-if-things-had-been-different questions) (For an account of explanatory depth, see [4.43]). However, the explanation involving the fiction might still be perfectly adequate for the purpose for which it is being deployed, and hence it need not even be counted as impoverished. For example, there might be some explananda (ones other than the explanandum of *how do cells achieve synchrony*) for which it simply does not matter *how* cells achieve synchrony; the fact that they *do* achieve synchrony might be all that is required for some purposes.

Weiskopf is not alone in trying to make room for nonmechanistic model explanations; Irvine [4.44] and Ross [4.45] have also recently defended nonmechanistic model explanations in cognitive science and biology. Their approaches argue for noncausal forms of model explanation, which we will turn to next.

### 4.3 Explanatory Models and Noncausal Explanations

Recently, there has been a growing interest in noncausal forms of explanation. Similar to Bokulich's [4.20, 21] approach, many of these seek to understand noncausal explanations within the context of Woodward's [4.23] counterfactual approach to explanation without the interventionist criterion that restricts his account specifically to causal explanation [4.25, 46]. Noncausal explanations are usually defined negatively as explaining by some means *other than* citing causes, though this is presumably a heterogeneous group. We have already seen one type of noncausal model-based explanation: [4.20, 21] structural model explanations in physics. More recently, examples have been given in fields ranging from biology to cognitive science. Highly mathematical model explanations are another type of noncausal explanation, though not all mathematical models are noncausal. A few recent examples are considered here.

In the context of biology and cognitive science, Irvine [4.44] has argued for the need to go beyond the causal-mechanical account of model explanation and defends what she calls a noncausal structural form of model explanation. She focuses specifically on reinforcement learning (RL) models in cognitive science and optimality models in biology. She notes that although RL and optimality models can be construed as providing causal explanations in some contexts, there are other contexts in which causal explanations miss the mark. She writes [4.44, p. 11]:

“In the account developed here, it is not the presence of idealisation or abstraction in models that

is important, nor the lack of description of causal dynamics or use of robustness analyses to test the models. Instead, it is the bare fact that some models and target systems have equilibrium points [that] are highly O-robust with respect to initial conditions and perturbations. [...] This alone can drive a claim about noncausal structural explanations.”

By O-robustness, Irvine means a robust convergence to an optimal state across a range of interventions, whether it be an optimization of fitness or an optimization of decision-making strategies. Her argument is that since interventions (in the sense of Woodward) do not make a difference to the convergence on the optimal state, that convergence cannot be explained causally, and is instead due to structural features of the model and target system it explains.

Another recent approach to noncausal model explanation is Batterman and Rice's [4.47] minimal model explanations. Minimal models are models that explain patterns of macroscopic behavior for systems that are heterogeneous at smaller scales. Batterman and Rice discuss two examples of minimal models in depth: the Lattice Gas Automaton model, which is used to explain large-scale patterns in fluid flow, and Fisher's Sex Ratio model, which is used to explain why one typically finds a 1 : 1 ratio of males to females, across diverse populations of species. In both cases, they argue [4.47, p. 373]:

“these minimal models are explanatory because there is a detailed story about why the myriad details that distinguish a class of systems are irrelevant

to their large-scale behavior. This story demonstrates, rather than assumes, a kind of stability or robustness of the large-scale behavior we want to explain under drastic changes in the various details of the system.”

They make two further claims about these minimal model explanations. First, they argue that these explanations are “distinct from various causal, mechanical, difference making, and so on, strategies prominent in the philosophical literature” [4.47, p. 349]. Second, they argue that the explanatory power of minimal models cannot be accounted for by any kind of mirroring or mapping between the model and target system (what they call the *common features* account). Instead, these noncausal explanations work by showing that the minimal model and diverse real-world systems fall into the same universality class. This latter claim has been challenged by *Lange* [4.48] who, though sympathetic to their claim that minimal models are a noncausal form of model explanation, argues that their explanatory power does in fact derive from the model sharing features in common with the diverse systems it describes (i. e., the *common features* account Batterman and Rice reject).

*Ross* [4.45] has applied the minimal models account to dynamical model explanations in the neurosciences. More specifically, she considers as an explanandum phenomenon the fact that a diverse set of neural systems (e.g., rat hippocampal neurons, crustacean motor neurons, and human cortical neurons *Ross* [4.45, p. 48]), which are quite different at the molecular level, nonetheless all exhibit the same *type I* excitability behavior. She shows that the explanation for this involves applying mathematical abstraction techniques to the various detailed models of each particular type of neural system and then showing that all these diverse systems converge on one and the same canonical model (known as the Ermentrout–Kopell model). After defending the explanatory power of these canonical models, *Ross* then contrasts this kind of noncausal model explanation with the causal–mechanical model approach [4.45, p. 46]:

“The canonical model approach contrasts with Kaplan and Craver’s claims because it is used to explain the shared behavior of neural systems without revealing their underlying causal–mechanical structure. As the neural systems that share this behavior consist of differing causal mechanisms [...] a mechanistic model that represented the causal structure of any single neural system would no longer represent the entire class of systems.”

Her point is that a noncausal explanation is called for in this case because the particular causal details are

irrelevant to the explanation of the universal behavior of class I neurons. The minimal models approach, as we saw above, is designed precisely to capture these sort explanations involving universality.

More generally, many highly abstract or highly mathematical model explanations also seem to fall into this general category of noncausal model explanations. *Pincock*, for example, identifies a type of explanation that he calls *abstract explanation*, which could be extended to model-based explanations. He writes “the best recent work on causal explanation is not able to naturally accommodate these abstract explanations” [4.49, p. 11]. Although some of the explanations *Pincock* cites, such as the topological (graph theory) explanation for why one cannot cross the seven bridges of Königsberg exactly once in a nonbacktracking circuit, seem to be genuinely noncausal explanations, it is not clear that all *abstract* explanations are necessarily noncausal. *Reutlinger* and *Andersen* [4.50] have recently raised this objection against *Pincock*’s account, arguing that an explanation’s being abstract is not a sufficient condition for it being noncausal. They argue that many causal explanations can be abstract too and so more work needs to be done identifying what makes an explanation truly noncausal. This is a particularly pressing issue in model-based explanations, since many scientific models are abstract in this sense of leaving out microphysical or concrete causal details about the explanandum phenomenon.

*Lange* [4.51] has also identified a kind of noncausal explanation that he calls a *distinctively mathematical* explanation. *Lange* considers a number of candidate mathematical explanations, such as why one cannot divide 23 strawberries evenly among three children, why cicadas have life-cycle periods that are prime, and why honeybees build their combs on a hexagonal grid. *Lange* notes that whether these are to count as distinctively mathematical explanations depends on precisely how one construes the explanandum phenomenon. If we ask why honeybees divide the honeycomb into hexagons, rather than other polygons, and we cite that it is selectively advantageous for them to minimize the wax used, together with the mathematical fact that a hexagonal grid has the least total perimeter, then it is an ordinary causal explanation (it works by citing selection pressures). If, however [4.50, p. 500]:

“we narrow the explanandum to the fact that in any scheme to divide their combs into regions of equal area, honeybees would use at least the amount of wax they would use in dividing their combs into hexagons. [...] this fact has a distinctively mathematical explanation.”

As *Lange* explains more generally [4.51, p. 485]:

“These explanations are noncausal, but this does not mean that they fail to cite the explanandum’s causes, that they abstract away from detailed causal histories, or that they cite no natural laws. Rather, in these explanations, the facts doing the explaining are modally stronger than ordinary causal laws.”

The key issue is not whether the explanans cite the explanandum’s causes, but whether the explana-

tion works *by virtue of* citing those causes. Distinctively mathematical (noncausal) explanations show the explanandum to be necessary to a stronger degree than would result from the causal powers alone.

As this literature makes clear, distinguishing causal from noncausal explanations is a subtle and open problem, but one crucial for understanding the wide-spread use of abstract mathematical models in many scientific explanations.

## 4.4 How-Possibly versus How-Actually Model Explanations

Models and computer simulations can often generate patterns or behaviors that are strikingly similar to the phenomenon to be explained. As we have seen, however, that is typically not enough to conclude that the model thereby explains the phenomenon. An important distinction here is that between a *how-possibly* model explanation and a *how-actually* model explanation.

The notion of a how-possibly explanation was first introduced in the 1950s by Dray in the context of explanations in history. Dray conceived of how-possibly explanations as a rival to the DN approach, which he labeled *why-necessarily* explanations [4.52, p. 161]. Dray interpreted how-possibly explanations as ones that merely aim to show why a particular phenomenon or event “need not have caused surprise” [4.52, p. 157]; hence, they are answers to a different kind of question and can be considered complete explanations in themselves. Although Dray’s approach was influential, subsequent authors have interpreted this distinction in different ways. Brandon, in the context of explanations in evolutionary biology, for example, writes [4.53, p. 184]:

“A how-possibly explanation is one where one or more of the explanatory conditions are speculatively postulated. But if we gather more and more evidence for the postulated conditions, we can move the how-possibly explanation along the continuum until finally we count it as a how-actually explanation.”

On this view, the distinction is a matter of the degree of confirmation, not a difference of kind: as we get more evidence that the processes cited in the model are the processes operating in nature, we move from a how-possibly to how-actually explanation.

*Forber* [4.54], however, rejects this interpretation of the distinction as marking a degree of empirical support, and instead defends Dray’s original contention that they mark different kinds of explanations. More specifically, *Forber* distinguishes two kinds of how-possibly

explanations that he labels *global how-possibly* and *local how possibly* explanations [4.54, p. 35]:

“The global how-possibly explanations have theory, mathematics, simulations, and analytical techniques as the resources for fashioning such explanations. [...] The local how-possibly explanations draw upon the models of evolutionary processes and go one step further. They speculate about the biological possibilities relative to an information set enriched by the specific biology of a target system. [...] How-actually explanations, carefully confirmed by empirical tests, aim to identify the correct evolutionary processes that did, in fact, produce the target outcome.”

Although Forber’s distinction is conceptually helpful, it is not clear whether global versus local how-possibly explanations should, in fact, be seen as two distinct categories, rather than simply two poles of a spectrum.

Craver draws a distinction between how-possibly models and how-actually models that is supposed to track the corresponding two kinds of explanations. He notes that how-possibly models purport to explain (unlike phenomenological models, which do not purport to explain), but they are only loosely constrained conjectures about the mechanism. How-actually models, by contrast, describe the detailed components and activities that, in fact, produce the phenomenon. He writes [4.17, p. 361]:

“How-possibly models are [...] not adequate explanations. In saying this I am saying not merely that the description must be true (or true enough) but further, that the model must correctly characterize the details of the mechanism.”

Craver seems to see the distinction resting not just on the degree of confirmation (truth) but also on the degree of detail.

*Bokulich* [4.55] defends another construal of the how-possibly/how-actually distinction and applies it to model-based explanations more specifically. She considers, as an example, model-based explanations of a puzzling ecological phenomenon known as tiger bush. Tiger bush is a striking periodic banding of vegetation in semi-arid regions, such as southwest Niger. A surprising feature of tiger bush is that it can occur for a wide variety of plants and soils, and it is not induced by any local heterogeneities or variations in topography. By tracing how scientists use various idealized models (e.g., Turing models or differential flow models) to explain phenomena such as this, Bokulich argues a new insight into the how-possibly/how-actually distinction can be gained.

The first lesson she draws is that there are different levels of abstraction at which the explanandum phenomenon can be framed, which correspond to different explanatory contexts [4.55, p. 33]. These different explanatory contexts can be clarified by considering the relevant contrast class of explanations (for a discussion of contrast classes and their importance in scientific explanation, see [4.56, Chap. 5]). Second, she argues *pace* Craver that the how-possibly/how-actually distinction

does not track how detailed the explanation is. She explains [4.55, p. 334]:

“It is not the amount of detail that is relevant, but rather whether the mechanism represented in the model is the mechanism operating in nature. Indeed as we saw in the tiger bush case, the more abstractly the explanatory mechanism is specified, the easier it is to establish it as a how-actually explanation; whereas the more finely the explanatory mechanism is specified, the less confident scientists typically are that their particular detailed characterization of the mechanism is the actual one.”

Hence, somewhat counterintuitively, model explanations at a more fine-grained level are more likely to be how-possibly model explanations, even when they are nested within a higher level how-actually model explanation of a more abstract characterization of the phenomenon. She concludes that when assessing model explanations, it is important to pay attention to what might be called the scale of resolution at which the explanandum phenomenon is being framed in a particular explanatory context.

## 4.5 Tradeoffs in Modeling: Explanation versus Other Functions for Models

Different scientists will often create different models of a given phenomenon, depending on their particular interests and aims. Following *Giere*, we might note that “there is no best scientific model of anything; there are only models more or less good for different purposes” [4.57, p. 1060]. If this is right, then it raises the following questions: What are the features that make a model particularly good for the purpose of explanation? Are there tradeoffs between different modeling aims, such that if one optimizes a model for explanation, for example, then that model will fail to be optimized for some other purpose, such as prediction?

One of the earliest papers to explore this theme of tradeoffs in modeling is Levins’ paper *The Strategy of Model Building in Population Biology*. Levins writes [4.58, p. 422]:

“It is of course desirable to work with manageable models which maximize generality, realism, and precision toward the overlapping but not identical goals of understanding, predicting, and modifying nature. But this cannot be done.”

Levins then goes on to describe various modeling strategies that have evolved among modelers, such as sacrificing realism to generality and precision, or sac-

rificing precision to realism and generality. Levins in his own work on models in ecology favored this latter strategy, where he notes his concern was primarily qualitative not quantitative results, and he emphasizes the importance of robustness analyses in assessing these models.

Although Levins’s arguments have not gone unchallenged, Matthewson and Weisberg have recently defended the view that some tradeoffs in modeling are genuine. They focus on precision and generality, given the relevance of this tradeoff to the aim of explanatory power. After a technical demonstration of different kinds of tradeoffs between two different notions of generality and precision, they conclude [4.59, p. 189]:

“These accounts all suggest that increases in generality are, *ceteris paribus*, associated with an increase in explanatory power. The existence of tradeoffs between precision and generality indicates that one way to increase an explanatorily valuable desideratum is by sacrificing precision. Conversely, increasing precision may lead to a decrease in explanatory power via its effect on generality.”

Mapping out various tensions and tradeoffs modelers may face in developing models for vari-

ous aims, such as scientific explanation, remains a methodologically important, though underexplored topic.

More recently, *Bokulich* [4.60] has explored such tradeoffs in the context of modeling in geomorphology, which is the study of how landscapes and coastlines change over time. Even when it comes to a single phenomenon, such as braided rivers (i. e., rivers in which there is a number of interwoven channels and bars that dynamically shift over time), one finds that scientists use different kinds of models depending on whether their primary aim is explanation or prediction. When they are interested explaining why rivers braid geomorphologists tend to use what are known as *reduced complexity models*, which are typically very simple cellular automata models with a highly idealized representation of the fluvial dynamics [4.61]. The goal is to try to abstract away and isolate the key mechanisms responsible for the production of the braided pattern. This approach is contrasted with an alternative approach to modeling in geomorphology known as *reductionist modeling*. Here one tries to simulate the braided river in as much accurate detail and with as many different processes included as is computationally feasible, and then tries to solve the relevant Navier–Stokes equations in three dimensions. These reductionist models are the best available tools for predicting the features of braided rivers [4.61, p. 159], but they are so complex that they yield very little insight into *why* the patterns emerge as they do.

## 4.6 Conclusion

There is a growing realization that the use of idealized models to explain phenomena is pervasive across the sciences. The appreciation of this fact has led philosophers of science to begin to introduce model-based accounts of explanation in order to bring the philosophical literature on scientific explanation into closer agreement with actual scientific practice.

A key question here has been whether the idealizations and falsehoods inherent in modeling are *harmless* in the sense of doing no real explanatory work, or whether they have an essential – maybe even ineliminable – role to play in some scientific explanations. Are such fictions compatible with the explanatory aims of science, and if so, under what circumstances? While some inroads have been made on this question, it remains an ongoing area of research. As we saw, yet another controversial issue concerns the fact that many highly abstract and mathematical models seem to exemplify a noncausal form of explanation, contrary to the current orthodoxy in scientific explanation. Deter-

*Bokulich* uses cases such as these to argue for what she calls a division of cognitive labor among models [4.60, p. 121]:

“If one’s goal is explanation, then reduced complexity models will be more likely to yield explanatory insight than simulation models; whereas if one’s goal is quantitative predictions for concrete systems, then simulation models are more likely to be successful. I shall refer to this as the *division of cognitive labor among models*.”

As Bokulich notes, however, one consequence of this division of cognitive labor is that a model that was designed to optimize explanatory insight might fail to make quantitatively accurate predictions (a different cognitive goal). She continues [4.60, p. 121]:

“This failure in predictive accuracy need not mean that the basic mechanism hypothesized in the explanatory model is incorrect. Nonetheless, explanatory models need to be tested to determine whether the explanatory mechanism represented in the model is in fact the real mechanism operating in nature.”

She argues for the importance of robustness analyses in assessing these explanatory models, noting that while robustness analyses cannot themselves function as a nonempirical mode of confirmation, they can be used to identify those *qualitative* predictions or trends in the model that can appropriately be compared with observations.

mining what is or is not to count as a causal explanation turns out to be a subtle issue.

Finally, just because a model or computer simulation can reproduce a pattern or behavior that is strikingly like the phenomenon to be explained, does not mean that it thereby explains that phenomenon. An important distinction here is that between a how-possibly model explanation and a how-actually model explanation. Despite the wide agreement that such a distinction is important, there has been less agreement concerning how precisely these lines should be drawn.

Although significant progress has been made in recent years in understanding the role of models in scientific explanation, there remains much work to be done in further clarifying many of these issues. However, as the articles reviewed here reveal, exploring just how and when models can explain is a rich and fruitful area of philosophical investigation and one essential for understanding the nature of scientific practice.

# Models and Simulations

## 5. Models and Simulations

Nancy J. Nersessian, Miles MacLeod

In this chapter we present some of the central philosophical issues emerging from the increasingly expansive and sophisticated roles computational modeling is playing in the natural and social sciences. Many of these issues concern the adequacy of more traditional philosophical descriptions of scientific practice and accounts of justification for handling computational science, particularly the role of theory in the generation and justification of physical models. However, certain novel issues are also becoming increasingly prominent as a result of the spread of computational approaches, such as nontheory-driven simulations, computational methods of inference, and the important, but often ignored, role of cognitive processes in computational model building.

Most of the philosophical literature on *models and simulations* focuses on computational simulation, and this is the focus of our review. However, we wish to note that the chief distinguishing characteristic between a model and a simulation (model) is that the latter is dynamic. They can be *run* either as constructed or under a range of experimental conditions. Thus, the broad class of simulation models should be understood as com-

prising dynamic physical models and mental models, topics considered elsewhere in this volume.

This chapter is organized as follows. First in Sect. 5.1 we discuss simulation in the context of well-developed theory (usually physics-based simulations). Then in Sect. 5.2 we discuss simulation in contexts where there are no over-arching theories of the phenomena, notably agent-based simulations and those in systems biology. We then turn to issues of whether and how simulation modeling introduces novel concerns for the philosophy of science in Sect. 5.3. Finally, we conclude in Sect. 5.4 by addressing the question of the relation between human cognition and computational simulation, including the relationship between the latter and thought experimenting.

### 5.1 Theory-Based Simulation

A salient aspect of computational simulation, and the one which has attracted the most substantial philosophical interest so far, is its ability to extend the power and reach of theories in modern science beyond what could be achieved by pencil and paper alone. Work on simulations has concentrated on simulations built from established background theories or theoretical models and the relations between these simulations and theory. Examples have been sourced mainly from the physical sciences, including simulations in astrophysics, fluid dynamics, nanophysics, climate science and meteorology. *Winsberg* has been foremost in study-

ing theory-driven forms of simulation and promoting the importance of philosophical investigation of it by arguing that such simulations set a new agenda for philosophy of science [5.1–5]. He uses the case of simulation to challenge the longstanding focus of philosophy of science on theories, particularly on how they are justified [5.1, 3, 5]. Simulations, he argues, cannot simply be understood as novel ways to test theories. They are in fact rarely used to help justify theories, rather simulations apply existing theories in order to explore, explain and understand real and possible phenomena, or make predictions about how such phenomena will evolve in

time. Simulations open up a whole new set of philosophical issues concerning the practices and reliability of much modern science.

Winsberg's analysis of theory-based simulation shares much with *Cartwright's* [5.6] and *Morgan and Morrison's* [5.7] challenges to the role of theories. Like them, he starts by strongly disputing the presupposition that simulations are somehow deductive derivations from theory. Simulations are applied principally in the physical sciences when the equations generated from a theory to represent a particular phenomenon are not analytically solvable. The path from a theory to a simulation requires processes of computerization, which transform equations into tractable computable structures by relying on practices of discretization and idealization [5.8]. These practices employ specific transformations and simplifications in combination with those used to make tractable the application of theoretical equations to a specific phenomenon such as boundary conditions and symmetry assumptions. As such simulations are, according to *Winsberg* [5.1], better construed as particular articulations of a theory rather than derivations from theory. They make use of theoretical information and the credibility, explanatory scope and depth, of well-established theories, to provide warrant to simulations of particular phenomena. Inferences drawn by computational simulations have several features in this regard; they are *downward*, *motley* and *autonomous* [5.9]. Inferences are downward because they move from theory to the real world (rather than from the real world to theory). They are motley because they depend not just on theory but on a large range of extra-theoretical techniques and resources in order to derive inferences, such as approximation and simplification techniques, numerical methods, algorithmic methods, computer languages and hardware, and much trial and error. Finally, simulations are autonomous, in the sense of being autonomous from both theory and data. Simulations, according to Winsberg, are principally used to study phenomena where *data is sparse* and unavailable. These three conditions on inference from simulation require a specific philosophical evaluation of their reliability.

Such evaluation is complicated by the fact that relations between theory and inferences drawn from the simulation model are unclear and difficult to untangle. As *Winsberg* [5.1.9] suggests it is a complex task to unpack what role theories play in the final result given all these intervening steps. The fact that much validation of simulations is done through matching simulation outputs to the data, muddies the water further (see also [5.10]). A well-matched simulation constructed through a downward, motley and autonomous process from a nonetheless well-established theory raises the

question of the extent to which the confirmation afforded to the theory flows down to the simulation [5.2]. For instance, although fitting a certain data set might well be the dominant mode of validation of a simulation model, the model could be considered to hold outside the range of that data because the model applies a well-accepted theory of the phenomenon thought to hold under very general conditions.

There is widespread agreement that untangling the relations between theories and simulations, and the reliability of simulations built from theories will require more in depth investigation of the actual practices scientists use to justify the steps they make when building a simulation model. In the absence of such investigations discussions of justification are limited to considerations about whether a simulation fits the observational data or not. Among other things, this limitation hides from view important issues about the warrant of the various background steps that transform theoretical information into simulations [5.10]. In general, what is required is an *epistemology of simulation* which can discover rigorous grounds upon which scientists can and do sanction their results, and more properly the role of theory in modern science.

The concern with practices of simulation has opened up a new angle on the older discussion about the structure of theories. *Humphreys* [5.11] has used the entanglement of theory and simulation in modern scientific practice to reflect more explicitly upon the proper philosophical characterization of the structure of physical theories. Simulations, as with other models, are not logical derivations from theory which is a central, but incorrect, feature of the syntactic view. Humphreys also argues, however, that the now dominant semantic view of theories, which treats theories as nonlinguistic entities, is not adequate either. On the semantic view a syntactical formulation of a theory, and whether different formulations might be solvable or not, is not important for philosophical assessment of relations of representations to the world. Relations of representation are only in fact sensibly held by models not theories. Both Humphreys and Winsberg construe the semantic view as dismissing the role of theories in both normative and descriptive accounts of science, in place of models. But as *Humphreys* [5.12, p. 620] puts it, "the specific syntactic representation used is often crucial to the solvability of a theory's equations", and thus, the solvability of models derived from it. Computational tractability, as well as choices of approximation and simplification techniques, will depend on the particular syntax of a theory. Hence both the semantic and syntactic views are inadequate for describing theory in ways that capture their role in science.

## 5.2 Simulation not Driven by Theory

Investigations, such as those by Winsberg and others discussed in the previous section, have illustrated the importance of close attention to scientific practice and discovery when studying simulations. Simulation manifests application-intensive, rather than theoretical, processes of scientific investigation. As *Winsberg* [5.1] suggests choices about how to model a phenomenon reliably are developed often in the course of the to and fro *blood, sweat and tears* of the model-building process itself. Abstract armchair points of view, distant from an understanding of the contingent, but also technical and technological nature of these practices and their affordances, will not put philosophers in a position to create relevant normative assessments of good simulation practices. What has thus far been established by the accounts of theory-based simulation is that even in the case where there is an established theory of the phenomena, simulation model-building has a degree of independence from theory and theory-building.

However, though the initial focus on theory-based simulation in the study of simulation is not unsurprising given the historical preference in philosophy of science for treating *theory* as the principal unit of philosophical investigation, simulations are not just a tool of theory-driven science alone. Pushing philosophical investigation into model-building practices outside the domain of theory-driven science reveals whole new practices of scientific model production using computational simulations that are not in fact theory-based, in the sense of traditional physical sciences. Some of the most compelling and innovative fields in science today, including, for instance, big-data biology, systems biology and neuroscience, and much modeling in the social sciences, are not theory-driven. As *Winsberg* [5.5] admits (in response to *Parker* [5.13]), his description of simulation modeling is theory-centric, and neither necessarily applicable to understanding the processes by which simulation models are built in the absence of theory, nor an appropriate framework for assessing the reliability and informativeness of models built that way. This is not to say that characteristics of theory-based simulation are irrelevant to simulations that are not. Both theory and nontheory-based simulations share an independence of theory and there are likely to be similarities between them, but there are also profound differences.

One kind of simulation that is important in this regard is agent-based modeling. *Keller* [5.14] has labeled much agent-based modeling as *modeling from above* in the sense that such models are not constructed using a mathematical theory that governs the motions of agents. Agents follow local interactions rules. In many

fields in the social sciences and biology differential equations cannot be used to aggregate accurately agent or population behavior, but it is nonetheless possible to hypothesize or observe the structure of individual interactions. An agent-based model can be used to run those interactions over a large population to test whether the local structures can reproduce aggregate behavior [5.15]. As noted by *Grüne-Yanoff* and *Weirich* [5.16] agent-based modeling facilitates constructing remarkably complex models within computationally tractable constraints that often go well beyond what is possible with equation-based representations.

Agent-based models provide one exemplar of simulations that are not theory-driven. From an epistemological perspective, these simulations exhibit weak emergence [5.17]. The underlying mechanisms are thoroughly opaque to the users, and the way in which emergent properties come about can simply not be reassembled by studying the simulation processes. This opacity raises questions about the purpose and value of agent-based modeling. What kind of explanation and understanding does an agent-based simulation provide if the multiscale mechanisms produced in a simulation are cognitively inaccessible? Further, how is one to evaluate predictions and explanations from agent-based simulations which, in fields like ecology and economics, commonly simplify very complex interactions in order to create computationally tractable simulations. If a simplistic model captures a known behavior, can we trust its predictions? To address questions such as these we need an epistemology that can evaluate proposed techniques for establishing the robustness of agent-based models. One alternative is to argue that agent-based models require a novel epistemology that is able to rationalize their function as types of fictions rather than as representations [5.18, 19]. Another alternative, presented by *Grüne-Yanoff* and *Weirich* [5.16], is to argue that agent-based models provide in many cases functional rather than causal explanations of the phenomena they simulate [5.20]. Agent-based model simulations rarely control for all the potential explanatory factors that might be relevant to a given phenomenon, and any choice of particular interaction mechanism is usually thoroughly underdetermined. In practice, all possible mechanisms cannot be explored. But agent-based models can show reliably how particular lower-level capacities behave in certain ways, when modeled by suitably general interactions rules, and can constitute higher-level capacities no matter how multiply realized those interactions might be. Hence, such models, even though greatly simplified, can extract useful

information despite a large space of potential explananda.

Nontheory-driven forms of simulation such as agent-based models provide a basis for reflecting more broadly on the role theory plays in the production of simulations, and the warrant a theory brings to simulations based on it. Comparative studies of the kinds of arguments used to justify relying on a simulation should expose the roles well-established theories play. Our investigations of integrative systems biology (ISB) have revealed that not all equation-based modeling is theory-driven, if theory is construed in terms of theory in the physical sciences. The canonical meaning based on the physical sciences is something like a background body of laws and principles of a domain.

In the case of systems biology, researchers generally do not have access to such theory and in fact the kinds of theory they do make use of have a function different from what is usually meant by *theory* in fields like physics [5.21]. There are certain canonical theories in systems biology of how to mathematically represent interactions among, for instance, metabolites, in the form of sets of ordinary differential equations. These posit particular canonical mathematical forms for representing a large variety of interactions (see Biochemical Systems Theory [5.22]). In principle, for any particular metabolic network, if all the interactions and reactants are known, the only work for the modeler is to write down the equations for a particular network and calculate the parameters. The mathematics will take care of the rest since the mathematical formulations of interactions are general enough that any potential nonlinear behaviors should be represented if parameters are correctly fixed.

For the most part, however, these canonical frameworks do not provide the basic ontological information from which a representation of a system is ultimately drawn, in the way say that the Navier-Stokes equations of fluid dynamics describe fluids and their component interactions in a particular way. In practice, modelers in systems biology need to assemble that information themselves in the form of pathway diagrams which more or less list the molecules involved and then make their own decisions about how to represent molecular interactions. A canonical framework is better interpreted as a theory of how to approximate and simplify the information that the systems biologist has assembled about a pathway in order to reliably simulate the dominant dynamics of a network given sparse data and complex nonlinear dynamics. Hence, there is no real *theory articulation* in Winsberg's terms. Researchers do not articulate a general theory for a particular application. The challenge for systems biologists is to build a higher level or system level representation out of the

lower level information they possess. We have found that canonical templates mediate this process by providing a possible structure for gluing together this lower level information in a tractable way [5.21]. These theories do not offer any direct explanatory value by virtue of their use.

*Theory* can in fact be used not just to describe a body of laws and theoretical principles, but also to describe principles that instruct scientists on how to reliably build models of given classes of phenomena from a background theory. As Peck puts it [5.18, p. 393]:

“In traditional mathematical modeling, there is a long established research program in which standard methods, such as those used for differential equation modeling, are used to bring about certain ends. Once the variables and parameters and their relationships are chosen for the representation of the model, standard formulations are used to complete the modeling venture.”

If one talks about what physical scientists often start with it is not just the raw theory itself but well-established rules for formulating the theory and applying it with respect to a particular phenomenon. We might refer to this latter sense of *theory* as a theory of how to apply a background theory to reliably represent a phenomenon. The two senses of theory are exclusive. In the case of the canonical frameworks, what is meant by *theory* is something closer to this latter rather than former sense.

Additionally, the modelers we have studied are never in a position to rely on these frameworks uncritically and in fact no theory exists that specifies which representations to use that will reliably lead to a good representation in all data situations. In integrative systems biology the variety of data situations are very complex, and the data are often sparse and are rarely adequate for applying a set mathematical framework. This forces researchers in practice into much more intensive and adaptive model-building processes that certainly share much in common with the back and forth processes Winsberg talks about in the context of theory application. But these processes have the added and serious difficulty that the starting points for even composing the mathematical framework out of which a model should be built are open-ended and need to be decided based on thorough investigation of the possibilities with the specific data available.

Canonical frameworks are just an option for modelers and do not drive the model-building process in the way physical theories do. Currently, systems biology generally lacks effective theory of either kind. Modelers have many different choices about how to confront a particular problem that do not necessarily

involve picking up a canonical framework or sticking to it. MacLeod and Nersessian [5.21] have documented how the nontheory-derived model-building processes work in these contexts. Models are strategic adaptations to a complex set of constraints system biologists are working under [5.23]. Among these constraints are:

- Constraints of the biological problem: A model must address the constraints of the biological problem, such as how the redox environment is maintained in a healthy cell. The system involved is often of considerable complexity.
- Informational/data constraints: There are constraints on the accessibility and availability of experimental data and molecular and system parameters for constructing models.
- Cost constraints: ISB is data-intensive and relies on data that often go beyond what are collected by molecular biologists in small scale experiments. However, data are very costly to obtain.
- Collaboration constraints: Constraints on the ability to communicate effectively with experimental collaborators with different backgrounds or in different fields in order to obtain expert advice or new data. Molecular biologists largely do not understand the nature of simulation modeling, do not understand the data needs of modeling, and do not see the cost-benefit of producing the particular data systems biologists ask from them.
- Time-scale constraints: Different time scales operate with respect to generating molecular experimental data versus computational model testing and construction.
- Infrastructure constraints: There is little in the way of standardized databases of experimental information or standardized modeling software available for systems biologists to rely upon.
- Knowledge constraints: Modelers' lack knowledge of biological systems and experimental methods limits their understanding of what is biologically plausible and what reliable extrapolations can be made from the data sets available.
- Cognitive constraints: Constraints on the ability to process and manipulate models because of their complexity, and thus constraints on the ability to comprehend biological systems through modeling.

Working with these constraints requires them to be *adaptive problem-solvers*. Given the complexity of the systems, lack of data, and the ever-present problem of computational tractability, researchers have to experiment with different mathematical formulations, different parameter-fixing algorithms and approximation techniques in highly intensive trial and error processes.

They build models in nest-like fashion in which bits of biological information and data and mathematical and computational techniques, get combined to create stable models. These processes transform not only the shape of the solutions, but also the problems, as researchers figure out what actual problem can be solved with the data at hand. Simulation plays a central exploratory role in the process. This point goes further than Lenhard's idea of an explorative cooperation between experimental simulation and models [5.8]. Simulation in systems biology is not just for experimenting on systems in order to *sound out the consequences of a model* [5.8, p. 181], but plays a fundamental role in incrementally building the model and learning the relevant known and sometimes unknown features of a system and gaining an understanding of its dynamics. Simulation's roles as a cognitive resource make the construction of representations of complex systems without a theoretical basis possible (see also [5.24, 25]).

Similar conclusions have been drawn by Peck for ecology which shares with systems biology the complexity in its problems and a lack of generalizable theory. As Peck [5.18, p. 393] points out:

“there are no formal methodological procedures for building these types of models suggesting that constructing an ecological simulation can legitimately be described as an art.”

This situation promotes methodological pluralism and creative methodological exploration by modelers. Modelers in these contexts thus focus our attention on the deeper roles (sometimes called heuristic roles [5.5]) that simulation plays in the ability of researchers to explore potential solutions in order to solve complex problems.

These roles have added epistemological importance when it is realized that the *downward* character of simulation can be fact reversed in both senses we have mentioned above. This is a potentially significant difference between cases of theory and nontheory-driven simulation. Consider again systems biology. Firstly, the methodological exploration we witness amongst the researchers we have studied can be rationalized as precisely an attempt by the field to establish a good theory of how to build models of biological systems that work well given a variety of data situations. Since the complexities of these systems and computational constraints make this difficult to know at the outset, the field needs its freedom to explore the possibilities. Lab directors do encourage exploration, and part of the reason they do is to try to glean which practices work well and which do not given a lack of knowledge of what will work well for a given problem.

Secondly, systems biology aspires to a theory of biological systems which will detail general system-level characteristics of biological systems but also the design principles underlying biological networks [5.26, 27]. What is interesting about this theory, if it does emerge, is that it will in fact be theory generated *by* simulation rather than the other way around. Simulation makes possible the exploration of quite complex systems for generalities that can form the basis of a theory of systems biology. As such the use of simulations can also be upwards, not just downwards, to perhaps an unprecedented extent. Upward uses of simulation requires analysis that appears to fit better with

more traditional philosophical analysis of how theories are in fact justified, only in this case robust simulation models will possibly be the more significant source of evidence rather than traditional experiment and observation. How this affects the nature and reliability of our inferences to theory, and what kind of resemblance such theory might have to theory in physics, is something that will need investigation. Thus, further exploration of nontheory-driven modeling practices stand to provide a rich ground for investigation of novel practices that are emerging with simulation, but also for exploring the roles and meanings of *theory*.

### 5.3 What is Philosophically Novel About Simulation?

The question of whether or not simulation introduces new issues into the philosophy of science has emerged as a substantial debate in discussions of computational simulation. *Winsberg* [5.1, 3–5] and *Humphreys* [5.11, 12] are the major proponents of the view that simulation requires its own epistemology. Winsberg, for instance, takes the view that simulations exhibit “distinct epistemological characteristics . . . novel to the philosophy of science” [5.9, p. 443]. Winsberg and Humphreys make this assertion on the basis of the points we outlined in Sec. 5.2; namely, 1) the traditional limited concern of philosophy of science with the justification of theory, and 2) the relative autonomy of simulations and simulation-building from the theory. The steps involved in generating simulations, such as applying approximation methods designed to generate computational tractability, are novel to science. These steps do not gain their legitimacy from a theory but are “autonomously sanctioned” [5.1, p. 837]. Winsberg argues, for instance, that while idealization and approximation methods have been discussed in the literature it has mostly been from a representational perspective in terms of how idealized and approximate models represent or resemble the world and in turn justify the theories on which they are based. But since simulations are often employed where data are sparse, they cannot usually be justified by being compared with the world alone. Simulations must be assessed according to the reliability of the processes used to construct them, and these often distinct and novel techniques require separate philosophical evaluation. Mainstream philosophy of science with its focus on theoretical justification does not have the conceptual resources for accounting for applications using computational methods. Even where theory is concerned, both Humphreys and Winsberg maintain that neither of the established semantic and syntactic conception of theories, conceptions which fo-

cus on justification and representation, can account for how theories are applied or justified in simulation modeling.

However, *Frigg* and *Reiss* [5.28] have countered that these claims were overblown and in fact simulation raises no new questions or problems that are specific to simulation alone. Part of the disagreement might simply come down to whether one construes philosophy of science narrowly or broadly by limiting *philosophical questions* to in-principle and normative issues, while avoiding practical methodological ones. Another part of the disagreement is over how one construes *new issues* or *new questions* for philosophy, since certainly at some level the basic philosophical questions about how representations represent and what makes them reliably do so, are still the same questions.

To some extent, part of the debate might be construed as a disagreement over the relevance of contexts of discovery to philosophy of science. Classically contexts of discovery, the scientific contexts in which model-building takes place, are considered irrelevant to normative philosophical assessments of whether those models are justified or not. *Winsberg* [5.3] and *Humphreys* [5.12] seem willing to assert that one of the lessons for philosophy of science from simulation is that practical constraints on scientific discovery matter for constructing relevant normative principles – both in terms of evaluating current practice, which in the case of simulation-building is driven by all kinds of practical constraints, and in terms of normatively directing practice sensitively within those constraints.

Part of the motivation for using the discovery/justification distinction to define philosophical interest and relevance is the belief that there is a clear distinction between the two contexts. Arguably Frigg and Reiss are reinforcing the idea of a clear distinction by relying on widespread presupposition that

validation and verification are distinct independent processes [5.4]. Validation is the process of establishing that a simulation is a good representation, a quintessential concept of justification. Verification is the process of ensuring that a computational simulation adequately captures the equations from which it is constructed. Verification, according to Frigg and Reiss, represents the only novel aspects of modeling that simulation introduces. Yet it is a purely mathematical exercise that is of no relevance to questions of validation. As such, simulations involve no new issues of justification beyond those of ordinary models. Winsberg [5.3, 4], however, counters that there is, in practice, no clear division between processes of verification and validation. The equations chosen to represent a system are not simply selected on the basis of how valid they are, but also on the basis of decisions about computational tractability. Much of what validates a representation in practice occurs at the end stage, after all the necessary techniques of numerical approximation and discretization have been applied, by comparing the results of simulations with the data. As such, [5.5]:

“If we want to understand why simulation results are taken to be credible, we have to look at the epistemology of simulation as an integrated whole, not as clearly divided into verification and validation – each of which would look inadequate to the task.”

Hence what would otherwise seem to be distinct discovery and justification processes are in the context computational simulation interwoven.

Frigg and Reiss are right at some level that simulations do not change basic epistemological questions connected to the justification of models. They are also right that Winsberg in his downward, motley and autonomous description of simulation, does not reveal any fundamentally new observations on model-building that have not already been identified as issues by philosophers discussing traditional modeling. However, what appears to be really new in the case of simulation is: 1) the complexity of the philosophical problems of representation and reliability, and 2) the different methodological and epistemological strategies that have become available to modelers as a result of simulation.

Winsberg, in reply to Frigg and Reiss, has clarified what he thinks as novel about theory-based simulation as the *simultaneous confluence* of downward, motley and autonomous features of model-building [5.4]. It is the reliability and validity of the complex modeling processes instantiated by these three features that must be accounted for by an epistemology of simulation, and no current philosophical approaches are adequate to do so, particularly not those within traditional philosophical boundaries of analysis.

As a first step in helping with this task of assessing reliability and validity of simulation, philosophers such as Winsberg [5.29] have drawn lessons from comparison with experimentation, which they argue shares much with simulation in both function (enabling, for instance, in silico experiments) and also in terms of how the reliability of simulations is generated. Scientific researchers try to control for error in their simulations, and fix parameters, in ways that seem analogous to how experimenters calibrate their devices. Simulations build up credibility over long time scales and may have lives of their own independent of developments in other parts of science. These observations suggest a potentially rich analogy between simulations and Hacking’s account of experimentation [5.29]. In a normative step, based on these links, Parker [5.10] has suggested that in fact Mayo’s [5.30] rigorous error-statistical approach for experimentation should be an appropriate starting point for more thorough evaluation of the results of simulations. Simulations need to be evaluated by the degree to which they avoid false positives when it comes to testing hypotheses by successfully controlling for potential sources of error that creep in during the simulation process. At the same time a rather vigorous debate has emerged concerning the clarification of the precise epistemological dissimilarities or disanalogies between simulation and traditional experimentation (see for instance [5.31–36]). This question is in itself of independent philosophical interest for assessing the benefits and value of each as alternatives, but should also help define the limits of the relevance of experimentation as a model for understanding and assessing simulation practices.

From our perspective, however, the new methodological and epistemological strategies that modelers are introducing in order to construct and guarantee the reliability of simulation models could prove to be the most interesting and novel aspect of simulation with which philosophers will have to grapple. Indeed, while much attention has focused on the contrasts and similarities between simulations, experiments and simulation experiments, no one has called attention to the fact that real-world experiments and simulations are also being used in concert to enhance the ability of researchers to handle uncertain complex systems. One of the labs we have studied conducts *bimodal* modeling, where the modelers conduct their own experiments in the service of building their models. We have analyzed the case of one modeler’s behavior in which model-building, simulation and experimentation were tightly interwoven [5.37]. She used a conjunction of experiment and simulation to triangulate on errors and uncertainties in her model, thus demonstrating that the two can be combined in practice in sophisticated ways.

Her model-building would not have been possible without the affordances of both simulation and her ability to perform experimentation precisely adapted to test questions about the model as she was in the process of formulating it. Simulation and experiment closely coupled in this fashion offers the possibility of extending the capacity to produce reliable models of complex phenomena.

Bimodal modeling is relatively easy to characterize epistemologically since experimentation is used to validate and check the simulations as the model is being constructed. Simulations are not relied on independent of experimental verification. Often, however, experimental or any kind of observational data are hard to come by for practical or theoretical reasons. More philosophically challenging will be to evaluate the new epistemological strategies researchers are in fact developing for drawing inferences in these often deeply uncertain and complex contexts with the aid of computation. *Parker* [5.38, 39], for instance, identifies the practice in climate science and meteorology of ensemble modeling. No theory of model-building exists that tells climate and weather modelers how to go from physical theory to reliable models. Different formulations using different initial conditions, models structures and different parameterizations of those models that fit the observational data can be developed from the physical theory. In this situation modelers average over results from large collections of models, using different weighting schemas, and argue for the validity of these results on the basis that these models collectively represent the possibility space. However, considerable philosophical questions emerge as to the underlying justifiability of these ensemble practices and the probability weightings being relied upon. Background theory can provide little guidance in this context and in the case of climate modeling there is little chance for predictively testing performance. Further, the robustness of particular ensemble choices is often very low and justifications for picking out particular ensembles are rarely carefully formulated.

The ability to generate and compare large numbers of complex models in this way is a development of modern computational power. In our studies we have also come across novel argumentation, particularly connected with parameter-fixing [5.40]. Because the parameter spaces these modelers have to deal with are so complex, there is almost no chance of getting a best fit solution. Instead modelers produce multiple models often using Monte Carlo techniques that converge on similar behavior and output. These models have different parameterizations and ultimately represent the underlying mechanisms of the systems differently. However, modelers can nonetheless make specific

arguments about network structure and dynamic relationships among specific variables. There is not usually any well-established theory that licenses these arguments. The fact that the models converge on the same relevant results is motivation for inferring that these models are right at least about those aspects of the system for which they are designed to account. Unfortunately, because access to real-world experimentation is quite difficult, it is hard to judge how reliable this technique is in producing robust models. What is novel about this kind of strategy is that it implicitly treats parameter-fixing as an opportunity, not just a problem, for modelers. If instead of trying to capture the dynamics of whole systems modelers just fix their goals on capturing robust properties and relations of a system, the potential of finding results that work within these constraints in large parameter-spaces increases, and from the multiple models obtained modelers can pare down to those that converge. The more complex problem thus seems to allow a pathway for solving a simpler one. Nonetheless, whether we should accept these kinds of strategies as reliable and the models produced as robust remains the fundamental question, and an overarching question for the field itself. It is a reasonable reaction to suspect that something important is being given up in the process, which will affect how well scientists can assess the reliability and importance of the models they produce. Whether the power computational processes can adequately compensate for the potential distortions or errors introduced is one of the most critical and novel epistemological questions for philosophy today.

The kinds of epistemological innovations we have been considering raise deeper questions about the purposes of simulation, particularly in terms of traditional epistemic categories like understanding, explanation and so on. Of course at one extreme some simulations of the purely data-driven kind is purely phenomenological. Theory plays no role in its generation, and is not sought as its outcome. However in other cases some form of understanding at least is sought. In many cases though, where theory might be thought the essential agent of understanding, the complexity of the equations and resulting complexity of the computational processes that instantiate them, simply block any way of decomposing the theory or theoretical model in order to understand how the theory might explain a phenomena and thus assess the accuracy and plausibility of the underlying mechanisms it might prescribe. *Humphreys* labels this *epistemic opacity* [5.11]. *Lenhard* [5.41] in turn identifies a form of pragmatic understanding that can replace theoretical understanding when a simulation model is epistemically opaque. This form of understanding is pragmatic in the sense of being an understanding of how

to *control* and *manipulate* phenomena, rather explain them using background theoretical principles and laws. Settling for this form of understanding is a choice made by researchers in order to handle more complex problems and systems using simulations. But it is a novel one in the context of physics and chemistry. In systems biology we recognize something similar [5.40]. Researchers give up accurate mechanistic understanding of their systems for more pragmatic goals of gaining network control, at least over specific variables. To do so they use simplification and parameter-fitting techniques that obscure the extent to which their models capture the underlying mechanisms. Mechanistic ex-

planation is thus given up, for some weaker form of understanding.

Finally, computational modeling and simulation in the situations we have been considering in this section are driving a profound shift in the nature and level of human cognitive engagement in scientific production processes and their outputs [5.12, 24, 25, 42, 43]. So much of philosophy of science has been based on intuitive notions of human cognitive abilities. Our concepts of explanation and understanding are constructed implicitly on the basis of what we can grasp as humans. With simulation and big-data science those kinds of characterizations may no longer be accurate or relevant [5.44].

## 5.4 Computational Simulation and Human Cognition

It is on this last point that we turn to consider the ways in which human cognitive processes are implicated in processes of simulation model-building. Computational science, of the nonbig data or nonmachine learning kind which we have focused on here, is as Humphrey's calls it, a "hybrid scenario" as opposed to an "automated scenario" [5.12, p. 616]. In his words:

"This distinction is important because in the hybrid scenario, one cannot completely abstract from human cognitive abilities when dealing with representational and computational issues. . . . We are now faced with a problem, which we can call the *anthropocentric predicament*, of how we, as humans, can understand and evaluate computationally-based scientific methods that transcend our own abilities."

Unlike machine-learning contexts, computational modeling is in many cases a practice of using computation to extend traditional modeling practices and our own capabilities to draw insight out of low-data contexts and complex systems for which theory provides at best a limited guide. In this way cognitive capacities are often heavily involved. The *hybrid* nature of computational science thus motivates the need for understanding how human agents cognitively engage with and control opaque computational processes, and in turn draw information out of them. Evaluating these processes – their productiveness and reliability – requires in the first step having some understanding of them. As we will see, although computational calculation processes are beyond our abilities, at least in the case of systems biology the use of computation by modelers is often far more integrated with their own cognitive processes and understanding, and thus far more under their control, than we might think.

As we have seen there are several lines of philosophical research on computational simulation that un-

derscore it is through the processes of model-building – taken to comprise the incremental and interwoven processes of constructing the model and investigating its dynamics through simulation – that the modeler comes to develop at least a pragmatic understanding of the phenomena under investigation. Complex systems, such as investigated in systems biology, present perhaps the extreme case in which these practices are the *primary* means through which modelers, mostly nonbiologists, develop understanding of the systems. In our investigations, modelers called the building and *running* of their models under various conditions *getting a feel for the model*, which enables them to get a feel for the dynamics of the system.

In our investigations we have witnessed that modelers (mainly engineers) with little understanding of biology have been able to provide novel insights and highly significant predictions, later confirmed by biological collaborators, for the systems they are investigating through simulation. How is it possible that engineers with little to no biological training can be making significant biological discoveries? A related question concerns how complete novices are making scientific discoveries through simulations crowdsourced by means of video games such as Foldit and EteRNA, which appear to enable nonscientists to quickly build accurate/veridical structures representing molecular entities they had no prior knowledge of [5.45, 46]. *Nersessian* and *Chadrasekharan*, individually and together [5.24, 25, 42, 47–49], have argued that the answer to this question lies in understanding how computational simulation enhances human cognition in discovery processes. Because of the visual and manipulative nature of the crowdsourcing cases, the answer points in the direction of the *coupling* of the human sensorimotor systems with simulation models. These crowdsourcing models represent conceptual knowledge developed by the sci-

entific community (e.g., structure of proteins) as computational representations with a control interface that can be manipulated through the gamer's actions. The interface enables these novices to build new representations drawing on tacit/implicit sensorimotor processes. Although the use of crowdsourcing simulations in scientific problem solving is new, the human sensorimotor system has been used explicitly to detect patterns, especially in dynamic data generated by computational models, since the dawn of computational modeling. Entire disciplines and methods have been built using visualized patterns on computer screens. Complexity theory [5.50, 51], artificial life [5.52, 53] and computational chemistry [5.54, 55] provide a few exemplars where significant discoveries have been made.

Turning back now to the computational simulations used by scientists that we have been discussing, all of the above suggests that the model-building processes facilitate a close coupling between the model and the researcher's mental modeling processes even in the absence of a dynamic visualization. The building process manipulates procedural and declarative knowledge in the imagination and in the representation, creating a *coupled cognitive system* of model and modeler [5.25, 42, 43, 48, 56, 57]. This coupling can lead to explicit understanding of the dynamics of the system under investigation. The notion of a coupled cognitive system is best understood in terms of the framework of distributed cognition [5.58, 59], which was developed to study cognitive processes in complex task environments, particularly where external representations and other cognitive artifacts and, possibly, groups of people, accomplish the task. The primary unit of analysis is the socio-technical system that generates, manipulates and propagates representations (internal and external to people). Research leading to the formation of the distributed cognition framework has focused largely on the use of existing representational artifacts and less so on the building/creation of the artifacts. The central metaphor is that of the human *offloading* complex cognitive processes such as memory to the artifact, which, for example, in the canonical exemplar of the speed bug that marks critical airspeeds for a particular flight, replaces complex cognitive operations with a perceptual operation and provides a publically available representation that is shared between pilot and co-pilot.

In the research cited above, we have been arguing that *offloading* is not the right metaphor for understanding the cognitive enhancements provided through the building of novel computational representations. Rather, the metaphor should be that of *coupling* between internal and external representations. Delving into the modifications needed of the distributed cognition framework to accommodate the notion of a coupled

cognitive system would take us too far afield in this review (but see [5.25]). Instead, we will flesh out the notion a bit by noting some of the ways in which building and using simulation models enhance human cognitive capabilities and, in particular, extend the capability of the imagination system for simulative model-based reasoning.

A central, but yet not well-researched premise of distributed cognition is, as Hutchins has stated succinctly, that “humans create cognitive powers by creating the environments in which they exercise those powers” [5.58, p. 169]. Since building modeling-environments for problem solving is a major component of scientific research [5.49], scientific practices provide an especially good locus for examining the human capability to extend and create cognitive powers. In the case of simulation model-building, the key question is: *What are the cognitive changes involved in building a simulation model and how do these lead to discoveries?* The key cognitive change is that over the course of many iterations of model-construction and simulation, the model gradually becomes coupled with the modeler's imagination system (mental model simulation), which enables the modeler to explore different scenarios. The coupling allows *what if* questions in the mind of the modeler to be turned into detailed explorations of the system, which would not be possible in the mind alone. The computational model enables this exploration because as it is incrementally built using many data sets, the model's behavior, in the systems biology case, for instance, comes to parallel the dynamics of the pathway. Each replication of experimental results adds complexity to the model and the process continues until the model is judged to fit all available data well. This judgment is complex, as it is based on a large number of iterations where a range of factors such as sensitivity, stability, consistency, computational complexity and so forth are explored. As the model gains complexity it starts to reveal or expose many details of the system's behavior enabling the modeler to interrogate the model in ways that are not possible in the mind alone (thought experimenting) or in real-world experiments. It makes evident many details of the system's behavior that the modeler could not have imagined alone because of the fine grain and complexity of the details.

The parallel between computation simulation experimenting and thought experimenting is one philosophers have commented on, but the current framing of the discussion primarily centers on the issue of interpreting simulations and whether computational simulations should be construed as *opaque* thought experiments [5.60, 61]. Di Paolo et al. [5.60] have argued that computational models are more opaque than thought experiments, and as such, require more *system-*

*atic enquiry* through probing of the model's behavior. In a similar vein, Lenhard [5.61] has claimed that thought experiments are more *lucid* than computational models, though it is left unclear what is meant by *lucid* in this context, particularly given the extensive discussions around what specific thought experiments actually demonstrate. In the context of the discussion of the relation of thought experimenting and computational simulation, we have argued that the discussion should be shifted from issues of interpretation to a process-oriented analysis of modeling [5.47]. Nersessian [5.62] casts thought experimenting as a form of *simulative model-based reasoning*, the cognitive basis of which is the human capacity for mental modeling. Thought experiments (conceptual models), physical models [5.63] and computational models [5.47, 48] form a spectrum of simulative model-based reasoning in that all these types of modeling generate and test counterfactual situations that are difficult (if not impossible) to implement in the real world. Both thought experiments and computational models support simulation of counterfactual situations, however, while thought experiments are built using concrete elements, computational models are built using variables. Simulating counterfactual scenarios beyond the specific one constructed in the thought experiment is difficult and requires complex cognitive transformations to move away from the concrete case to the abstract, generic case. On the other hand, computational simulation constructs the abstract, generic case from the outset. Since computational models are made entirely of variables, they naturally support thinking about parameter spaces, possible variations to the design seen in nature, and why this variation occurs rather than the many others that are possible.

Thought experiments are a product of a resource environment in science where the only tools available were writing implements, paper (blackboards, etc.) and the brain. Computational models create cognitive enhancements that go well beyond those resources and enable scientists to study the complex, dynamic and nonlinear behaviors of the phenomena that are the focus of contemporary science.

Returning to the nature of the cognitive enhancements created, the coupling of the computational model with the modeler's imagination system significantly enhances the researcher's natural capacity for simulative model-based reasoning, particularly in the following ways:

- It allows running many more simulations, with many variables at gradients not perceivable or manipulable by the mind, which can be compared and contrasted.

- It allows testing what-if scenarios with changes among many variables that would be impossible to do in the mind.
- It allows stopping the simulation at various points and checking and tracking its states. If some desirable effect is seen, variables can be tweaked in process to get that effect consistently.
- It allows taking the system apart as modules, simulating them, and putting them together in different combinations.
- It allows changing the time in which intermediate processes kick in.

These complex manipulations expose the modeler to system-level behaviors that are not possible to examine in either thought alone or in real-world experimentation. The processes involved in building the distributed model-based reasoning system comprising simulation model and modeler enhance several cognitive abilities. Here we will conclude by considering three (for a fuller discussion see [5.25]). First, the model-building process brings together a range of experimental data. Given Internet search engines and online data bases, current models synthesize more data than ever before and create a synthesis that exists nowhere in the literature and would not be possible for modelers or biologists to produce on their own. In effect, the model becomes a *running literature review*. Thus, modeling enhances the synthesizing and integrating capabilities of the modeler, which is an important part of the answer as to how a modeler with scant biological knowledge can make important discoveries. Second, an important cognitive effect of the model-building is to enhance the modeler's powers of abstraction. Most significantly, through the gradual process of thousands of runs of simulations and analyses of system dynamics for these, the modeler gains an external, global view of the system as a whole. Such a global view would not be possible to develop just from mental simulation, especially since the interactions among elements are complex and difficult to keep track of separately. The system view, together with the detailed understanding of the dynamics, provides the modeler with an intuitive sense (*a feeling for the model*) of the biological mechanisms that enables her to extend the pathway structure in a constrained fashion to accommodate experimental data that could not be accounted for by the current pathway from which the model started. Additionally, this intuitive sense of the mechanism built from interaction with the model helps to explain the success of the crowdsourcing models noted above (see also [5.64]).

Finally, the model enhances the cognitive capacity for counterfactual or possible-worlds thinking. As noted in our discussion of thought experimenting, the

model-building process begins by capturing the reactions/interactions using variables. Variables provide a place-holder representation, which when interpreted with combinations of numbers for these variables, can generate model data that parallels the known experimental data. One interesting feature of the place-holder representation is that it provides the modeler with a flexible way of thinking about the reactions, as opposed to the experimentalist who works with only one set of values. Once the model is using the experimental values, the variables can take any set of values, as long as they generate a fit with the experimental data. The modeler is able to think of the real-world values as only *one possible scenario*, to examine why this scenario is commonly seen in nature, and envision other scenarios that fit. Thinking in variables supports both the objective modelers often have of altering or redesigning a reaction (such as the thickness of lignin in plant wall for biofuels) and the objective of developing generic design patterns and principles. More broadly, the variable representation significantly expands the imagination space of the modeler, enabling counterfactual explorations of possible worlds that far outstrip the potential of thought experimenting alone.

A more microscopic focus like this one on the actual processes by which computational simulation is coupled with the cognitive processes of the modeler begins to help break down some of the mystery and seeming inscrutability surrounding computation conveyed by the

idea that computational processes are offloaded automated processes from which inferences are derived. The implications of this research into hybrid nature of simulation modeling are that modelers might often have more control over and insight into their models and their alignment with the phenomena than philosophers have realized. Given the emphasis placed in published scientific literature on fitting the data and predictive success for validating simulations, we might be missing out on the important role that these processes internal to the model-building or discovery context appear to be playing (from a microanalysis of practice) in support of the models constructed. Indeed, the ability of computational modeling to support highly exploratory investigative processes makes it particularly relevant for philosophers to have fine-grained knowledge of model-building processes in order to begin to understand why models work as well as they do and how reliable they can be considered to be.

**8 Forms of Abduction  
and an Inferential Taxonomy**

Gerhard Minnameier, Frankfurt am Main,  
Germany

**9 Magnani's Manipulative Abduction**

Woosuk Park, Daejeon, Korea

In the last century, abduction was extensively studied in logic, semiotics, the philosophy of science, computer science, artificial intelligence, and cognitive science. The surge of interest in abduction derived largely from serious reflection on the neglect of the logic of discovery at the hands of logical positivists and Popper, especially their distinction between the context of discovery and the context of justification. At the same time, the desire to recover the rationality of science that has been seriously challenged by the publication of Kuhn's *The Structure of Scientific Revolutions* might be another important factor. However, the consensus is that researchers have failed to secure the core meaning of abduction, let alone to cover the full range of its applications. The controversial status of abduction can be immediately understood if we consider our inability to answer the following questions satisfactorily:

- What are the differences between abduction and induction?
- What are the differences between abduction and the well-known hypothetico-deductive method?
- What does Peirce mean when he says that abduction is a kind of inference?
- Does abduction involve only the generation of hypotheses or their evaluation as well?
- Are the criteria for the best explanation in abductive reasoning epistemic or pragmatic, or both?
- How many kinds of abduction are there?

Fortunately, the situation has improved much in the last two decades. To say the least, some ambitious attempts to attain a unified overview of abduction have been made, e.g., in Gabbay and Woods (2005), Magnani (2001), and Aliseda (2006). Each of these attempts emphasizes its own strengths and achievements. For example, Aliseda's book represents some logical and computational approaches to abduction quite well. Gabbay and Woods, by introducing the distinction between explanatory/non-explanatory abductions, adopt a broadly logical approach comprehending practical reasoning of real-life logical agents. By introducing his multiple distinctions between different kinds of abduction, i.e., selective/creative, theoretical/manipulative, and sentential/model-based, Magnani (2001, 2009) develops an eco-cognitive view of abduction, according to which instances of abduction are found not only in science and any other human enterprises, but also in animals, bacteria, and brain cells. Part B of this Handbook presents an overview of the most recent research on the foundational and cognitive issues on abduction inspired by all this.

In **Chap. 6** John Woods provides us with the broader context in which the significance of abductive reasoning can be appreciated. He asks whether abduction's epistemic peculiarities can be readily accommodated in philosophy's mainline *theories of knowledge*, and whether abduction provides any reason to question the assumption that the goodness of drawing a conclusion from premises depends on an underlying relation of *logical consequence*. His answer to these questions amounts to a timely response to Hintikka's announcement of abduction as the central problem in contemporary epistemology, as well as the signal of naturalistic turn in logic.

Gerhard Schurz's **Chap. 7** presents a thorough classification of different patterns of abduction. In particular, it attempts the most comprehensive treatment of the patterns of creative abduction, such as *theoretical model abduction*, *common cause abduction*, and *statistical factor analysis*. This is significant, for, compared to selective abductions, creative abductions are rarely discussed, although they are essential in science. By appealing to *independent testability* and *explanatory unification*, a demarcation between scientifically fruitful abductions and speculative abductions is also proposed. Applications of abductive inference in the domains of belief revision and instrumental/technological reasoning represent the author's most recent interest in the border between logic and the philosophy of science.

In **Chap. 8** Gerhard Minnameier, by appropriating all recent studies on abduction, presents a well-rounded overview of the intricate relationships among deduction, induction, and abduction. By taking Peirce's claim seriously that (1) that there are only three kinds of reasoning, i.e. abduction, deduction, and induction, and (2) that these are mutually distinct, he wants to clarify the very notion of abduction. For this purpose, Minnameier carefully examines the fundamental features of the three inferences. He also suggests a novel distinction between two dimensions: i.e., *levels* of abstraction and *domains* of reasoning. To say the least, his taxonomy of inferential reasoning seems to provide us with a nice framework in which different forms of inferences can be systematically accommodated.

Finally, Woosuk Park counts Lorenzo Magnani's discovery of manipulative abduction as one of the most important developments in recent studies on abduction in **Chap. 9**. After briefly introducing Magnani's distinction between theoretical and manipulative abduction, Park discusses how and why Magnani counts diagram-

matic reasoning in geometry as the prime example of manipulative abduction. Among the commentators of Peircean theorematic reasoning, Magnani is unique in equating theorematic reasoning itself as abduction. Park also discusses what he counts as some common characteristics of manipulative abductions, and how and why Magnani views manipulative abduction as a form of practical reasoning. Ultimately, he argues that it is manipulative abduction that enables Magnani to extend abduction to all directions to develop the eco-cognitive model of abduction.

The authors of this part follow the following commonly accepted abbreviation used to refer to the editions of Peirce's work:

# Reorienting

## 6. Reorienting the Logic of Abduction

John Woods

Abduction, still a comparatively neglected kind of premiss-conclusion reasoning, gives rise to the questions I want to consider here. One is whether abduction's epistemic peculiarities can be accommodated happily in the mainline philosophical *theories of knowledge*. The other is whether abduction provides any reason to question the assumption that the goodness of drawing a conclusion from premisses depends on an underlying relation of logical *consequence*. My answer each time is no. I will spend most of my time on the first. Much of what I'll say about the second is a promissory note.

Three facts about today's logic stand out:

1. Never has it been done with such technical virtuosity
2. Never has there been so much of it
3. Never has there been so little consensus about its common subject matters.

It would seem that the more we have of it, the less our inclination to get to the bottom of its sprawlingly incompatible provisions. There is nothing remotely like this in real analysis, particle physics or population genetics. There is nothing like it in the premiss-conclusion reasonings of politics and everyday life. Left undealt with, one might see in logic's indifference to its own rivalries some sign of not quite knowing its own mind.

It could be said that one of logic's more stimulating events in our still-young century is the revival of the idea that it is a universal discipline, that when all is said and done there is a core structure to which all the multiplicities of our day are ultimately answerable. If the historical record is anything to go on, the cornerstone

of that core structure is the relation of *logical consequence*. It occasions some sensible operational advice: If in your work you seek to *enlarge* logic's present multiplicities, have the grace to say why you think it qualifies as logic, that is, embodies logic's structural core. This is not idle advice. I hope to give it heed in the pages to follow, as we turn our attention to the logic of abduction.

Although logic's dominant focus has been the consequence relation, in the beginning its centrality owed comparatively little to its *intrinsic* appeal. Consequence was instrumentally interesting; it was thought to be the relation in virtue of which premiss-conclusion reasoning is safe, or whose absence would expose it to risk. Reasoning in turn had an *epistemic* motivation. Man may be many kinds of animal, but heading the list is his cognitive identity. He is a knowledge-seeking and knowledge-attaining being to which his survival and prosperity are indissolubly linked, indispensable to which is his capacity to adjust what he believes to what follows from what. We might say then that as

long as logic has retained its interest in good and bad reasoning it has retained this same epistemic orientation. Accordingly, a logic of good and bad reasoning carries *epistemological* presuppositions that aren't typically explicitly developed.

It would be premature to say that abduction by now has won a central and well-established place in the research programs of modern logic, but there are some hopeful signs of progress (important sources include [6.1–13]). In the literature to date there are two main theoretical approaches, each emphasizing the different sides of a product-process distinction. The logical (or product) approach seeks for truth conditions on abductive consequence relations and of such other properties as may be interdefinable with it. The computational (or process) approach constructs computational models of how hypotheses are selected for use in ab-

ductive contexts. It is not a strict partition. Between the logical and computational paradigms, abductive logic programming and semantic tableaux abduction occupy a more intermediate position. Whatever its precise details, the logic-computer science dichotomy is not something I welcome. It distributes the theory of abductive reasoning into different camps that have yet to learn how to talk to one another in a systematic way. A further difficulty is that whereas abduction is now an identifiable research topic in logic – albeit a minority one – it has yet to attain that status in computer science. Such abductive insights as may occur there are largely in the form of *obiter dicta* attached to the main business at hand (I am indebted to Atocha Aliseda for insightful advice on this point). This leaves us awkwardly positioned. The *foundational* work for a comprehensive account of abductive reasoning still awaits completion.

## 6.1 Abduction

### 6.1.1 Peirce's Abduction

Although there are stirrings of it in Aristotle's notion of *apagogē* [6.14], we owe the modern idea of abduction to Peirce. It is encapsulated in the *Peircean abduction schema*, as follows [6.15, CP 5.189]:

“The surprising fact C is observed.  
But if A were true, C would be a matter of course.  
Hence there is reason to suspect that A is true.”

Peirce's schema raises some obvious questions. One is how central to abduction is the factor of surprise. Another is the issue of how we are to construe the element of suspicion. A third concerns what we are expected to do with propositions that creep thus into our suspicions. A fourth is what we are to make of the idea that an occurrence of something is a matter of course. Like so many of his better ideas and deeper insights, Peirce has nothing like a fully developed account of abduction. Even so, the record contains some important ideas, seven of which I'll mention here:

- P1 Abduction is triggered by surprise [6.15, CP 5.189].
- P2 Abduction is a form of guessing, underwritten innately by instinct ([6.16, p. 128], [6.15, CP 5.171], [6.17, CP 7.220]).
- P3 A successful abduction provides no grounds for believing the abduced proposition to be true [6.16, p. 178].
- P4 Rather than believing them, the proper thing to do with abduced hypotheses is to send them off

to experimental trial ([6.15, CP 5.599], [6.18, CP 6.469–6.473], [6.17, 7.202–219]).

- P5 The connection between the truth of the abduced hypothesis A and the observed fact C is subjunctive [6.15, CP 5.189].
- P6 The inference that the abduction licenses is not to the proposition A, but rather that A's truth is something that might plausibly be suspected [6.15, CP 5.189].
- P7 The *hence* of the Peircean conclusion is ventured defeasibly [6.15, CP 5.189].

Let us note that P3 conveys something of basic importance. It is that successful abductions are *evidentially inert*. They offer no grounds for believing the hypotheses abduced. What, then, is the good of them?

### 6.1.2 Ignorance Problems

Seen in Peirce's way, abductions are responses to ignorance problems. An agent has an ignorance problem in relation to an epistemic target when it can't be attained by the cognitive resources presently at his command, or within easy and timely reach of it. If, for some proposition A, you want to know whether A is the case, and you lack the information to answer this question, or to draw it out by implication or projection from what you currently do know, then you have an ignorance problem with respect to A.

Two of the most common responses to ignorance problems are (1) *subduance* and (2) *surrender*. In the first case, one's ignorance is removed by new knowl-

edge, and an altered position is arrived at, which may serve as a positive basis for new action. In the second case, one's ignorance is fully preserved, and is so in a way that cannot serve as a positive basis for new action (new action is action whose decision to perform is lodged in reasons that would have been afforded by that knowledge). For example, suppose that you've forgotten when Barb's birthday is. If her sister Joan is nearby you can ask her, and then you'll have got what you wanted to know. This is subduance. On the other hand if Joan is traveling incognito in Peru and no one else is about, you might find that knowing Barb's birthday no longer interests you. So you might rescind your epistemic target. This would be surrender.

There is a third response that is sometimes available. It is a response that splits the difference between the prior two. It is abduction. Like surrender, abduction is ignorance-preserving, and like subduance, it offers the agent a positive basis for new action. With subduance, the agent overcomes his ignorance. With surrender, his ignorance overcomes him. With abduction, his ignorance remains, but he is not overcome by it. It offers a reasoned basis for new action in the presence of that ignorance. No one should think that the goal of abduction is to *maintain* that ignorance. The goal is to make the best of the ignorance that one chances to be in.

### 6.1.3 The Gabbay–Woods Schema

The nub of abduction can be described informally. You want to know whether something  $A$  is the case. But you don't know and aren't in a position here and now to get to know. However, you observe that if some further proposition  $H$  were true, then it together with what you already know would enable you to answer your question with regard to  $A$ . Then, on the basis of this subjunctive connection, you infer that  $H$  is a conjecturable hypothesis and, on that basis, you release it provisionally for subsequent inferential work in the relevant contexts.

More formally, let  $T$  be an agent's epistemic target at a time, and  $K$  his knowledge base at that time. Let  $K^*$  be an immediate successor of  $K$  that lies within the agent's means to produce in a timely way. Let  $R$  be an attainment relation for  $T$  and let  $\rightsquigarrow$  denote the subjunctive conditional relation.  $K(H)$  is the revision of  $K$  upon the addition of  $H$ .  $C(H)$  denotes the conjecture of  $H$  and  $H^c$  its activation. Accordingly, the general structure of abduction can be captured by what has come to be known as the Gabbay–Woods schema [6.6, 19, 20]:

1.  $T! E$  [The  $!$  operator sets  $T$  as an epistemic target with respect to some state of affairs  $E$ ]

2.  $\neg R(K, T)$  [fact]
3. Subduance is not presently an option [fact]
4. Surrender is not presently an option [fact]
5.  $H \notin K$  [fact]
6.  $H \notin K^*$  [fact]
7.  $\neg R(H, T)$  [fact]
8.  $\neg R(K(H), T)$  [fact]
9.  $H \rightsquigarrow R(K(H), T)$  [fact]
10.  $H$  meets further conditions  $S_1, \dots, S_n$  [fact]
11. Therefore,  $C(H)$  [sub-conclusion, 1–7]
12. Therefore,  $H^c$  [conclusion, 1–8].

It is easy to see that the distinctive epistemic feature of abduction is captured by the schema. It is a given that  $H$  is not in the agent's knowledge set  $K$ . Nor is it in its immediate successor  $K^*$ . Since  $H$  is not in  $K$ , then the revision of  $K$  by  $H$  is not a knowledge-successor set to  $K$ . Even so,  $H \rightsquigarrow R(K(H), T)$ . But that subjunctive fact is evidentially inert with respect to  $H$ . So the abduction of  $H$  leaves the agent no closer than he was before to achieving the knowledge he sought. Though abductively successful,  $H$  doesn't enable the abducer to attain his epistemic target. So we have it that successful abduction is ignorance-preserving. Of course, the devil is in the details. Specifying the  $S_i$  is perhaps the hardest open problem for abductive logic. In much of the literature it is widely accepted that  $K$ -sets must be consistent and that its consistency must be preserved by  $K(H)$ . This strikes me as unrealistic. Belief sets are often, if not routinely, inconsistent. Also commonly imposed is a minimality condition. There are two inequivalent versions of it. The simplicity version advises that complicated hypotheses should be avoided as much as possible. It is sometimes assumed that truth tends to favor the uncomplicated. I see no reason to accept that. On the other hand, simplicity has a prudential appeal. Simple ideas are more easily understood than complicated ones. But it would be overdoing things to elevate this desideratum to the status of a logically necessary condition. The other version is a form of Quine's maxim of minimum mutilation. It bids the theorist to revise his present theory in the face of new information in ways that leave as much as possible of the now-old theory intact. It advises the revisionist to weigh the benefits of admitting the new information against the costs of undoing the theory's current provisions. This, too, is little more than prudence. No one wants to rule out Planck's introduction of the quantum to physics, never mind the mangling of old physics that ensued. Another of the standard conditions is that  $K(H)$  must entail the proposition for which abductive support has been sought. In some variations inductive implication is substituted. Both I think are too strong. Note also that none of the three – consistency, minimality or implica-

tion – could be thought of as *process* protocols. The  $S_i$  are conditions on hypothesis selection. I have no very clear idea about how this is done, and I cannot but think that my ignorance is widely shared. Small wonder that logicians have wanted to offload the *logic of discovery* to psychology. I will come back to this briefly in due course. Meanwhile let's agree to regard line (10) as a promissory note [6.21, Chap. 11].

#### 6.1.4 The Yes-But Phenomenon

Perhaps it won't come as much of a surprise to learn of the resistance with which the ignorance-preservation claim has been met when the Gabbay–Woods schema has been presented to (what is by now a sizable number of) philosophical audiences. There are those who think that precisely because it strips good abductions of evidential force, the G–W schema misrepresents Peirce. Others think that precisely because it is faithful to Peirce's conditions the G–W schema discredits the Peircean concept of abduction. Of particular interest is the hesitation shown by philosophers who are actually inclined to *accept* the schema, and *accept* the Peircean notion. It may be true, they seem to think, that abduction is ignorance-preserving, but it is not a truth to which they take kindly. Something about it they find unsatisfying. There is a conventional way of giving voice to this kind of reticence. One does it with the words, *Yes, but . . .* So we may speak of this class of resisters as the ignorance-preservation *yes-but*s.

Some philosophers are of the view that there are at least three grades of evidential strength. There is evidential strength of the truth-preserving sort; evidential strength of the probability-enhancing sort; and evidential strength of a weaker kind. This latter incorporates a notion of evidence that is strong in its way without being either deductively strong or inductively strong. It is, as we might say, induction's poor cousin. Proponents of this approach are faced with an interesting challenge. They must try to tell us what it is for premisses nondeductively to favor a conclusion for which there is no strong inductive support. If the weak cousin thesis is false, lots of philosophers are nevertheless drawn to it. So perhaps the better explanation of the *yes-but*s' resistance to the ignorance-preservation claim is that they think that it *overstates* the poor cousin thesis, that it makes of abduction a poorer thing than it actually is. The poor cousin thesis says that abduction is the weakest evidential relation of the family. But the ignorance-preservation thesis says that it is an evidential relation of no kind, no matter how weak. Accordingly, what the *yes-but*s are proposing is tantamount to retention of the G–W schema for abduction *minus* Peirce's clause P3. This would allow success-

fully abduced hypotheses the promise of *poor-cousin* evidential backing; but it wouldn't be backing with no evidential force. It is an attractive idea, but it cuts too far.

There are too many cases in which successful reasoning, indeed brilliant reasoning, has the very characteristic the reformers would wish to suppress. A case in point is Planck's quantum hypothesis. In the physics of 1900s, black body radiation lacked unifying laws for high and low frequencies. Planck was disturbed by this. Notwithstanding his lengthy acquaintanceship with it, the disunification of the black body laws was a surprising event. It was, for physics, not a matter of course. Planck wanted to know what it would take to ease his cognitive irritation. Nothing he knew about physics answered this question. Nothing he would come to know about physics would answer it either, as long as physics was done in the standard way. Planck recognized that he would never attain his target until physics were done in a new way, in a way sufficiently at odds with the present paradigm to get some movement on this question; yet not so excessively ajar from it as to make it unrecognizable as physics. That day in 1900 when he announced to his son that he had overturned Newton, Planck was drawn to the conditional that if the quantum hypothesis  $Q$  were true then  $K(Q)$  – that is, physics as revised by the incorporation of  $Q$  – would enable him to reach his target. So he put it to work accordingly. At no stage did Planck think that  $Q$  was true. He thought it lacked physical meaning. He thought that his reasoning provided no evidence that  $Q$  was true and no grounds for believing it to be true. Peirce wanted a logic that respected this kind of thinking. This is what I want too. The poor cousin thesis doesn't do this, and cannot.

Ignorance removal is prompted by the reasoner's desire to know something he doesn't now know, or to have more knowledge of it than he currently does. What are the conditions under which this happens? It seems right to say that without an appreciation of the general conditions under which a human reasoner is in a state of knowledge, this is a question without a principled answer. If, as I aver, there are abductive modes of reasoning prompted by the desire to improve one's epistemic condition which, even when wholly successful, do not fulfill that objective, there must be two particular considerations thanks to which this is so. One would have to do with abduction. The other has to do with knowledge. A fair part of this first factor is captured by the Gabbay–Woods schema (or so I say). The second is catered for by the right theory of knowledge, if there is one. We asked why, if a philosopher accepted the Gabbay–Woods schema for abduction, would he dislike its commitment to the ignorance-preservation claim? The possibility that we're now positioned to con-

sider is that his yes-but hesitancy flows from how he approaches the general question of knowledge. That is to say, it is his *epistemology* that makes him nervous,

not his *logic*. If so, the *yes* part of *yes, but ...* is directed to the logic, but the *but part* is directed to the epistemology.

## 6.2 Knowledge

### 6.2.1 Epistemology

I said in the abstract that epistemological considerations affecting the goodness or badness of premiss-conclusion reasoning are little in evidence in mainstream logic. In so saying, I intend no slight to the now large growing and prospering literature on epistemic logics [6.22–24]. For the most part these logics construct formal representations of the standard repertoire of properties – consequence, validity, derivability, consistency, and so on – defined for sentences to which symbols for *it is known that*, and *it is believed that* function as sentence operators. A central task for these logics is to construct a formal semantics for such sentences, typically on the assumption that these epistemic expressions are modal operators, hence subject to a possible worlds treatment. Notwithstanding their explicitly epistemic orientation, it remains true that there is in this literature virtually no express contact with any of the going epistemologies. So here, too, if they operate at all epistemological considerations operate tacitly as part of an unrevealed epistemological background information. I intend something different here. I want to bring epistemology to the fore, which is precisely where it belongs in logics of premiss-conclusion reasoning of all kinds.

I want also to move on to what I think may be the right explanation of the yes-but's dissatisfactions. Before getting started, a caveat of some importance should be flagged. The explanation I'm about to proffer attributes to the yes-but's an epistemological perspective that hardly anyone shares; I mean by this hardly any epistemologist shares, a notable exception is [6.25]. There is a good chance that whatever its intrinsic plausibility, this new explanation will lack for takers. Even so, for reasons that will appear, I want to persist with it for awhile. Here is what it proposes.

#### The Right-Wrong Thesis

While the Gabbay–Woods schema gets something right about abduction, it nevertheless gets ignorance-preservation *wrong*. What it gets right is that good abductions are evidentially inert. What it gets wrong is that this lack of evidential heft entails a corresponding failure to lift the abducer in any degree from his present ignorance.

#### Corollary 6.1

There are abductive contexts in which knowledge can be attained in the absence of evidence.

The idea of knowledge without supporting evidence isn't entirely new or in the least shocking. There is a deeply dug-in inclination to apply this characterization to quite large classes of cases. Roughly, these are the propositions knowledge of which is a priori or independent of experience; or, as with Aristotle's first principles, are known without the necessity or even possibility of demonstration; or, as some insist, are the immediate disclosures of sense and introspection. Disagreements have arisen, and still do, about whether these specifications are accurate or sustainable, but it would be a considerable exaggeration to call this sort of evidential indifference shocking, and wildly inaccurate as a matter of historical fact to think of it as new.

In truth, apriorism is beside the point of the right-wrong thesis and its corollary. The knowledge that falls within their intended ambit is our knowledge of contingent propositions, whether of the empirical sciences or of the common experience of life. The right-wrong claim is that there are contingent propositions about the world which, without being in any way *epistemically privileged*, can be ignorance-reducing by virtue of considerations that lend them no evidential weight. So what is wanted is a theory of knowledge that allows this to happen.

The historically dominant idea in philosophy is that knowledge is true belief plus some other condition, usually identified as justification or evidence. This, the *J*-condition, has been with us at least since Plato's *Theaetetus*, and much scholarly ink has been spilled over how it is best formulated and whether it might require the corrective touch of some further condition. But, as a general idea, the establishment bona fides of the *J*-condition are as rock solid as anything in philosophy.

The account of knowledge I am looking for arises at the juncture of two epistemological developments. One is the trend towards naturalism [6.26] and the other is the arrival of reliabilism [6.27]. It is a theory in which the *J*-condition fails as a general constraint on epistemically unprivileged contingent knowledge. Accordingly, my first task is to try to downgrade the condition, to deny it a defining role. Assuming some success with the

first, my second task will be to find at the intersection of these trends an epistemological orientation – perhaps I would better call it an epistemological *sensibility* – which might without too much strain be reconciled to the loss of the *J*-condition. For ease of reference let me baptize this orientation, this sensibility, the *causal response turn*.

Whereupon task number three, which is to identify those further features of the causal response model that link up the notions of evidence and knowledge in the heterodox ways demanded by the right-wrong thesis.

### 6.2.2 Losing the *J*-Condition

The *J*-condition has attracted huge literature and underwritten a good deal of strategic equivocation. On *engaged* readings of the condition, a person's belief is justified or evidenced only if he himself has produced his justification then and there, or he has presented the evidence for it on the spot. On *disengaged* readings, a person is justified in believing if a justification exists but hasn't been invoked, or evidence exists but hasn't been adduced or even perhaps found. The engaged and disengaged readings raise an interesting question. How deeply engaged does one have to be to meet the *J*-condition on knowledge? Most epistemologists formulate the engaged-disengaged distinction as one between internalist and externalist justification.

Engagement here is a matter of *case making*. The two readings of *J* define a spectrum, but for present purposes there is little that needs saying of what lies within. It suffices to note that in its most engaged sense a belief is justified or evidenced only if the believer can himself make the case for it here and now. At the other extreme, the belief is justified or evidenced if a case for it is available in principle to someone or other. In the first case, the individual in question has a high degree of case-making engagement. In the other, his engagement is a gestural, anonymous and proxied one: it is engagement in name only.

Suppose the following were true. Suppose that, for every piece of epistemically unprivileged contingent knowledge *p*, there were a structure of facts in virtue of which *p* is the case. Suppose further that for every such *p* a person knows, it would be possible in principle to discern this structure of the facts and the in-virtue-of-relation it bears to *p*'s truth. (I don't think there is any realistic chance of this being so, but let's assume it for the point at hand.) Suppose, finally, that we agreed to say that when in principle knowledge of that structure and that relation exists with respect to a *p* that a subject *S* knows, there exists a justification of *S*'s belief that *p*. For ease of reference, let's call these *factive* justifications. Factive justifications are justifications at their most

disengaged. They stand in radical contrast to highly engaged justifications, which we may call *forensic*.

By construction of the case presently in view, factive justification will be the constant companion of any piece of epistemically unprivileged contingent knowledge that *S* chances to have. But we have in this constancy not conditionhood but concomitance. Factive justification is a faithful accompaniment of such knowledge, but it is not a constituent of it. Forensic justification is another story. We might grant that if, when *S* knows that *p*, he has a forensic justification for his belief, then his justification will have made a contribution to this knowledge. But in relation to all that *S* knows it is comparatively rare that there is a forensic justification. Here is a test case, with a tip of the hat to Peirce: Do you know who your parents are? Of course you do! Very well, then, let's have your forensic justification.

This is troublesome. If we persist in making forensic justification a condition on knowledge, the result is skepticism on an undesirable scale. If, on the other hand, we decide to go with factive justification, then justifications exist whenever knowledge exists, but they aren't conditions on this knowledge. They are not a structural element of it. Whereupon we are met with the *J*-condition dilemma.

#### *J*-Condition Dilemma

Depending on how it is read, the *J*-condition is either an irrelevant concomitant of knowledge, or a skepticism-inducing discouragement of it.

The forensic-factive ambiguity runs through all the idioms of *J*-attribution. Concerning his belief that *p* there might be evidence for *p* that *S* adduces or there may be evidence for *p* that exists without attribution. There may be reasons for it that *S* gives, or reasons for it that exist without being given. Like confusions repose in careless uses of *have*. If we allow that *S* has a justification or has evidence or has reasons whenever these things exist factively, we mislicense the inference from the factive to the forensic, allowing, in so doing, *S* to have justifications that he's never heard of.

### 6.2.3 The Causal Response Model of Knowledge

The causal response (CR) model of knowledge is rightly associated with reliabilism. In all the going forms of it, the *J*-condition is preserved [6.28]. One of the few places in the reliabilist literature where we see stirrings of the pure version of the causal model is Alvin Goldman's first reliabilist paper, which appeared in 1967. It is a rare place in Goldman's foundational corpus where the *J*-condition, if there at all, is given shortest shrift. In some versions, the *J*-condition is

satisfied when one's belief has been reached by reliable *procedures*. In others, the condition is met when the belief was reliably produced, that is, produced by belief-forming *mechanisms* that were working reliably. In contrast to the standard versions, the *pure* version is one in which the *J*-condition is eliminated, rather than reinterpreted along reliabilist lines. As a first approximation, the pure theory characterizes knowledge as follows:

“*S* knows that if and only if *p* is true, *S* believes that, the belief was produced by belief-forming devices, in good working order, operating as they should on good information and in the absence of Gettier nuisances and other hostile externalities.”

Fundamental to what I've been calling the pure theory is the conviction that knowledge is not in any essential or general way tied to case making, that *knowing* is one thing and *showing* another. This is not to say that case making is never implicated in knowledge. There are lots of beliefs that would not have been had in the absence of the case makings that triggered their formation. Think here of a mother's sad realization that her son is guilty of the crime after all, or a nineteenth century mathematician's grudging acknowledgment of the transfinite. But as a general constraint, case making is rejected by pure causalists; by causalists of the sort that Goldman was trying to be in 1967.

### 6.2.4 Naturalism

Epistemology's naturalized turn supplies a welcoming habitat for the CR model. Naturalism comes in various and competing versions, but at the core of them all is the insistence that human knowledge is a natural phenomenon, achieved by natural beings in accordance with their design and wherewithal, interacting in the causal nexi in which the human organism lives out his life. Unlike the *J* theorist, the CR theorist is a respecter of the passive side of knowledge. He knows that there are large classes of cases in which achieving a knowledge of something is a little more than just being awake and on the scene. Even where some initiative is required by the knower, the resultant knowledge is always a partnership between doing and being done to. So even worked-for knowledge is partly down to *him* and partly down to his *devices*.

It would be wrong to leave the impression that, on the CR model, knowing things is just a matter of doing what comes naturally. There are ranges of cases in which knowledge is extremely difficult to get, if gettable at all. There are cases in which knowledge is unattainable except for the intelligence, skill, training and expertise of those who seek it. Everyone has an

aptitude for knowledge. But there are cases galore in which aptitude requires the supplementation of vocation and talent – and training. CR theorists are no less aware of this than their *J* rivals. The difference between them falls in where the emphasis falls. Among *J* theorists there is a tendency to generalize the hard cases. Among CR theorists there is a contrary tendency to keep the hard cases in their place.

Let me say again that *J*-theories give an exaggerated, if equivocal, place to the role of showing in knowing. Contrary to what might be supposed, the CR model is no disrespecter of the showing-knowing distinction, albeit with a more circumscribed appreciation of showing. I want to turn to this now.

### 6.2.5 Showing and Knowing

Consider the case of Fermat's Last Theorem. The theorem asserts that for integers  $x$ ,  $y$ , and  $z$ , the equation  $x^n + y^n = z^n$  lacks a solution when  $n > 2$ . Fermat famously left a marginal note claiming to have found a proof of his theorem. I want to simplify the example by stipulating that he did not have a proof and did not think or say that he did. The received wisdom is that Fermat went to his grave not knowing that his theorem is true. The received wisdom is that no one knew whether the theorem is true until Andrew Wiles' proof of it in 1995. If the forensically conceived *J* model were true, this would be pretty much the way we would expect the received wisdom to go.

If the *J* model is hard on knowledge, the CR model is a good deal more accommodating. It gives to knowledge a generous provenance. But I daresay that it will come as a surprise that, on some perfectly plausible assumptions, Fermat did indeed know the truth of his theorem, never mind (as we have stipulated) that he was all at sea about its proof. Fermat was no rookie. He was a gifted and experienced mathematician. He was immersed in a sea of mathematical sophistication. He was a mathematical virtuoso. Fermat knew his theorem if the following conditions were met: It is true (as indeed it is), he believed it (as indeed he did), his highly trained belief-forming devices were in good order (as indeed they were) and not in this instance misperforming (as indeed they were not), and their operations were not compromised by bad information or Gettier nuisances (as indeed was the case). So Fermat and generations of others like-placed knew the theorem well before its proof could be contrived.

We come now to a related point about showing and knowing. Showing and knowing mark two distinct goals for science, and a corresponding difference in their satisfaction conditions. Not unlike the law, science is in significant measure a case-making profession –

a forensic profession – made so by the premium it places on *knowing* when knowledge has been achieved, rather than just achieving it. This has something to do with its status as a profession, subject to its own exacting requirements for apprenticeship, advancement and successful practice. These are factors that impose on people in the showing professions expectations that regulate *public announcement*. Fermat may well have known the truth of his theorem and may have had occasion to say so to a trusted friend or his mother. But he was not to say it for publication. Publication is a vehicle for case making, and case making is harder than knowing. Journal editors don't give a toss for what you know. But they might sit up and notice if you can show what you know.

### 6.2.6 Explaining the Yes-Buts

The ignorance-preservation claim is rooted in the idea of the no evidence-no knowledge thesis.

#### The No Evidence–No Knowledge Thesis

Since successful abduction is evidentially inert, it is also epistemically inert. But this is justificationism: No advance in knowledge without some corresponding advance in evidence.

The CR model jettisons justificationism. It denies the very implication in which the ignorance-preservation thesis is grounded. It is not hard to see that the evidence, whose abductive absence Peirce seizes upon, is not evidence in the factive sense. Peirce insists that we have no business believing a successfully abducted hypothesis. Peirce certainly doesn't deny that behind any plausibly conjectured hypothesis there is a structure of facts in virtue to which it owes its truth value. Peirce thinks that our track record as abductive guessers is remarkably good. He is struck by the ratio of right guesses to guesses. He is struck by our aptitude for correcting wrong guesses. The evidence whose absence matters here is forensic, it is evidence by which an abducer could vindicate his belief in the hypothesis at hand. But Peirce thinks that in the abductive context nothing vindicates that belief.

We come now to a critical observation. There is nothing in Peirce's account that tells us that abducted hypotheses aren't believed as a *matter of fact*. Some clearly are not. At the time of their respective advancements, Planck didn't believe the quantum hypothesis and Gell-Mann didn't believe the quark hypothesis. But it takes no more than simple inspection to see that there are masses of cases to the contrary, that abductive success is belief-*inducing* on a large scale.

There is in this commonplace fact something for the CR theories to make something of. Let  $H$  be one

of those successfully abducted hypotheses that happen to be true and, contrary to Peirce's advice, believed by its abducer  $S$ . What would it take to get us seriously to propose that, when these conditions are met,  $S$ 's belief-forming device's are malfunctioning or are in poor operating order. Notice that a commonly held answer is not available here, on pain of question begging. It cannot be said that unevidenced belief is itself evidence of malfunction and disorder. That is, it cannot be said to the CR-theorist, since implicit in his rejection of justificationism is his rejection of this answer.

Is there, then, any reason to suppose that the arousal of unevidenced belief might be some indication of *properly* functioning belief formation? Ironically enough, there is an affirmative answer in Peirce himself. Peirce is much taken with our capacity for right guessing. Our facility with guessing is so impressive that Peirce is driven to the idea that good guessing is something the human animal is built for. But if we are built for good guessing, and good abduction is a form of guessing, how can the abduction of true hypotheses not be likewise something we're built for? Accordingly, there is a case for saying that.

#### Knowledge Enhancement

In the CR model of knowledge, there are numbers of instances in which successful abduction is not only not ignorance preserving, but actually *knowledge enhancing*.

Part of what makes for the irony of Peirce's enthusiasm for right guessing is his insistence that guesses not be indulged by belief. In this he is a justificationist. Abducers have no business in believing unevidenced propositions, never mind their abductive allure. This is enough of a basis to pin the ignorance-preservation thesis on Peirce, but *not* on a CR theorist who accepts the Gabbay–Woods schema. What this shows is that theirs is not a disagreement about abduction. It is a disagreement about knowledge.

There isn't much likelihood that yes-buts will flock to this accommodation. The reason is that hardly anyone (any philosopher anyway) thinks the CR model is true in its pure form. There is no space left to me to debate the ins and outs of this. Suffice it to say that it offers the abductive logician the very relief that the yes-buts pine for. Besides, the CR theory just might be true [6.21].

### 6.2.7 Guessing

In line (10) of the G–W schema the  $S_i$  occur as placeholders for conditions on hypothesis selection. Previously, I said that I didn't know what these conditions

are [6.7]. In point of fact there are two things that I don't know. One is the normative conditions in virtue of which the selection made is a worthy choice. The other is the causal conditions that enable the choice to be made. It is easy to see that there are a good many  $H$ s that could serve as antecedents in line (9)'s  $H \leftrightarrow R(K(H), T)$  without disturbing its truth value. It is also easy to see that a good many of *those*  $H$ s would never be abductively concluded, never mind their occurrence there. It is clear that a reasonable choice of  $H$  must preserve the truth of (9). It is also clear that this is not enough for abductive significance. A reasonable choice must have some further features. I am especially at a loss to describe how beings like us actually go about finding things like that. Perhaps it will be said that my difficulty is a reflection on me, not on the criteria for hypothesis selection. It is true that the number of propositions that could be entertained is at least as large as the number of  $H$ s that slot into the antecedent of (9) in a truth-preserving way. Let's think of these as constituting the hypothesis-selection space. Selection, in turn, is a matter of cutting down this large space to a much smaller proper subset, ideally a unit set. Selection, to this same effect, would be achieved by a search engine operating on the hypothesis-selection space. Its purpose would be to pluck from that multiplicity the one, or few ones, that would serve our purposes.

There is nothing remotely mystifying or opaque about search engines (why else would we bother with Google?). So isn't the problem I'm having with the  $S_i$  that I'm not a software engineer? Wouldn't it be prudent to outsource the hypothesis-selection task to someone equipped to perform it? To which I say: If that is a doable thing we should do it. There is no doubt that algorithms exist in exuberant abundance for search tasks of considerable variety and complexity. There are algorithms that cut down a computer system's search space to one answering to the algorithm's flags. Perhaps such an arrangement could be said to model hypothesis selection. But it is another thing entirely as to whether, when we ourselves are performing them, our hypothesis selections implement the system's algorithms. So I am minded to say that *my* questions about the  $S_i$  are not comprehensively answerable by a software engineer.

Here is where guessing re-enters the picture, which is what Peirce thinks that hypothesis selection is. Peirce is struck by how good we are at it. By this he needn't have meant that we have more correct guesses than incorrect. It is enough that, even if we make fewer correct guesses than incorrect, the ratio of correct to incorrect is still impressively high. We get it right, rather than wrong, with a notable frequency. Our opportunities for getting it wrong are enormous. Relative to the propositions that could have been guessed at, the number of

times that they are rightly guessed is amazing; so much so that Peirce is led to surmise that our proclivity for right guesses is innate. Of course, not all good guessing is accurate. A good guess can be one that puts the guessed-at proposition in *the ball park*, notwithstanding that it might actually not be true. Here, too, good guesses might include more incorrect ones than correct. But as before, the ratio of correct to merely good could be notably high. So the safer claim on Peirce's behalf is that beings like us are hardwired to make for good, although not necessarily correct, guesses with a very high frequency. It is lots easier to make a ball-park guess than a true one; so much so that the hesitant nativist might claim a hardwired proclivity for ball-park, yet not for truth, save as a welcome contingency, which in its own turn presents itself with an agreeable frequency. Thus the safe inference to draw from the fact that  $H$  was selected is that  $H$  is in the ball park. The inference to  $H$ 's truth is not dismissable, but it is weaker.

Needless to say, nativism has problems all its own. But what I want to concentrate on is a problem it poses for Peircian abduction. At the heart of all is what to make of ball-park guesses. The safest thing is to propose is that, even when false, a ball-park hypothesis in a given context is one that bears serious operational consideration there. There might be two overarching reasons for this. *One* is that ball-park hypotheses show promise of having a coherently manageable role in the conceptual spaces of the contexts of their engagement. Take again the example of Planck. The quantum hypothesis was a big wrench to classical physics. It didn't then have an established scientific meaning. It entered the fray without any trace of a track record. Even so, for all its foreignness, it was a ball-park hypothesis. What made it so was that  $P(Q)$  was a theory revision recognizable as *physics*. Contrast  $Q$  with *the gold fairy will achieve the sought-for unification*. Of course, all of this turns on the assumption that Peirce got it right in thinking that hypothesis selection is guessing, and to note that good guessing is innate. Call this the *innateness hypothesis*. The *second* consideration is that the frequency of true hypotheses to ball-park hypotheses is notably high.

Whether he (expressly) knows how it's done, when an abductive agent is going through his paces, there is a point at which he selects a hypothesis  $H$ . If the innateness thesis holds, then the agent has introduced a proposition that has an excellent shot at being ball-park, and a decent shot of being true. On all approaches to the matter, an abduction won't have been performed in the absence of  $H$ ; and on the G-W approach, it won't have been performed correctly unless  $H$  is neither believed nor (however weakly) evidenced by its own abductive success. On the other, our present reflections suggest

that the very fact that  $H$  was *selected* is evidence that it is ball-park, and less good but not nonexistent evidence that it is true. Moreover,  $H$  is the antecedent of our subjunctive conditional (9)  $H \rightsquigarrow R(K(H), T)$ . If  $H$  is true so is  $R(K(H), T)$  by modus ponens; and if  $R(K(H), T)$  holds the original ignorance problem is solved by a form of subduance. In which case, the abduction simply *lapses*. It lapses because the nonevidential weight lent to a successfully *abducted* hypothesis is, on the G–W model, weaker than the evidential support given it by way of the innateness hypothesis as regards its very *selection*.

If, on the other hand,  $H$  is not true, but ball-park – hence favorably evidenced – and being evidenced is closed under consequence, then the reasoning at hand also goes through under the obvious adjustments.

The problem is that there are two matters on which Peirce can't have his cake and eat it too. If he retains the innateness thesis he can't have the ignorance-preservation thesis. Equally, if he keeps ignorance preservation he must give up innateness, which *nota bene* is not the thesis that guessing is innate but that *good* guessing is innate. Yet if we give up innateness we're back to where we started, with less than we would like to say about the actual conditions for which the G–W  $S_i$  are mere placeholders. I leave the innateness-ignorance preservation clash as an open problem in the abduction research program. Since, by our earlier reasoning, there is an epistemology (CR) that retains ignorance preservation only as a contingent property of some abductions, my present uncertain inclination is to retain G–W as modified by CR and to rethink innateness. But I'm open to offers. I'll get back to this briefly in the section to follow.

Having had my say about the epistemological considerations that play out in the logic of abduction, I want to turn to the question of how, or to what extent, a logic of abduction will meet universalist conditions on logic. I want to determine whether or to what extent abductive theories embody the structural core assumed by universalists to be common to any theory that qualifies for admittance to the province of logic.

Whatever the details, abduction is a form of premiss-conclusion reasoning. By the conclusions-consequence thesis, whenever the reasoning is good the conclusion that's drawn is a consequence of those premisses. As logics have proliferated, so too the consequences, albeit not exactly in a strict one-to-one correspondence. If today there are more logics than one can shake a stick at, there is a concomitant plenitude of consequences relations. Much of what preoccupies logicians presently is the classification, individuation, and interrelatedness of this multiplicity. Whatever their variations, there is one distinction to which they all an-

swer. Some consequence relations are truth-preserving; all the others aren't. Truth-preserving consequence is (said to be) monotonic. (It isn't. To take an ancient example, Aristotle's *sylogistic* consequence is truth-preserving but nonmonotonic.) Premises from which a conclusion follows can be supplemented at will and the conclusion will still follow. One way of capturing this point is that truth-preserving consequence is impervious to the openness of the world. As far as consequencehood is concerned, the world might as well be closed. Once a consequence of something, always a consequence of it. It is strikingly otherwise with non-truth-preserving consequence. It is precisely this indifference to the openness of the world that is lost.

### 6.2.8 Closed Worlds

When we were discussing the  $J$  condition on knowledge, we called upon a distinction between the factive justification of a belief and its forensic justification. In a rough and ready way, a factive justification is down to the *world*, whereas a forensic justification is down to *us*. We find ourselves at a point at which the idea of factivity might be put to further good use. To see how, it is necessary to acknowledge that the distinction between open and closed worlds is systematically ambiguous. In one sense it marks a contrast between *information states* at a time, with the closed world being the state of total information, and open ones states of incomplete information. In the other sense, a closed world can be called factive. A closed world at  $t$  is everything that is the case at  $t$ . It is the totality of facts at  $t$ . A closed world is also open at  $t$ , not with regard to the facts that close it at  $t$ , but in respect of the facts thence to come. We may suppose that the world will cease to open at the crack of doom, and that the complete inventory of all the facts that ever were would be logged in the right sort of Domsday Book. It is not, of course, a book that any of us will get to read. Like it or not, we must make do with openness. Both our information states and the world are open at any  $t$  before the crack. But the diachronics of facticity outpace the accuracy of information states. When there is a clash, the world at  $t$  always trumps our information about it at  $t-n$ .

At any given time the world will be more closed than its concurrent information states. At any given time the state of the world outreaches the state of our knowledge of it. When we reason from premisses to conclusions we are not negotiating with the world. We are negotiating with informational reflections of the world. We are negotiating with information states. Given the limitations on human information states, our representations of the world are in virtually all respects

open, and most premises-conclusion relations are susceptible to rupture. Truth-preserving consequences are an interesting exception. The world can be as open as openness gets, but a truth-preserving consequence of something is always a consequence of it, never mind the provisions at any  $t$  of our information states. Nonmonotonic consequence is different: Today a consequence tomorrow a nonconsequence.

We might think that the more prudent course is to cease drawing conclusions and postpone the decisions they induce us to make until our information state closes, until our information is permanently total. The ludicrousness of the assumption speaks for itself. Cognitive and behavioral paralysis is not an evolutionary option. Thus arises the closed world assumption. Given that belief and action cannot await the arrival of total information, it behooves us to draw our conclusions and take our decisions when the likelihood of informational defeat is least high, at which point we would invoke the assumption that for the matter at hand the world might just as well be closed.

The key question about the closed world assumption is the set of conditions under which it is reasonable to invoke it. The follow-up question is whether we're much good at it. I am not much inclined to think that we have done all that well in answering the first question. But my answer to the second is that, given the plenitude of times and circumstances at which to invoke it, our track record is really quite good; certainly good enough to keep humanity's knowledge-seeking project briskly up and running. Even so, the closed world assumption is vulnerable to two occasions of defeat. One is by way of later information about later facts. Another is by way of later information about the facts now in play. It is easy to see, and no surprise at all, that new facts will overturn present information about present facts with a frequency that matches the frequency of the world's own displacement of old facts by new. Less easy to see is how we manage as well as we do in invoking closure in the absence of information about the present destructive facts currently beyond our ken. Here, too, we have a cut-down problem. We call upon closure in the hopeful expectation that no present unannounced fact will undo the conclusions we now draw and the decisions they induce us to make. Comparatively speaking, virtually all the facts there are now are facts that no one will ever know. That's quite a lot of facts, indeed it is nondenumerably many (for isn't it a fact that, for any real number, it is a number, and is self-identical, and so on?).

There is a point of similarity between hypothesis selection and the imposition of world closure. Our good

track record with both invites a nativist account each time. Oversimplified, we are as good as we are at selecting hypotheses because that's the way we were built. We are as good as we are at closing the world because that too is the way we were built. I suggested earlier that in abductive contexts the very fact that  $H$  has been selected is some evidence that it is true (and even better evidence that it is ball-park). But this seems to contradict the Peircian thesis that abductive success confers on  $H$  nothing stronger than the suspicion that it might be true. Since Peirce's account of abduction incorporates both the innateness thesis and the no-evidential-support thesis, it would appear that Peirce's account is internally inconsistent. I said a section ago that I had a slight leaning for retaining the no-evidence thesis and lightening up on the innateness thesis. Either way is Hobson's choice. That, anyhow, is how it appears.

In fact, however, the appearance is deceptive. There is no contradiction. Peirce does not make it a condition on abductive hypothesis-selection that  $H$  enter the fray entirely untouched by reasons to believe it or evidence that supports it. He requires that the present support-status of  $H$  has no role to play in the abductive process. That  $H$  is somewhat well supported doesn't, if true, have any premissory role here. Moreover, it is not the goal of abduction to make any kind of case for  $H$ 's truth. The goal is to find an  $H$  which, independently of its own epistemic status, would if true enable a reasoner to hit his target  $T$ . But whatever the target is, it's not the target of wanting to know whether  $H$  is true. It is true that, if all goes well, Peirce asserts that it may be defeasibly concluded that there is reason to suspect that  $H$  might be true. But, again, abduction's purpose is not to make a case for  $H$ , no matter how weakly. The function of the suspectability observation is wholly retrospective. It serves as a hypothesis-selection vindicator. You've picked the (or a) right hypothesis only if the true subjunctive conditional in which it appears as antecedent occasions the abducer's satisfaction that that, in and of itself, would make it reasonable to suspect that  $H$  might be so. In a way, then, the G-W schema misrepresents this connection. It is not that the abduction implies  $H$ 's suspectability, but rather that the abduction won't succeed unless the truth of line (9) induces the suspectability belief [6.21] (for more on the causal role in inference, readers could again consult [6.21]). And that won't happen if the wrong  $H$  has been selected, never mind that it preserves (9)'s truth. For the point at hand, however, we've arrived at a good result. The innateness thesis and the no-support thesis are both implicated in the Peircean construal of abduction, but are in perfect consistency.

## 6.3 Logic

### 6.3.1 Consequences and Conclusions

I said at the beginning that for nearly two and a half millennia the central focus of logic has been the consequence relation. More basic still was a concomitant preoccupation with premiss-conclusion reasoning. For a very long time logicians took it as given that these two matters are joined at the hip.

#### Conclusions and Consequences

When someone correctly draws a conclusion from some premisses, his conclusion is a consequence of them.

#### Corollary 6.2

If a conclusion drawn from some premisses is not a consequence of them, then the conclusion is incorrectly drawn.

If this were so, it could be seen at once that there is a quite intuitive distinction between the consequences that a premiss set has and the consequences that a reasonable reasoner would *conclude* from it. Any treatment of logic in which this distinction is at least implicitly present, there is a principled role for agents, for the very beings who draw what conclusions they will from the consequences that flow from the premisses at hand. In any such logic there will be at least implicit provision for the nature of the agent's involvement. In every case the involvement is epistemically oriented. People want to know what follows from what. They want to know how to rebut an opponent. They want to know whether, when this follows from that that, they can now be said to know that. In a helpful simplification, it could be said that logic got out of the agency business in 1879. It is not that agency was overlooked entirely, but rather that it was scandalously short-sheeted. For consequence, the having-drawing distinction would fold into having; and having, it would be said, would be the very things drawn by an ideally rational reasoner. Of course, this downplaying of cognitive agency was never without its dissenters. Indeed today we are awash in game theoretic exuberance, to name just one development of note.

### 6.3.2 Semantics

Consequence derives its semantic character from its attachment to truth, itself a semantic property in an odd baptismal bestowal by Tarski. In the deductive case, it is easy to see how truth is implicated in consequence and how, in turn, consequence assumes its status as a semantic relation. Not only does truth ground the very definition of consequence, but it makes for a re-

lation that is also truth-preserving. The monotonicity of consequence provides the sole instance in which a consequence is impervious to the informational openness of the world. It is the one case in informational openness at  $t$  that is indifferent to the world's factive closure at  $t$ , to say nothing of its final closure at the crack of doom. It has long been known that logicians, then and now, harbor an inordinate affection for deductive consequence. It's not hard to see why. Deductive consequence has proved more responsive to theoretical treatment than any of the nondeductive variety. But more centrally, it is the only consequence relation that captures permanent chunks of facticity.

Whatever else we might say, we can't say that nonmonotonic relations are relations of *semantic* consequence. If  $B$  is a nonmonotonic consequence of  $A$  it holds independently of whatever makes for the *truth* of  $A$  and  $B$ . Sometimes perhaps it holds on account of probability conditions on  $A$  and  $B$ , but probability has nothing to do with truth. If there is such a thing as probabilistic consequence – think here of Carnap's partial entailment – it is not a semantic relation. We may have it now that the evidence strongly supports the charge against Spike in last night's burglary. We might come to know better tomorrow. We might learn that at the time of the offense Spike was spotted on the other side of town. So the world at  $t$  didn't support then the proposition that Spike did do it, never mind the state of information the day after  $t$ .

No one doubts that yesterday there existed between the evidence on hand and the charge against Spike a relation of epistemic and decisional importance, a kind of relation in whose absence a survivable human life would be impossible. But a fair question nevertheless presses for attention: Where is the gain in conceptualizing these vital premiss-conclusion relations as relations of logical *consequence*? Where is the good of trying to construe nonmonotonic relations on the model of attenuated and retrofitted monotonic consequences? My own inclination is to say that talk of nonmonotonic consequence misconceives the *import* of nonmonotonicity. We tend to think of it as a distinguishing feature of consequence relations, when what it really is is the defining feature of nontruth preservation.

When premiss-conclusion reasoning is good but not truth-preserving, it is made so by an underlying relation. Any theory of premiss-conclusion reasoning had better have something to say about this, about its nature and how it operates. We should give it the name it both deserves and better reflects how it actually does function. Let's call it *conclusionality*. Conclusionality is an epistemic or epistemic/prudential relation. It is a relation

that helps rearrange our belief states, hence possessing decisional significance. Any struggle to discern whether it is also a consequence relation seems to me to be sailing into the wind.

Abductive conclusions are on the receiving end of this relation; they are occupants of its converse domain. If our present reflections can be made to stand, there is no relation of abductive consequence; and it will cause us no end of distraction trying to figure out how to make it one. It hardly needs saying that depriving a logic of abduction of its own relation of abductive consequence must of necessity rearrange how abductive logic is conceptualized. There are plenty of logicians more than ready to say that a logic without consequence relations is a logic in name only – a logic *façon de parler*, hence a logic that fails universalistic prescriptions. I am otherwise minded. Logic started with *conclusionality* relations. It was adventitiousness, not essence, that brought it about that the ones first considered were also consequence relations. Logic has had a good innings right from the beginning. In a way, this has been unfortunate. The success we've had with consequence has obscured our view of conclusionality. It has led us to think that the more we can get conclusionality *in gen-*

*eral* to be a species of consequence, the faster we'll achieve some theoretical respectability. We would be better served to place conclusionality at the core of logic and to place consequence in an annex of less central importance. If we did that, we could reinstate the logic of abduction and equip it for admittance into universalist respectability. But we could also reinvest to good effect all that energy we've devoted to consequentializing the conclusionality relation, in a refreshed effort to figure how conclusionality actually works in the epistemically sensitive environments in which, perforce, the human organism must operate.

**Acknowledgments.** I would know a good deal less than I presently do about abduction without stimulating instruction from Dov Gabbay, Lorenzo Magnani, Atocha Aliseda, Ahti-Veikko Pietarinen, Peter Bruza, Woosuk Park, Douglas Niño and more recently – especially in relation to sections 11 and 12 – Madeleine Ransom. To all my warmest thanks. My student Frank Hong has also pitched in with astute suggestions; equal gratitude to him. For technical support and everything else that matters, Carol Woods is my go-to gal. Without whom not.

# Patterns of Abductive Inference

Gerhard Schurz

This article understands abductive inference as encompassing several special patterns of inference to the best explanation whose structure *determines* a promising explanatory conjecture (an abductive conclusion) for phenomena that are in need of explanation (Sect. 7.1). A *classification* of different patterns of abduction is given in Sect. 7.2, which is intended to be as complete as possible. A central distinction is that between *selective abductions*, which choose an optimal candidate from a given multitude of possible explanations (Sects. 7.3 and 7.4), and *creative abductions*, which introduce new theoretical models or concepts (Sects. 7.5–7.7). While the discussion of selective abduction has dominated the literature, creative abductions are rarely discussed, although they are essential in science. This paper introduces several kinds of creative abduction, such as *theoretical model abduction*, *common-cause abduction*, and *statistical factor analysis*. A demarcation between scientifically fruitful abductions and speculative abductions is proposed, by appeal to two interrelated criteria: *independent testability* and *explanatory unification*. Section 7.8 presents applications of abductive inference in the domains of belief revision and instrumental/technological reasoning.

## 7.1 General Characterization of Abductive Reasoning and IBE

This article is based upon the work in *Schurz* [7.1] where abductive inferences are described as special patterns of inference to the best explanation (IBE) whose structure determines a promising explanatory conjecture (an abductive conclusion), and thus serves as a *search strategy* for finding explanations for given phenomena. However, depending on the explanatory *target* and the background knowledge, there are rather *different patterns* of abductive inference. Sections 7.2–7.7 give a detailed reconstruction of these patterns of abductive inference. Section 7.8 presents applications of abduction in the domains of belief revision and instrumental reasoning. The introductory section explains three general theses that underlie the analysis and terminology of this chapter.

### Thesis 7.1 (Induction versus abduction)

*Peirce* [7.2, CP 2.619–2.644], [7.3, CP 5.14–5.212] distinguished between three families of reasoning patterns: deduction, induction, and abduction. Deductions are *non-ampliative* and *certain*: given the premises are true, the conclusion *must* be true. In contrast, inductions and abductions are *ampliative* and *uncertain*, which means that even if the truth of the premises is taken for granted, the conclusion may be false, and is therefore subject to *further testing*.

My first thesis is that induction and abduction are two *distinct families* of ampliative reasoning that are *not reducible* to each other. For this reason, I do *not* regard induction as an umbrella term for all kinds of ampliative (non-deductive) inferences [7.4, p. 42], [7.5], [7.6, p. 28]. Rather, I understand induction in the *narrow Humean sense* in which a property or regularity is *transferred* from the past to the future, or from the observed to the unobserved.

Inductions and abductions can be distinguished by their different *targets*. Both serve the target of extending our knowledge beyond observation, but in different respects. Inductions serve the goal of inferring something about the *future course of events*, which is important for planning, that is, adapting our actions to the course of events. In contrast, abductions serve the goal of inferring something about the unobserved *causes* or *explanatory reasons* of observed events, which is of central importance for manipulating the course of events, that is, adapting the course of events to our wishes [7.3, CP 5.189], [7.7, p. 35]. That abductions cannot be reduced to inductions follows from the fact that inductions cannot introduce new concepts or conceptual models; they merely transfer them to new instances. In contrast, some kinds of ab-

ductions *can* introduce new concepts [7.3, CP 5.170]. Following *Magnani* [7.8, p. 20], [7.9], I call abductions that introduce new concepts or models *creative*, in contrast to *selective* abductions whose task is to choose the best candidate from among a given multitude of possible explanations.

### Thesis 7.2 (Inference to the best available explanation may not be good enough)

Most authors agree that Harman's IBE [7.10] has to be modified in (at least) the following respect: Nobody knows *all* possible explanations for a given phenomenon, and therefore, what one really has instead of an IBE is an inference to the *best available* explanation, in short an IBAE.

However, as *Lipton* [7.11, p. 58] has pointed out – and this is my second thesis: the best available explanation is not always *good enough* to be rationally acceptable. If a phenomenon is poorly understood, then one's best available explanation is usually *pure speculation*. In the early history of human mankind, the best available explanations of otherwise unexplainable natural phenomena, such as the rising of the Sun or the coming of the rain, was in terms of the actions of supernatural agents. Speculative explanations of this sort fail to meet important scientific demands that are discussed in Sect. 7.1.

Summarizing, the rule IBE is not feasible, and the rule IBAE is not generally acceptable. What is needed for more satisfying versions of abductive rules are (1) *minimal criteria* for the *acceptability* of scientific abductions, and (2) *comparative criteria* for the *quality* of the abducted explanations. Concerning (2), many authors have pointed out [7.12, pp. 443] that a *unique* criterion for the quality of an explanation does not exist – we rather have several criteria that may come into mutual conflict. For example, *Lipton* [7.11, pp. 61] argued that in scientific abductions we do not prefer the *likeliest* (most probable) explanation, but the *loveliest* explanation (that with highest explanatory strength), while *Barnes* [7.13] objected that loveliness without likeliness is scientifically unacceptable. One result of the present article, which has a direct bearing on this debate, is that there is *no general answer* to these questions, because the evaluation criteria for different kinds of abductions are different. For example, in the area of selective factual abductions, comparative plausibility criteria are important, while in the area of creative second-order existential abductions, one needs only minimal acceptability criteria.

### *Thesis 7.3 (The strategic role of abduction as means for discovery)*

All inferences have a *justificatory* (or *inferential*) and a *strategic* (or *discovery*) function, but to a different degree. The justificatory function consists of the justification of the conclusion, *conditional* on the justification of the premises. The strategic function consists of *searching* for the most promising conjecture (conclusion), which is set out for further empirical testing, or in *Hintikka's* words, which stimulates new *questions* [7.14, p. 528], [7.15, Sect. 14].

In deductive inferences the justificatory function is fully realized, because the premises guarantee the truth of the conclusion. Deductive inferences may also serve important strategic functions, because many different conclusions can be derived from the same premises. In inductive inferences, there is not much search strategy involved, because the inductive conclusions of a premise set are narrowly defined by the operations of generalization over instances. So the major function of inductive inferences is justificatory, but their justificatory value is uncertain. In contrast, in abductive inferences, the strategic function becomes *dominant*. Different from the situation of induction, in abduction problems we are often confronted with thousands of possible explanatory conjectures – anyone in the village might be the murderer. The essential function of abductions is their role as *search* strategies that tell us which explanatory conjecture we should set out *first* for further inquiry [7.14, p. 528] – or more generally, which suggest a *short* and *most promising* (though not necessarily successful) path through the exponentially excessive *search space* of possible explanatory reasons.

In contrast, the justificatory function of abductions is minor. *Peirce* pointed out that abductive hypotheses are *prima facie* not even probable, as inductive hypotheses, but merely possible [7.3, CP 5.171]. Only upon being confirmed by further tests may an abductive hypothesis become probable. However, I cannot completely agree with *Peirce* or other authors [7.14, 16], [7.17, p. 192] who think that abductions are merely a discovery procedure and whose justificatory value is zero. As *Niiniluoto* pointed out, “abduction as a motive for pursuit cannot always be sharply distinguished from considerations of justification” [7.12, S442]. *Niiniluoto's* point is confirmed by a Bayesian analysis: If a hypothesis  $H$  explains an explanandum  $E$  (where  $P(H), P(E) \neq 0, 1$ ), then  $P(E|H)$  ( $E$ 's posterior probability) has been raised compared to  $P(E)$  ( $E$ 's prior probability), which implies (by probability theory) that  $P(H|E) > P(H)$ , i. e.,  $E$  raises  $H$ 's probability, if only a little bit.

It is essential for a good search strategy that it leads us to an optimal conjecture in a reasonable amount of

time. In this respect, the rule of IBE fails completely. It just tells us that we should choose the best (available) explanation without giving us any clue of how to find it. To see the problem, as presented by a humorous example, think of someone in a hurry who asks an IBE-philosopher for the right way to the railway station and receives the following answer: *Find out which is the shortest way among all ways between here and the train station – this is the route you should choose.* In other words, IBE merely reflects the justificatory but misses the strategic function of abduction, which in fact is its *essential* function. For this reason, the rule of IBE is, epistemically, rather uninformative [7.18, p. 281].

*Peirce* once remarked that there are sheer myriads of possible hypotheses that would explain a given experimental phenomena, yet scientists usually manage to find the true hypothesis after only a small number of guesses [7.19, CP 6.5000]. But *Peirce* did not propose any abductive rules for conjecturing new theories; he rather explained this miraculous ability of human minds by their *abductive instincts* [7.20, CP 5.47, fn. 12; 5.172; 5.212]. The crucial question seems to be whether there can be anything like a *logic* of discovery. *Popper* and the logical positivists correctly observed that the justification of a hypothesis is independent from the way it was discovered. This does not imply, however, that it would not be *desirable* to have *in addition* good rules for discovering explanatory hypotheses – if there only *were* such rules [7.16]. This paper intends to show that there *are* such rules; in fact, every kind of abduction pattern presented in this paper constitutes such a rule.

The majority of the recent literature on abduction has aimed at *one* most general schema of abduction that matches every particular case. I do not think that good heuristic rules for generating explanatory hypotheses can be found along this route, because such rules are dependent on the *specific type* of abductive scenario, for example, concerning whether the abduction is mainly selective or creative (etc.). In the remainder of this paper, I will pursue a different route to characterizing abduction, which consists of modeling various particular schemata of abduction, each fitting a particular kind of conjectural situation. Two major results of my paper can be summarized as follows:

#### *Result 7.1*

There exist rather *different kinds* of abductive patterns. While some of them enjoy a broad discussion in the literature, others have been neglected, although they play an important role in science. The epistemological role and the evaluation criteria of abduction are different for the different patterns of abduction.

**Result 7.2**

In all cases, the crucial function of a pattern of abduction or IBE consists in its function as a *search strategy* that leads us, for a given kind of *scenario*, to the most promising explanatory conjecture, which may then subject to further test. In selective abductions, the difficulty usually lies in the fact that the search space of possible conjectures is very *large*. On the other hand, in creative

abductions the difficulty often consists in finding just *one* conjecture that meets the required constraints.

More important than my general theses and results are the *particular results* of the following sections, in which I model each kind of abduction as a specific inference *schema* in which the most promising explanatory conjecture is structurally determined.

**7.2 Three Dimensions for Classifying Patterns of Abduction**

I classify patterns of abduction along three dimensions:

1. Along the kind of *hypothesis* that is abduced, i. e., that is produced as a conjecture
2. Along the kind of *evidence* that the abduction is meant to explain
3. According to the *beliefs* or *cognitive mechanisms* that *drive* the abduction.

I signify the different kinds of abduction according to the first dimension. But the three dimensions are not

independent: the properties of an abductive pattern in the second and third dimension are in characteristic covariance with its status in the first dimension. Also, how the evidence together with the background knowledge conveys *epistemic support* to the abduced hypothesis, and by which follow-up procedures the abduced hypotheses is put to further test, depend crucially on the kind of abduced hypothesis. Figure 7.1 anticipates my classification of kinds of abductive patterns as a first orientation for the reader – the listed kinds of abduction are explained in Sects. 7.2–7.7.

Kind of abduction	Evidence to be explained	Abduction produces	Abduction is driven by
<b>Factual abduction</b>	Singular empirical facts	New facts (reasons/causes)	Known laws or theories
— <i>Observable-fact-abduction</i>	"	Factual reasons	Known laws
— <i>First-order existential abduction</i>	"	Factual reasons postulating new unknown individuals	"
— <i>Unobservable-fact-abduction</i> (Historical abduction)	"	Unobservable facts (facts in the past)	"
<b>Law abduction</b>	Empirical laws	New laws	"
<b>Theoretical-model-abduction</b>	General empirical phenomena (laws)	New theoretical models of these phenomena	Known theories
<b>Second-order existential abduction</b>	"	New laws/theories with new concepts	Theoretical background knowledge (b.k.)
— <i>Micro-part abduction</i>	"	Microscopic composition	Extrapolation of b.k.
— <i>Analogical abduction</i>	"	New laws/theories with analogous concepts	Analogy with b.k.
— <i>Hypothetical cause abduction</i>	"	Hidden (unobservable) causes	(see below)
— <i>Speculative abduction</i>	(")	(")	Speculation
— <b>Common-cause abduction</b>	"	Hidden <i>common</i> causes	Causal unification
— <i>Strict common-cause abduction</i>	"	New theoretical concepts	"
— <i>Statistical factor analysis</i>	"	"	"
— <i>Abduction to reality</i>	Introspective phenomena	Concept of external reality	"

**Fig. 7.1** Classification of kinds of abduction

### 7.3 Factual Abduction

In factual abductions, both the evidence to be explained and the abducted hypothesis are *singular facts*. Factual abductions are always *driven* by known implicational laws going from causes to effects, and the abducted hypotheses are found by backward reasoning, inverse to the direction of the law-like implications. Factual abduction may also be called *retroduction*; *Chisholm* [7.21, Ch. IV.2] speaks of *inverse induction*. This kind of abduction has the following structure (the double line = indicates that the inference is uncertain and preliminary)

*Known law:* If  $Cx$ , then  $Ex$   
*Known evidence:*  $Ea$  has occurred  
 =====  
*Abducted conjecture:*  $Ca$  could be the reason.

One may call the factual abduction schema *the official Peirce abduction schema*, since *Peirce* [7.2, CP 2.619–2.644] formalized abduction in this way and named it *hypothesis*; later he generalized abduction in the way described in Sect. 7.1. Factual abductions are omnipresent in common sense reasoning, and presumably rely on inborn abductive instincts of hominids. Prototypical examples are detective stories [7.22], or more generally, all sorts of *causal interpretations of traces*. The AI literature is focused almost exclusively on factual abductions (Sect. 7.3.4). Depending on the epistemological nature of the abducted fact, one can distinguish between the following three subpatterns.

#### 7.3.1 Observable-Fact Abduction

Here one reasons according to the fact-abduction schema from observed effects ( $Ea$ ) to non-observed but observable causes ( $Ca$ ) in the background of known laws. The follow-up test procedure consists of the attempt to gain direct evidence for the abducted conjecture. In the example of a murder case, such direct evidence would be given, for example, by a confession of the putative murderer.

In the setting of factual abduction, the problem often consists of the *combinatorial explosion* of the search space of possible causes, in the presence of a rich background store of laws but in the *absence* of a rich factual knowledge. Thus, factual abductions are primarily *selective* in the sense of *Magnani* [7.8, p. 20], and their epistemic support depends on the degree to which the background knowledge increases their *probability* in comparison to alternative possible causes. Consider the following example: If your evidence consists of the trace of the imprints of sandals

on an elsewhere empty beach, then your immediate conjecture is that somebody was recently walking here. How did you arrive at this conjecture? Classical physics allows for myriads of ways of imprinting footprints into the sand of the beach, which reach from cows wearing sandals on their feet to footprints that are drawn into the sand or blown by the wind, etc. The majority of these possible abductive conjectures will never be considered by us because they are extremely improbable. The major strategic algorithm that we apply in factual abduction cases of this sort is a *probabilistic elimination technique*, which usually works in an unconscious manner: our mind quickly scans through our large memory store containing millions of memorized possible scenarios and only those that have minimal plausibility pop up in our consciousness.

So, probabilistic evaluation of possible causes given certain effects and elimination of implausible causes plays a central role in factual abductions. *Fumerton* [7.23, p. 592] has gone further and argued that factual abduction can even be *reduced* to ordinary inductive-statistical inference. More precisely, he argues that the first inference pattern (below) can be reduced to the second inference pattern (below) in the following way (where  $P(-)$  denotes subjective-epistemic and  $p(-)$  statistical probability, and  $K$  expresses background knowledge).

*Abductive inference :*  
 $L : \forall x(Fx \rightarrow Gx)$   
 $Ga$   
 =====  
 $Fa$  (*presupposition :*  
 $P(Fa|Ga \wedge L \wedge K) = \text{high}$ )

Fumerton's  
 reduction: ↓

*Inductive – statistical inference :*  
 $L' : p(Fx|Gx) = \text{high}$   
 $Ga$   
 =====  $P(Fa|Ga \wedge L') = \text{high}$   
 $Fa$

Although Fumerton's reduction seems reasonable in some cases, I see two reasons why his argument is not generally correct. Firstly, the abductive hypothesis is probabilistically evaluated not merely in the light of the evidence  $Ga$  and an inverse statistical law  $L'$ , but in the light of the entire background knowledge  $K$ . Fumerton may reply that the inference pattern on the right may be appropriately extended so that it includes background

knowledge. But secondly, Fumerton’s proposed transformation does not correspond to psychological reality, nor would it be strategically recommendable. Every individual case (or effect) is *different*, and hence, only a small fraction of possible cause-effect scenarios are encountered frequently enough in a human lifetime in order to be represented by Fumerton-like conditional probabilities. For example, if you are *not* a turtle expert and you observe the trace of a turtle in the sand, then the only way in which you may arrive at the right guess that there was a turtle crawling here is by careful backward reasoning combined with elimination. Unless you are a turtle hunter, it is unlikely that you will have explicitly stored information concerning the typical sand traces of turtles via a corresponding forward conditional of the sort proposed by Fumerton.

### 7.3.2 First-Order Existential Abduction

This subcase of factual abduction occurs when the antecedent of a law contains so-called *anonymous* variables, i. e., variables that are not contained in the consequent of the law. In the simplest case, the formal structure of first-order existential abduction is as follows (cf. also [7.24, p. 57]).

L :  $\forall x \forall y (Ryx \rightarrow Hx)$   
 logically equivalent :  $\forall x (\exists y Ryx \rightarrow Hx)$   
 Ha  
 =====  
 Conjecture :  $\exists y Rya$

Instantiating the consequent of the law with *a* and backward chaining yields a law-antecedent in which one variable remains uninstantiated (*Rya*). In such a case, the safest abductive conjecture is one in which we existentially quantify over this variable. We have already discussed an example of this sort in Sect. 7.3.1: from the footprint in the sand we abductively infer that *some* man was walking on the beach. *Prendinger* and *Ishizuka* [7.25, p. 322] call first-order existential abduction *element-creative abduction*, because here the existence of an unknown object is hypothesized.

Note, however, that only in some cases will we be satisfied with the existential conjecture. In other cases, in particular in criminal cases, all depends on finding out *which* individual is the one whose existence we conjecture – who was the murderer? Here one is not satisfied with a first-order existential abduction but want to have a proper, fully-instantiated fact abduction.

In observable-fact abduction, the abducted hypothesis may at later stages of inquiry be confirmed by direct observation – for example, when we later meet the man

who had walked yesterday on this beach. In this case, the weak epistemic support that the abductive inference conveys to the conjecture gets replaced by the strong epistemic support provided by the direct evidence: abduction has played an important strategic role, but it no longer plays a justificatory role. This is different, however, in all of the following patterns of abduction, in which the abductive hypothesis is not directly observable, but only indirectly confirmable via its empirical consequences.

### 7.3.3 Unobservable-Fact Abduction

This kind of abduction has the same formal structure as observable-fact abduction, but the abducted fact is unobservable. The *typical* case of unobservable-fact abductions are *historical-fact abductions*, in which the abducted fact is unobservable because it is located in the distant past. The abducted fact may also be unobservable in principle, because it is a theoretical fact. However, in such a case the abduction is usually not driven by simple implicational laws, but by a quantitative theory, and the abducted theoretical fact corresponds to a theoretical model of the observed phenomenon: This sort of abduction differs crucially from law-driven factual abduction and is therefore treated under the separate category of *theoretical-model abduction* (Sect. 7.5).

Historical-fact abductions are of obvious importance for all historical sciences [7.12, p. 442]. Assume, for example, that biologists discover marine fossil records, say fish bones, in the ground of dry land. They conjecture abductively, given their background theories, that some geological time span ago there was a sea here. Their hypothesis cannot be directly verified by observations. So the biologists look for further empirical consequences that follow from the abducted conjecture plus background knowledge – for example, further geological indications such as calcium deposits, or marine shell fossils, etc. If the latter findings are observationally verified, the abductive conjecture is confirmed. Logically speaking, an unobservable-fact abduction performs a combination of abductive backward reasoning and deductive or probabilistic forward reasoning to consequences that can be put to further test. This is graphically displayed by the *bold arrow* in Fig. 7.2.

If the empirical consequence *Ea* is verified, then both pieces of evidence *Ga* and *Ea* provide epistemic support for the abducted hypothesis *Ha* (modulo probabilistic considerations in the light of the background knowledge). So, the initial abductive inference has not only a strategic value, but *keeps* its justificatory value.

**Fig. 7.2** Historical-fact abduction (the *bold arrow* indicates the route of the abduction process)

### 7.3.4 Logical and Computational Aspects of Factual Abduction

If one’s background knowledge does not contain general theories but just a finite set of (causal) implicational laws, then the set of possible abductive conjectures is finite and can be generated by *backward-chaining* inference procedures. In this form, abductive inference has frequently been studied in AI research [7.26, 27]. Given is a knowledge base  $\mathbf{K} = \langle \mathbf{L}[x], \mathbf{F}[a] \rangle$  in form of a finite set  $\mathbf{L}[x]$  of monadic implicational laws going from conjunctions of open literals to literals, and a finite set  $\mathbf{F}[a]$  of facts (closed literals) about the individual case  $a$ . (A literal is an atomic formula or its negation.) Given is moreover a certain *goal*, which is a (possibly conjunctive) fact  $G_a$  that needs to be explained. One is not interested just in any hypotheses that (if true) would explain the goal  $G_a$  given  $\mathbf{K}$ , but only in those hypotheses that are not further potentially explainable in  $\mathbf{K}$  [7.28, p. 133], [7.29].

So formally, the candidates for abducible hypotheses are all closed literals  $A[a]$  such that  $A[a]$  is neither a fact in  $\mathbf{F}[a]$ , nor the consequent (*head*) of a law, i. e.,  $A[a]$  cannot be further explained by other laws in  $\mathbf{K}$ . The set of all possible abductive conjectures  $A[a]$  for arbitrary abduction tasks in  $\mathbf{K}$  is called the set of *abducibles*  $\mathbf{H}[a]$ . The *abductive task* for goal  $G_a$  is then defined as follows: Find *all possible* explanations, i. e., all *minimal* sets  $\mathbf{E}[a]$  of singular statements about  $a$  such that:

- (i)  $\mathbf{E}[a] \subseteq \mathbf{F}[a] \cup \mathbf{H}[a]$

- (ii)  $\mathbf{L}[x] \cup \mathbf{F}[a] \cup \mathbf{E}[a]$  is consistent
- (iii)  $\mathbf{L}[x] \cup \mathbf{E}[a]$  logically implies  $G[a]$  (by forward chaining).

Those elements of the explanatory sets  $\mathbf{E}[a]$  that are abducibles are the abductive hypotheses for  $G[a]$ .

This kind of abduction problem is graphically displayed in Fig. 7.3 in the form of a so-called *and-or tree* [7.30, Ch. 13]. The *labeled* nodes of an and-or tree correspond to literals, unlabeled nodes represent conjunctions of them, and the directed edges (arrows) correspond to laws in  $\mathbf{L}[x]$ . Arrows connected by an *arc* are and-connected; those without an arc are or-connected. Written as statements, the laws underlying Fig. 7.3 are  $\forall x(Fx \rightarrow Gx)$ ,  $\forall x(Hx \rightarrow Gx)$ ,  $\forall x(Q_1x \wedge Q_2x \rightarrow Gx)$ ,  $\forall x(R_1x \wedge R_2x \rightarrow Fx)$ ,  $\forall x(Sx \rightarrow Hx)$ ,  $\forall x(T_1x \wedge T_2x \rightarrow Hx)$ ,  $\forall x(Ux \rightarrow Q_1x)$ ,  $\forall x(Vx \rightarrow Q_2x)$ . Besides the goal  $G_a$ , the only known fact is  $T_1a$ .

Algorithms for this sort of task have been implemented, for example, in the programming language Prolog in the form of backward-chaining with backtracking to all possible solutions.

The task of finding *all* possible explanations has exponential complexity and, thus, is intractable (that is, the time of this task increases exponentially in the number of data points and possible hypotheses). Only the complexity of finding some explanation has polynomial complexity and is tractable [7.26, Ch. 7, p. 165, Th. 7.1, 7.2]. Therefore it is crucial to constrain the search space by probabilistic (or plausibilistic) evaluation methods. A simple heuristic strategy is the *best-first* search: for each or-node one processes only that successor that has the highest plausibility value (among all successors of this node). The route of a best-first abduction search is depicted in Fig. 7.3 by the *bold arrow*.

A related but more general framework for factual abductions via backward reasoning is abduction within Beth tableaux [7.15], [7.7, Ch. 4]. Even more general frameworks are Gabbay’s *labeled deductive systems* [7.31, Part III] and abduction within *epistemic dynamic logic* [7.32]. An alternative approach for computing abductive hypotheses is abductive rea-

**Fig. 7.3** Search space for a factual abduction problem. + indicates a known fact, \* indicates possible abductive hypotheses. The *numbers* are probability values (they do not add up to 1 because of an unknown residual probability). The *bold arrow* indicates the route of a best-first search, which leads to the abductive conjecture  $T_2a$

soning in the framework of *adaptive logic* [7.33, 34]. Here one infers singular explanatory hypotheses by backward chaining defeasibly and excludes them as soon as contradicting abnormality statements turn out to be derivable in later stages of the proof. As a result, one doesn't compute all possible minimal explanations (consistent with the knowledge base) but only those that are undefeated.

Besides probabilistic elimination, the second major technique of constraining the search space is *intermediate information acquisition*: not only the ultimately abducted conjectures, but also intermediate conjectures (nodes) along the chosen search path can be set out for further empirical test – or in the framework

of Hintikka et al. [7.15], they may stimulate further interrogative inquiry [7.35, Ch. 6]. As an example, consider again a criminal case: If backward reasoning leads to the possibility that the butler could have been the murderer, and along an independent path, that the murderer must have been left handed, then before continuing the abductive reasoning procedure one better finds out first whether the butler is indeed left handed. There are also some AI abduction systems that incorporate question-asking modules. For example, the RED system, designed for the purpose of red-cell antibody identification based on antigen-reactions of patient serum, asks intermediate questions of a database [7.26, pp. 72].

### 7.4 Law Abduction

In this kind of abduction, both the evidence to be explained and the abducted hypothesis are implicational laws, and the abduction is driven by one (or several) known implicational laws. Because of the latter fact, this kind of abduction is more similar to factual abductions than to theory-driven abductions that are discussed in Sect. 7.5. Law abductions can already be found in Aristotle, and they correspond to what Aristotle has called the mind's power of *hitting upon the middle term* of a syllogism (An. Post., I, 34). Here is an example.

Background law:  $\forall x(Cx \rightarrow Ex)$   
 Whatever contains sugar tastes sweet

Empirical law to be explained:  $\forall x(Fx \rightarrow Ex)$   
 All pineapples taste sweet

=====

Abducted conjecture:  $\forall x(Fx \rightarrow Cx)$   
 All pineapples contain sugar.

A more general example of law abduction in qualitative chemistry is this,

All substances that contain molecular groups of the form  $C$  have property  $E$ .

All substances of empirical kind  $S$  have certain empirical properties  $E$ .

=====

Conjecture: Substances of kind  $S$  have molecular characteristics  $C$ .

In the case where there are several causal laws of the form  $\forall x (C_i x \rightarrow Ex)$ , one has to select the most *plausible* one. In any case, the conclusions of law abductions are conjectural and in strong need of further support.

Flach and Kakas [7.27, pp. 21] have argued that a law abduction can be *reduced* to the following combination of a fact abduction and an inductive generalization

Background law:  $\forall x(Cx \rightarrow Ex)$

Observed facts:  $Fa_i \wedge Ea_i \quad 1 \leq i \leq n$   
 $\rightarrow$  Induction basis for:  $\forall x(Fx \rightarrow Ex)$

===== Factual abduction

Abducted hypotheses:  $Ca_i \quad 1 \leq i \leq n$   
 hence:  $Fa_i \wedge Ca_i \quad 1 \leq i \leq n$   
 $\rightarrow$  Induction basis for:  $\forall x(Fx \rightarrow Cx)$ .

This decomposition, however, is somewhat artificial. Law abductions are usually performed in one single conjectural step. We don't form the abductive hypothesis that  $x$  contains sugar for each observed pineapple  $x$ , one after the other, and then generalize it, but we form the law-conjecture *pineapples contain sugar* at once.

All patterns of abduction that we have discussed so far are driven by known qualitative implication laws, and they are mainly *selective*, i. e., their driving algorithm draws a most promising candidate from a class of possible conjectures, which is very large but in principle constructible. Discussion of such patterns dominates the abduction literature. The patterns of abductions to be discussed in the next sections are rarely discussed in the literature. They are not driven by implicational laws, but either by scientific theories, or by (causal) unification procedures. Moreover, they are not mainly selective but mainly *creative*, that is, the underlying abduction operation constructs something new, for example a new theoretical model or a new theoretical concept.

## 7.5 Theoretical-Model Abduction

The explanandum of a theoretical-model abduction is typically a well-confirmed and reproducible empirical phenomenon expressed by an *empirical law* – for example, the phenomenon that wood floats in water but a stone sinks in it. The abduction is driven by an *already established* scientific theory that is usually quantitatively formulated. The abductive task consists in *finding theoretical* (initial and boundary) *conditions* that describe the causes of the phenomenon in the theoretical language and that allow the mathematical derivation of the phenomenon from the theory. Halonen and Hintikka [7.36] argue that this task makes up the essential point of the scientist’s explanatory activity. Formally, these theoretical conditions are expressed by factual or law-like statements, but their semantic content corresponds to what one typically calls a *theoretical model* for a particular kind of phenomenon within a *given* theory, whence I speak of *theoretical-model abduction*. Note also that with my notion of a *model* I do not imply a particular kind of formalization of models: they can be represented by *statements* or by set-theoretical *models* [7.37, p. 109]. A general translation between sentential and model-theoretic theory representations is developed in Schurz [7.38].

As an example, consider Archimedes’ theoretical model of the phenomenon of buoyancy. Here one searches for a theoretical explanation of the fact that certain substances like stones and metals sink in water while others like wood and ice float on water, *solely in terms of mechanical and gravitational effects*. Archimedes’ ingenious abductive conjecture was that the amount of water that is supplanted by the floating or sinking body tends to lift the body upwards, with a force  $f_w$  that equals the weight of the supplanted water (Fig. 7.4). If this force is greater than the weight of the body ( $f_B$ ) the body will float, otherwise it will sink. Since the volume of supplanted water equals the volume of the part of the body that is underwater, and since the weight is proportional to the mass of a body, it follows that the body will sink exactly if its density (mass per volume) is greater than the density of water.

The situation of theoretical-model abduction is rather different from the situation of factual abductions: one does *not* face here the problem of a huge multitude of possible theoretical models or conjectures, since the given theory *constrains* the space of possible causes to a small class of basic parameters (or generalized *forces*) by which the theory models the domain of phenomena that it intends to explain. In the Archimedean case, the given theory presupposes that the ultimate causes can only be contact forces and gravitational forces – other ultimate causes such as intrinsic capacities of bodies

to float or invisible water creatures, etc., are excluded. Therefore, the real difficulty of theoretical-model abduction does not consist in the elimination of possible explanations – this elimination is already achieved by the given theory – but of finding just *one* plausible theoretical model that allows the derivation of the phenomenon to be explained. If such a theoretical model is found, this is usually celebrated as a great scientific success.

Theoretical-model abduction is the typical theoretical activity of *normal science* in the sense of Kuhn [7.39], that is, the activity of extending the application of a given theory core (or paradigm) to new cases, rather than changing a theory core or creating a new one. If the governing theory is *classical physics*, then examples of theoretical model abduction come in the hundreds, and physics text books are full of them. Examples are the theoretical models underlying:

1. The trajectories (paths) of rigid bodies in the constant gravitational field of the Earth (free fall, parabolic path of ballistic objects, gravitational pendulum, etc.)
2. The trajectories of cosmological objects in position-dependent gravitational fields (the elliptic orbits of planets, Kepler’s laws, the Moon’s orbit around the Earth, and the lunar tides, interplanet perturbations, etc.)
3. The behavior of solid, fluid or gaseous macroscopic objects viewed as systems of more-or-less coupled mechanical atoms (the modeling of pressure, friction, viscosity, the thermodynamic explanation of heat and temperature, etc.); and finally
4. The explanation of electromagnetic phenomena by incorporating electromagnetic forces into classical physics [7.40, Ch. 5.3].

While for all other kinds of abductions we can provide a *general* formal pattern and algorithm by which one can *generate* a most promising explanatory hypothesis, we cannot provide such a general pattern for theoretical model abduction because here all depends

Fig. 7.4 Theoretical conditions that allow the mechanical derivation of the law of buoyancy

on which theory is assumed in the background. But if the theory is specified, then such patterns can often be provided: they are very similar to what Kitcher [7.41, p. 517] calls a schematic explanatory argument, except that the explanandum is now given and the particular explanatory premises have to be found within the framework of the given theory. See the example in Tab. 7.1.

Theoretical-model abduction can also be found in higher and more special sciences than physics. In chemistry, the explanations of the atomic component ratios (the chemical gross formulae) by a three-dimensional molecular structure are the results of theoretical-model abductions; the given theory here is the periodic table plus Lewis' octet rule for forming chemical bonds. A computational implementation is the automatic abduction system DENDRAL [7.42, pp. 234], which abducts the chemical structure of organic molecules, given their mass spectrum and their gross formula.

Theoretical model abductions also take place in evolutionary theory. The reconstruction of evolutionary trees of descent from given phenotypic similarities is a typical abductive process. The basic evolutionary-theoretical premise here is that different biological species descend from common biological ancestors from which they have split apart by discriminative mutation and selection processes. The alternative abductive conjectures about trees of descent can be evaluated by probability considerations. Assume three species  $S_1$ ,  $S_2$ , and  $S_3$ , where both  $S_1$  and  $S_2$  but not  $S_3$  have a new property  $F$  – in Sober's example,  $S_1$  is sparrows,  $S_2 =$  robins,  $S_3 =$  crocodiles, and  $F =$  having wings [7.43, pp. 174–176]. In this case, the tree of descentance  $T_1$  where the common ancestor  $A$  first splits into  $S_3$  and the common ancestor of  $S_1$  and  $S_2$ , which has already  $F$ , requires only one mutation-driven change of non- $F$  into  $F$ , while the alternative tree of

Fig. 7.5 Two alternative trees of descentance; \* = mutation of non- $F$  into  $F$

descentance  $T_2$  in which  $A$  first splits into  $S_1$  and a common  $F$ -less ancestor of  $S_2$  and  $S_3$  requires two such mutations (Fig. 7.5). So probabilistically  $T_1$  is favored as against  $T_2$ .

There are some well-known examples where closeness of species due to common descent does not go hand in hand with closeness in terms of phenotypic similarities: Examples of this sort are recognized because there are several independent kinds of evidence that the tree of descentance must simultaneously explain, in particular:

1. Phenotypic similarities
2. Molecular similarities
3. The fossil record [7.44, Ch. 17].

An example of qualitative-model abduction in the area of humanities is interpretation [7.31, Sect. 4.1]. The explanandum of interpretations are the utterances, written text, or the behavior of given persons (speakers, authors, or agents). The abduced models are conjectures about the beliefs and intentions of the given persons. The general background theory is formed by certain parts of folk psychology, in particular the general premise of all rational explanations of actions, namely, that normally or ceteris paribus, persons act in a way that is suited to fulfill their goals given their beliefs about the given circumstances [7.45, Sect. 1]. More specific background assumptions are hermeneu-

Table 7.1

#### Abduction pattern of Newtonian particle mechanics:

*Explanandum:* A kinematical process involving (a) some moving particles whose position, velocity and acceleration at a variable time  $t$  is an empirical function of their initial conditions, and (b) certain objects defining constant boundary conditions (e.g., a rigid plane on which a ball is rolling, or a large object that exerts a gravitational force, or a spring with Hooke force, etc.)

Generate the abduced conjecture as follows: (i) Specify for each particle its mass and all non-neglectible forces acting on it in dependence on the boundary conditions and on the particle's position at the given time. (ii) Insert these specifications into Newton's second axiom (which says that for each particle  $x$  and time  $t$ , the sum of all forces on  $x$  at  $t$  equals the mass of  $x$  times the acceleration of  $x$  at  $t$ ). (iii) Try to solve the resulting system of differential equations. (iv) Check whether the resulting time-dependent trajectories fit the empirical function mentioned in the explanandum; if yes, the conjecture is preliminarily confirmed; if no, then search for (perturbing) boundary conditions and/or forces that may have been overlooked.

tic rationality presumptions [7.46], Grice’s maxims of communicative cooperation [7.47], and common contextual knowledge. The investigation of interpretation as an abductive process is also an important area in AI [7.48].

What all abduction schemata discussed so far have in common is that they are driven by *known* laws or

theories, and hence, they work within a *given conceptual space*. In other words, the abduction schemata discussed so far cannot introduce *new concepts*. In the next section we turn to abduction schemata that can do this: Since their explanans postulate the existence of a new kind of property or relation, we call them *second-order existential abductions*.

## 7.6 Second-Order Existential Abduction

The explanandum of a second-order existential abduction consists of one or several general empirical phenomena, or laws. What one abducts is an at least a *partly* new property or kind of concept governed by an at least partly new theoretical law. Depending on whether the concept is merely partly or completely new, the abduction is driven by extrapolation, analogy, or by pure unification. We discuss these kinds of abductions in the following subsections Sects. 7.6.1–7.7.4.

### 7.6.1 Micro-Part Abduction

In this most harmless case of second-order existential abduction, one abducts a hypothesis about the unobservable micro-parts of observable objects that obey the *same* laws as the macroscopic objects, in order to explain various observed empirical phenomena. The prototypical example is the *atomic hypothesis* that was already conjectured in antiquity by Leucippus and Democritus and was used to explain such phenomena as the dissolution of sugar in water. These philosophers have abducted a new natural kind term: *atoms*, which are the smallest parts of all macroscopic bodies, being too small to be observable, but otherwise obeying the *same* mechanical laws as macroscopic bodies. So what one does here is to *extrapolate* from macroscopic concepts and laws to the microscopic domain – whence we may also speak here of *extrapolative* abduction. In the natural sciences after Newton, the atomic hypothesis turned out to have enormous explanatory power. For example, Dalton’s atomic hypothesis had successfully explained Avogadro’s observation that equal volumes of gases contain the same number of gas particles. Dalton also postulated that all substances are composed of molecules built up from certain atoms in certain integer-valued ratios, in order to explain the laws of constant proportions in chemical reactions [7.49, pp. 259]. The different states of aggregation of substances (solid, fluid, and gaseous) are explained by different kinds of intermolecular distances and interactions. We conclude our list of examples here, although many more applications of the atomic hypothesis could be mentioned.

Extrapolative micro-part abductions differ from analogical abductions insofar as the atoms are not merely viewed as *analogical* to mechanical particles; they are literally taken as tiny mechanical particles (though too small to be observable). Nevertheless one may view extrapolative abductions as a *pre-stage* of analogical abductions, which we are going to discuss now.

### 7.6.2 Analogical Abduction

Here one abducts a partially new concept together with partially new laws that connect this concept with given (empirical) concepts, in order to explain the given law-like phenomenon. The concept is only partly new because it is analogical to familiar concepts, and this is the way in which this concept was discovered. So analogical abduction is *driven* by analogy. We first consider *Thagard’s* [7.24] example of sound waves.

*Background knowledge:* Laws of propagation and reflection of water waves.

*Phenomenon to be explained:* Propagation and reflection of sound

=====

*Abductive conjecture:* Sound consists of atmospheric waves in analogy to water waves.

According to *Thagard* [7.24, p. 67] analogical abduction results from a *conceptual combination*: the already possessed concepts of wave and sound are combined into the combined concept of a sound wave. I think that this early analysis of *Thagard* [7.24] is too simple. In my view, the crucial process that is involved in analogical abduction is a *conceptual abstraction* based on an *isomorphic* or *homomorphic mapping*. What is abducted by this analogy is not only the combined concept of sound wave, but at the same time the *theoretical* concept of a *wave in abstracto* (the later paper of *Holyoak* and *Thagard* [7.50] supports this view).

A clear analysis of analogy based on conceptual abstraction has been given by *Gentner* [7.51]. According

to Gentner's analysis, an analogy is a *partial isomorphic* mapping  $m$  between two relational structures, the *source* structure  $(D, (F_i : 1 \leq i \leq m), (R_i : 1 \leq i \leq n))$  and the *target* structure  $(D^*, (F_i^* : 1 \leq i \leq m^*), (R_i^* : 1 \leq i \leq n^*))$ , where the  $F_i$  are monadic predicates and the  $R_i$  are relations. Gentner argues convincingly [7.51, p. 158] that an analogical mapping preserves only the *relations* of the two structures (at least many of them, including second-order relations such as *being-a-cause-of*), while monadic properties are not preserved. This is what distinguishes an *analogy* from a *literal similarity*. For example, our solar system is literally similar to the star system X12 in the Andromeda galaxy, inasmuch as the X12 central star is bright and yellow like our sun, and surrounded by planets that are similar to our planets. Thus, our sun and the X12 star have many (monadic) properties in common. On the other hand, an atom (according to the Rutherford theory) is merely analogical to our solar system: the positively charged nucleus is surrounded by electrons just as the sun is surrounded by planets, being governed by a structurally similar force law. But concerning its monadic properties, the atomic nucleus is very different from the sun and the electrons are very different from the planets. Formally, then, an analogical mapping  $m$  maps a subset  $D'$  of  $D$  bijectively into a subset  $D'^*$  of  $D^*$ , and many (but not necessarily all) relations  $R_i$ , with  $i \in I \subset \{1, \dots, n\}$ , into corresponding relations  $R_{m(i)}^*$ , such that the following holds: For all  $a, b \in D'$  and  $R_i$  with  $i \in I$ ,  $aR_i b$  iff  $m(a)R_{m(i)}^*m(b)$ , where *iff* stands short for *if and only if*. In this sense, the Rutherford-analogy maps *sun* into *nucleus*, *planet* into *electron*, *gravitational attraction* into *electrical attraction*, *surrounding* into *surrounding*, etc. It follows from the existence of such a partial isomorphic mapping that, for every explanatory law  $L$  expressed in terms of mapping-preserved relations that hold in the  $D'$ -restricted source structure, its starred counterpart  $L^*$  will hold in the  $D'^*$ -restricted target structure. In this way, explanations can be transferred from the source to the target structure.

Every partial isomorphism gives rise to a *conceptual abstraction* by putting together just those parts of both structures that are isomorphically mapped into each other: the resulting structure  $(D', (R_i : i \in I))$ , which is determined up to isomorphism, is interpreted in an *abstract* system-theoretic sense. In this way, the

abstract model of a *central force system* arises, with a *central body*, *peripheral bodies*, a *centripetal* and a *centrifugal force* [7.51, p. 160]. So, finding an abductive analogy consists in finding the *theoretically essential* features of the source structure that can be generalized to other domains, and this goes hand-in-hand with forming the corresponding conceptual abstraction. In our example, the analogical transfer of water waves to sound waves can only work if the theoretically essential features of (water) waves have been identified, namely, that waves are produced by *coupled oscillations*. The abductive conjecture of sound waves also stipulates that sound consists of coupled oscillations of the molecules of the air. Only after the theoretical model of sound waves has been formed, does a *theoretical* explanation of the propagation and reflection of sound waves become possible.

### 7.6.3 Hypothetical (Common) Cause Abduction

This is the most fundamental kind of conceptually creative abduction. The explanandum consists either (a) in *one* phenomenon or (b) in *several* mutually *inter-correlated* phenomena (properties or regularities). One abductively conjectures in case (a) that the phenomenon is the effect of one *single* hypothetical (unobservable) cause, and in case (b) that the phenomena are effects of one *common* hypothetical (unobservable) cause. I will argue that only case (b) constitutes a scientifically worthwhile abduction, while (a) is a case of pure speculation. In both cases, the abductive conjecture postulates a *new unobservable entity* (property or kind) together with *new laws* connecting it with the observable properties, without drawing on analogies to concepts with which one is already familiar. This kind of abduction does not presuppose any background knowledge except knowledge about those phenomena that are in need of explanation. What drives hypothetical-cause abduction is the search for explanatory *unification*, usually in terms of hidden or common causes – but later on, we will also meet cases where the unifying parameters have a merely instrumentalistic interpretation. Hypothetical (common) cause abduction is such a large family of abduction patterns that we treat it separately in the next section.

## 7.7 Hypothetical (Common) Cause Abduction Continued

Salmon [7.52, pp. 213] has emphasized the importance of finding common-cause explanations for the justification of scientific realism. However, Salmon does not inform us about the crucial difference between scien-

tific common-cause abduction and speculative (cause) abduction. In the next two subsections I argue that the major criterion for this distinction is *causal unification* and (connected with this) *independent testability*.

### 7.7.1 Speculative Abduction Versus Causal Unification: A Demarcation Criterion

Ockham’s razor is a broadly accepted maxim among IBE-theorists: an explanation of observed phenomena should postulate as few new theoretical (unobservable) entities or properties as possible [7.53, pp. 97–100]. Upon closer inspection this maxim turns out to be a gradual optimization criterion, for an explanation is better, the *fewer* theoretical (*hidden*) entities that it postulates, and the *more* phenomena it explains. However, by introducing sufficiently many hidden variables one can *explain* anything one wants. Where is the borderline between *reasonably many* and *too many* hidden variables postulated for the purpose of explanation? Based on Schurz [7.1, p. 219], [7.54, pp. 246], [7.40, pp. 112] I suggest the following demarcation criterion.

DC (Demarcation Criterion) for 2nd-Order Abduction:

The introduction of *one* new theoretical variable (entity or property) merely for the purpose of explaining *one* phenomenon is always *speculative* and post facto, i. e., has no independently testable empirical consequences. Only if the postulated theoretical variable explains *many intercorrelated* but analytically independent phenomena, and in this sense yields a *causal* or *explanatory unification*, is it a legitimate scientific abduction that is independently testable and, hence, worthy of further investigation.

Let us explain the criterion (DC) by way of examples. The simplest kind of speculative abduction *explains* every particular phenomenon *P* by a special power who (or which) has caused this phenomenon. In what follows, read  $\psi(\varphi)$  as *some power of kind  $\psi$  intends that  $\varphi$  happens*, where the formula  $\varphi$  may either express a singular fact or an empirical regularity or law that is frequently clothed in the form of an empirical disposition. Accordingly, we have two kinds of speculative abductions – see Table 7.2.

Speculative abductions have been performed by our human ancestors since the earliest times. All sorts of unexpected events can be pseudo-explained by speculative fact-abductions. They do *not* achieve unification, because for every event (*E*) a special hypothetical wish of God ( $\psi(E)$ ) has to be postulated [7.55, p. 86]. For the same reason, such pseudo-explanations are entirely *post hoc* and don’t entail any empirical predictions by which they could be independently tested.

Speculative law-abductions were especially common in the Middle Ages: every special healing capacity of a certain plant (etc.) was attributed to a special power that God had implanted in nature for human benefit. The example of the *virtus dormitiva* was ironically employed by Molière, and famous philosophers have used it as a paradigm example of a pseudo-explanation [7.56, Book 5, Ch. 7, Sect. 2], [7.57, Ch. 6, Sect. 2]. Speculative law-abductions violate Ockham’s principle since we have already a sufficient cause for the disposition to make one sleepy, namely the natural kind *opium*, so that the postulated power amounts to a redundant multiplication of causes. More formally, the schema does not offer unification because for every elementary empirical law one has to introduce two elementary hypothetical laws to explain it [7.55, p. 87]. For the same reason, the abductive conjecture has no predictive power that goes beyond the predictive power of the explained law.

I do not want to diminish the value of cognitive speculation by this analysis. Humans have an inborn instinct to search for causes [7.58, Ch. 3], and cognitive speculations are the predecessor of scientific inquiry. However, it was pointed out in Sect. 7.1 that the best available *explanations* are often not good enough to count as rationally acceptable. The above speculative abduction patterns can be regarded as the *idling* of our inborn explanatory search activities when applied to events for which a proper explanation is out of reach.

In contrast to these empty causal speculations, scientific common cause abductions have usually led to

Table 7.2

Speculative Fact-Abduction :	Example:
Explanandum E: $Ca$	John got a cold.
=====	
Conjecture H: $\psi(Ca) \wedge \forall \varphi(\psi(\varphi) \rightarrow \varphi)$	God wanted John to get a cold, and whatever God wants, happens.
Speculative Law-Abduction:	Example:
Explanandum E: $\forall x(Ox \rightarrow Dx)$	Opium has the disposition to make people sleepy (after consuming it).
=====	
Conjecture H: $\forall x(Ox \rightarrow \psi(Dx)) \wedge \forall x(\psi(Dx) \rightarrow Dx)$	Opium has a special power (a <i>virtus dormitiva</i> ) that causes its disposition to make people sleepy.

genuine theoretical progress. The leading principle of causal unification is the following.

(CC) Causal Connection Principle: If two properties or kinds of events are probabilistically dependent, then they are *causally connected* in the sense that either one is a cause of the other (or vice versa), or both are effects of a common cause (where  $X$  is a cause of  $Y$  iff a directed path of cause-effect relations leads from  $X$  to  $Y$ ).

The causal connection principle (CC) does not entail that every phenomenon must have a sufficient cause – it merely says that all correlations result from causal connections. This principle has been empirically corroborated in *almost every* area of science, in the sense that conjectured common causes have been identified in later stages of inquiry; the only known exception is quantum mechanics. Here we treat (CC) not as a *dogma*, but as a meta-theoretical principle that *guides* our causal abductions. (CC) is a consequence of the more general *causal Markov* condition, which is the fundamental axiom of the *theory of causal nets* [7.59, pp. 396], [7.40, p. 16], [7.60, pp. 29]. Schurz and Gebharter [7.61, Sect. 2] demonstrate that the causal Markov condition can itself be justified via an explanatory abduction inasmuch as it yields the best and only plausible explanation of two (in)stability properties of statistical correlations: screening-off and linking-up.

The way that the causal connection principle leads to common-cause abduction is as follows: Whenever we encounter several *intercorrelated phenomena*, and – for some reason or other – we can *exclude* that one causes the other(s), then (CC) requires that these phenomena must have some (unobservable) common cause that simultaneously explains all of them. The most important scientific example of this sort is common cause abduction from *correlated dispositions*: since dispositions cannot cause other dispositions, their correlations must have a common intrinsic cause.

### 7.7.2 Strict Common-Cause Abduction from Correlated Dispositions and the Discovery of New Natural Kinds

In this section I analyze common-cause abduction in a *deductivistic* setting, which is appropriate when the domain is ruled by *strict* laws. Probabilistic generalizations are treated in Sect. 7.7.3. Recall the schema of speculative law-abduction, where *one* disposition  $D$  occurring in one (natural) kind  $F$  was pseudo-explained by a causal *power*  $\psi(D)$ . In this case of a *single* disposition, the postulate of a causal power  $\psi(D)$  that mediates between  $F$  and  $D$  is an unnecessary multiplication of causes. But in the *typical* case of a scientifically productive common-cause abduction, we have several (natural) kinds  $F_1, \dots, F_n$  all of which have a set of characteristic dispositions  $D_1, \dots, D_m$  in common – with the result that all these dispositions are correlated. Assuming that it is excluded that one disposition can cause another one, then by principle (CC) these correlated dispositions must be the common effects of a certain intrinsic structure that is present in all of the kinds  $F_1 \dots, F_n$  as their common cause. For example, the following dispositional properties are common to certain substances such as *iron, copper, tin, etc.* (Fig. 7.6): a characteristic glossing, smooth surface, characteristic hardness, elasticity, ductility, high conductivity of heat and of electricity. Already before the era of modern chemistry, craftsmen had abducted that there exists a characteristic intrinsic property of substances that is the common cause of all these (more-or-less strictly) correlated dispositions, and they called it *metallic character*  $Mx$ . To be sure, the natural kind term *metal* of premodern chemistry was theoretically hardly understood. But the introduction of a new (theoretical) natural kind term is the first step in the development of a *new research program*. The next step was then to construct a *theoretical model* of the postulated kind *metal*, by which one can give an explanation of *how* the structure of a *metal* can cause all these correlated

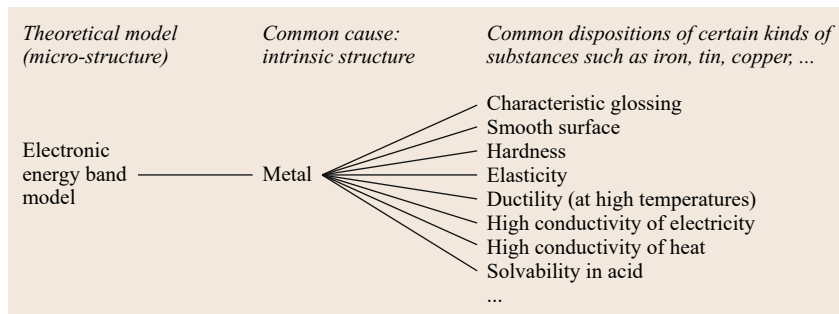

Fig. 7.6 Common-cause abduction of the chemical kind term *metal*

dispositions at once. In combination with *atomic* (and molecular) hypotheses the abducted natural kind terms of chemistry became enormously fruitful. In modern chemistry, the molecular microstructure of metals is modeled as an *electron band* of densely layered energy levels among which the electrons can easily shift around [7.62, pp. 708].

The structural pattern of the example in Fig. 7.6 can be formalized as in Tab. 7.3. The abductive conjecture *H* logically implies the explanandum *E* and yields a *unification* of  $n \cdot m$  empirical (elementary) laws by  $n + m$  theoretical (elementary) laws, which is a *polynomial reduction* of elementary laws. At the same time, *H* generates novel empirical consequences by which it can be *independently tested*, as follows. *H* does not only postulate the theoretical property  $\psi x$  to be a merely *sufficient* cause of the dispositions; it also assumes that these dispositions are an *empirical indicator* of the theoretical property  $\psi x$  [7.54, p. 111]. This indicator relation may either be reconstructed in a strict form (as indicated in brackets [ $\leftrightarrow$ ]), or in a weaker probabilistic form. In either case, if we know for some new kind  $F^*$  that it possesses *some* of the dispositions, then the abducted common-cause hypothesis predicts that  $F^*$  will also possess all the other dispositions. This is a novel (qualitatively new) prediction. For example, we can predict solubility in acid for a new kind of metallic ore, even if this ore has never been put into acid before. Novel predictions are a characteristic virtue of genuine scientific theories that go beyond simple empirically inductive generalizations [7.54, p. 112].

Having described the basic principles and mechanisms of common-cause abduction, we must add four important clarifications:

1. *Instrumentalist versus realist interpretations:* In common-cause abduction, a new theoretical property is postulated or *discovered* that accomplishes a unified explanation of correlated empirical phenomena. Even if the theory-core describing this property it is independently confirmed in later experiments, there is no guarantee that the hypothesized theoretical property has *realistic* refer-

ence. Also a purely *instrumentalistic* interpretation of a theoretical concept is possible, as a useful means of unifying empirical phenomena (which is defended, for example, by *van Fraassen* [7.63]). However, the more empirically successful a theory becomes, the more plausible it is to assume that the theoretical concept producing this success actually *does* refer to something real [7.64, Sect. 6.2].

2. *Addendum on dispositions:* I understand dispositions as *conditional* (or *functional*) properties: That an object  $x$  has a disposition  $D$  means that whenever certain initial conditions  $C$  are (or would be) satisfied for  $x$ , then a certain reaction  $R$  of  $x$  will (or would) take place. This understanding of dispositions is in accordance with the *received view* [7.65, p. 44], [7.66]. Dispositional properties are contrasted with *categorical* properties, which are not defined in terms of conditional effects, but in terms of *occurrent* intrinsic structures or states (in the sense of *Earman* [7.67, p. 94]). Dispositional properties can have categorical properties such as molecular structures as their *causal basis*, but they are *not identical* with them. Although the received view is not uncontroversial [7.68, 69], it is strongly supported by the situation that underlies common-cause abduction (Fig. 7.7): Here *different* dispositions have the *same* molecular structure as their common cause; so they cannot be identical with this molecular structure.

*Prior et al.* [7.66, p. 255] argue that since dispositions are *functional* properties, they can only be the effects of (suitable) categorical causes, but cannot themselves act as causes. If this argument is not convincing enough, here is a more detailed argument showing why, at least normally, dispositions cannot cause each other. Assume  $D_1$  and  $D_2$  are two correlated dispositions, each of them being equivalent with an empirical regularity of the above-mentioned form:  $D_i x \leftrightarrow_{\text{def}} \forall t (C_i x t \rightarrow R_i x t)$  (for  $i \in \{1, 2\}$ ,  $t$  for the time variable). The implication expresses a cause-effect relation. Now, if  $D_1$  would cause  $D_2$ , the only possible causal reconstruction would be to assume that  $C_1$  causes  $C_2$ , which causes

Table 7.3

<b>Common-cause abduction (abducted theoretical concept: <math>\psi</math>).</b>
<i>Explanandum E:</i> All kinds $F_1, \dots, F_n$ have the dispositions $D_1, \dots, D_m$ in common. $\forall i \in \{1, \dots, n\} \forall j \in \{1, \dots, m\} : \forall x (F_i x \rightarrow D_j x)$ .
=====
<i>Abductive conjecture H:</i> All $F_1s, \dots, F_ns$ have a common intrinsic and structural property $\psi$ that is a cause and an indicator of all the dispositions $D_1, \dots, D_m$ . $\forall i \in \{1, \dots, n\} : \forall x (F_i x \rightarrow \psi x) \wedge \forall j \in \{1, \dots, m\} : \forall x (\psi x \rightarrow [\leftrightarrow] D_j x)$ .

$R_2$ , which in turn causes  $R_1$  ( $C_1 \rightarrow C_2 \rightarrow R_2 \rightarrow R_1$ ). But normally this is impossible, since the initial conditions are freely manipulable and, hence, causally independent. For example, my decision to irradiate a substance with light (to test for its glossing) can in no way cause my decision to heat it (to test for its ductibility).

A final remark: When I speak of a molecular structure as being the *cause* of a disposition, I understand the notion of *cause* in a more general sense than the narrow notion of event causation. This extended usage of *cause* is *reducible* to the notion of event causation as follows: A disposition  $Dx$ , being defined as the conditional property  $\forall t(Cxt \rightarrow Rxt)$ , is *caused* by a categorical property  $\psi x$  iff each manifestation of the disposition's reaction,  $Rxt$ , is caused by  $\psi x$  together with the initial conditions  $Cxt$ , or formally, iff  $\forall x\forall t(Lx \wedge Cxt \rightarrow Rxt)$ .

3. The precise explication of causal unification – many *effects* explained by one or just a few *causes* – presupposes formal ways of *counting* elementary phenomena, expressed by elementary statements. There are some technical difficulties involved with this. Solutions to this problem have been proposed in Schurz [7.70], Gemes [7.71], and more recently in Schurz and Weingartner [7.72]. The following explication is sufficient for our purpose: We represent every given belief system (or set of statements)  $K$  by the set of all those elementary statements  $S$  of the underlying language that are *relevant* consequences of  $K$ , in the sense that no predicate in  $S$  is replaceable by another arbitrary predicate (of the same place-number), salva validitate of the entailment  $K \parallel -S$ . Here, a statement  $S$  is called *elementary* iff  $S$  is not logically equivalent to a nonredundant conjunction of statements  $S_1 \wedge \dots \wedge S_n$ , each of which is shorter than  $S$ . Borrowing the terminology from Gemes [7.71], we call the elementary relevant consequences of  $K$   $K$ 's *content elements*. It can be shown that every set of sentences is classically equivalent with the set of its content elements; so no information is lost by this representation [7.72, Lemma 7.2]. But note that our analysis of common-cause abduction does *not depend* on this particular representation method; it merely depends on the assumption that a natural method of decomposing the classical consequence class of a belief system  $K$  into a nonredundant set of *smallest* content elements exists.

Many more examples of common-cause abduction in the natural sciences can be given. For example, Glauber's discovery of the central chemical concepts of *acids*, *bases*, and *salts* in the 17th century was based

on a typical common-cause abduction [7.49, pp. 196]. The fundamental common-cause abduction of Newtonian physics was the abduction of the *gravitational force* as the common cause of the disposition of bodies on the Earth to fall and the disposition of the planets to move around the Sun in elliptic orbits. Here, Newton's qualitative stipulation of the gravitational force as the counterbalance of the centrifugal force that acts on the circulating planets was his *abductive* step, while his quantitative calculation of the mathematical form of the gravitational law was a deduction from Kepler's third law plus this abductive conjecture [7.73, p. 203]. Another example is the abduction of the goal(s) of a person as the common cause of her behavior under various conditions. Prendinger and Ishizuka [7.25, p. 324] have utilized common-cause abduction in *automated web usage mining* to infer the interests of Internet users based on their browsing activities. Kornmesser [7.74] shows that common-cause abduction was the leading principle in the development of the *principles and parameters approach* in theories of generative grammar.

Common-cause abduction can also be applied to ordinary, nondispositional properties or (kinds of) events that are correlated. However, in this case one has first to consider more parsimonious causal explanations that do not postulate an unobservable common cause but stipulate one of these events or properties to be the cause of the others. For example, if the three kinds of events  $F$ ,  $G$ , and  $H$  (for example, eating a certain poison, having difficulties in breathing, and finally dying) are strictly correlated and always occur in the form of a temporal chain, then the most parsimonious conjecture is that these event types form a causal chain. Only in the special case where two (or several) correlated event types, say  $F$  and  $G$ , are strongly correlated, but we know that there *cannot* be a direct causal mechanism that connects them, is a common-cause abduction the most plausible conjecture. An example is the correlation of lightning and thunder: we know by induction from observation that light does not produce sound, and hence, we conjecture that there must be a common cause of both of phenomena.

We finally discuss our demarcation criterion (DC) in the light of *Bayesian confirmation* theory. According to criterion (DC), a speculative hypothetical cause explanation can *never* be regarded as confirmed by the evidence; only a common-cause explanation can. A Bayesian would probably object that our demarcation between single- and common-cause abduction is just a matter of degree [7.75, p. 141]. Recall from Sect. 7.1 that a given piece of evidence  $E$  raises the probability of *every* hypothesis  $H$  that increases  $E$ 's probability (since by Bayes' theorem,  $P(H|E)/P(H) =$

$P(E|H)/P(E)$ ). So according to standard Bayesian notions of confirmation [7.76] the evidence  $E$ : *John got a cold* does indeed confirm the speculative post facto speculation  $H_{\text{spec}}$ : *God wanted John to get a cold* – just to a minor degree in comparison to the scientific hypothesis  $H_{\text{sci}}$ : *John was infected by a virus*. So it seems that our demarcation criterion is in conflict with Bayesian confirmation theory.

Schurz [7.77] suggests a way of embedding (DC) into the Bayesian perspective. In all cases of *post facto* explanations, the hypothesis  $H$  results from fitting a latent (unobserved) first- or second-order variable  $X$  to the observed evidence  $E$ . So  $H$  entails the more general background hypothesis  $\exists XH(X)$  in which the latent variable  $X$  is unfitted and existentially generalized. In our example,  $\exists XH_{\text{spec}}(X)$  says: *There exists a God who wants some  $X$ , and whatever God wants, happens*.  $H_{\text{spec}}$  results from  $\exists XH_{\text{spec}}(X)$  by replacing  $X$  by *John got a cold* and omitting the existential quantifier. Note that  $\exists XH_{\text{spec}}(X)$  is a content element of  $H_{\text{spec}}$  that transcends (is not contained in) the evidence.

Schurz [7.77] argues that the probability-raising of  $H_{\text{spec}}$  by  $E$  is a case of *pseudo*-confirmation and not of genuine confirmation, because the probability increase of  $H_{\text{spec}}$  by  $E$  does not spread to  $H_{\text{spec}}$ 's evidence-transcending content element  $\exists XH_{\text{spec}}(X)$ . This follows from the fact that  $\exists XH_{\text{spec}}(X)$  can be fitted to *every possible* piece of evidence whatsoever. Therefore the probability of  $\exists XH_{\text{spec}}(X)$  remains as low as it was before conditionalization, for arbitrarily many pieces of evidence, whence the posterior probability of  $H_{\text{spec}}$  (which entails  $\exists X_{\text{spec}}H(X)$ ) also remains low.

Also note that the scientific hypothesis  $H_{\text{sci}}$  contains a latent variable  $X$  that has been fitted to the evidence  $E$ . In our example the unfitted hypothesis  $\exists XH_{\text{sci}}(X)$  says that *every disease is caused by some pathogenic agent  $X$* , which is fitted to John's cold by replacing  $X$  by *a virus*. In this case, however,  $H_{\text{sci}}$  implies further empirical consequences  $E'$  (e.g., that John's immune system will contain characteristic antibodies) by which it can independently tested. If such independent evidence  $E'$  raises the probability of  $H_{\text{sci}}$  as well, this is no longer the result of a post facto fitting, but an instance of *genuine* confirmation, because now this probability increase spreads to  $H_{\text{sci}}$ 's evidence-transcending content element  $\exists X_{\text{sci}}H(X)$  [7.77, Sect. 4].

### 7.7.3 Probabilistic Common-Cause Abduction and Statistical Factor Analysis

Statistical factor analysis is an important branch of statistical methodology whose analysis (according to my knowledge) has been neglected by philosophers of sci-

ence (with the exception of Haig [7.78], who shares my view of factor analysis). In this section I want to show that factor analysis is a certain generalization of hypothetical common-cause abduction, although sometimes it may be better interpreted in a purely instrumentalistic way. For this purpose, I assume that scientific concepts are represented as statistical random variables  $X, Y, \dots$ , each of which can take several values  $x_i, y_j$ . (A random variable  $X: D \rightarrow \mathbb{R}$  assigns to each individual  $d$  of the domain  $D$  a real-valued number  $X(d)$ ; a dichotomic property  $Fx$  is coded by a binary variable  $X_F$  with values 1 and 0.) The variables are assumed to be at least interval-scaled, and the statistical relations between the variables are assumed to be monotonic – the *linearity* assumption of factor analysis yields good approximations only if these conditions are satisfied.

Let us start from the example of the previous section, where we have  $n$  empirically measurable and highly intercorrelated variables  $X_1, \dots, X_n$ , i.e.,  $\text{cor}(X_i, X_j) = \text{high}$  for all  $1 \leq i, j \leq n$ . An example would be the scores of test persons on  $n$  different intelligence tests. We assume that none of the variables screens off the correlations between any other pair of variables (i.e.,  $\text{cor}(X_i, X_j|X_r) \neq 0$  for all  $r \neq i, j$ ), which makes it plausible that these  $n$  variables have a common cause, distinct from each of the variables – a theoretical factor, call it  $F$ . In our example,  $F$  would be the theoretical concept of intelligence. Computationally, the abductive conjecture asserts that for each  $1 \leq i \leq n$ ,  $X_i$  is approximated by a linear function  $f_i$  of  $F$ ,  $f_i(F(x)) = a_i F(x)$ , for given individuals  $x$  in the domain  $D$  (since we assume the variables  $X_i$  to be  $z$ -standardized, the linear function  $f_i$  has no additive term  $+b_i$ ). The true  $X_i$ -values are scattered around values predicted by this linear function,  $f_i(F)$ , by a remaining random dispersion  $s_i$ ; the square  $s_i^2$  is the *remainder variance*. According to the standard linear regression technique, the optimally fitting coefficients  $a_i$  are computed so as to *minimize* this remainder variance. Visually speaking, the  $X_i$ -values form a stretched cloud of points in an  $n$ -dimensional coordinate system, and  $F$  is a straight line going through the middle of the cloud such that the squared normal deviations of the points from the straight line are minimized.

So far we have described the linear-regression statistics of the abduction of *one* factor or cause. In factor analysis one also takes into account that the mutually intercorrelated variables may have not only one but *several* common causes. For example, the variables may divide into two subgroups with high correlations within each subgroup, but low correlations between the two subgroups. In such a case the reasonable abductive conjecture is that there are two independent common causes  $F_1$  and  $F_2$ , each responsible for the variables in one of the two subgroups. In the general picture of

factor analysis, there are  $n$  given empirical variables  $X_i$ , which are explained by  $k < n$  theoretical factors (or common causes)  $F_j$  as follows (for the following [7.79, Ch. 3]; note that I can describe here only the most common method of factor analysis without discussing subtle differences between different methods):

$$\begin{aligned} X_1 &= a_{11}F_1 + \dots + a_{1k}F_k + s_1 \\ &\dots \\ X_n &= a_{n1}F_1 + \dots + a_{nk}F_k + s_n. \end{aligned}$$

This is usually written in a matrix formulation:  $\mathbf{X} = \mathbf{F} \cdot \mathbf{A}'$ . While each variable  $X_i$  and factor  $F_j$  takes different values for the different individuals of the sample, the factor loadings  $a_{ij}$  are constant and represent the causal contribution of factor  $F_j$  to variable  $X_i$ . Given the further assumption that the factor variables  $F_j$  are standardized, each *factor loading*  $a_{ij}$  expresses the correlation between variable  $X_i$  and factor  $F_j$ ,  $\text{cor}(X_i, F_j)$ . Since the variance of each variable  $X_i$  equals the sum of the squared factor loadings  $a_{ij}^2$  and the remainder variance  $s_i$ , each squared factor loading  $a_{ij}^2$  measures the *amount of the variance of  $X_i$  explained* (i. e., statistically predicted) by factor  $F_j$ . The sum of the squared loadings of a factor  $F_j$ ,  $\sum_{1 \leq i \leq n} a_{ij}^2$ , measures the amount of total variance of the variables which is explained by  $F_j$ , and the sum of all of the squared loadings divided through  $n$  equals the percentage of variance explained by the extracted factors, which is a measure for the explanatory success of the factor-statistical analysis.

The major mathematical technique to find those  $k < n$  factors that explain a maximal amount of the total variance is the so-called principal component analysis. Instead of providing a detailed mathematical explanation, I confine myself to the following remarks. The  $k$  factors or axes are determined according to two criteria:

- (i) They are probabilistically independent (or orthogonal) to each other
- (ii) The amount of explained variance is maximized (i. e., the remainder variances are minimized).

Visually speaking, the first factor  $F_1$  is determined as an axis going through the stretched cloud of points in the  $n$ -dimensional coordinate system; then the next factor  $F_2$  is determined as an axis orthogonal to  $F_1$ , and so on, until the  $k < n$  factor axes are determined by the system of coefficients  $a_{ij}$ .

The success of an explanation of  $n$  variables by  $k < n$  factors is greater, the less the number  $k$  compared to  $n$ , and the higher the amount of the total variance explained by the  $k$  factors. This fits perfectly with my account of unification of a given set of  $n$

empirical variables by a small set of  $k$  theoretical variables, as explained in Sect. 7.7.1. While the amount of explained variance of the first factor is usually much greater than 1, this amount becomes smaller and smaller when one introduces more and more factors (in the trivial limiting case  $k = n$  the amount of explained variance becomes 100%). According to the Kaiser–Guttman criterion one should introduce new factors only as long as their amount of explained variance is greater than 1 [7.79, p. 75]. Hence, a theoretical factor is only considered nontrivial if it explains more than the variance of just one variable and, in this sense, offers a unificatory explanation to at least *some* degree. This is the factor analytic counterpart of my suggested demarcation criterion for hypothetical-cause abduction (DC).

We have seen in Sect. 7.7.2 that not only realistic but also instrumentalistic interpretations of the abducted factors are possible. In fact, several statisticians tend to interpret the results of a factor analysis cautiously as a merely instrumentalistic means of *data reduction* in the sense of representing a large class of intercorrelated empirical variables by a small class of independent theoretical variables. In spite of this fact, I think that the intended interpretation of the factors of a factor analysis is their realistic interpretation as common causes, for that is how they are designed. I regard the instrumentalistic perspective as an *important warning* that not every empirically useful theoretical structure must correspond to an existing structure of reality.

### 7.7.4 Epistemological Abduction to Reality

The relevance of abduction for realism is usually discussed within the context of theories and theoretical-entity realism. For many epistemologists [7.4, p. 44], [7.21, Chap. IV.5–6], the fundamental problem of common sense realism – the reasoning from introspective sense data to an external reality causing these perceptions – is an inference *sui generis*, and its justification is a problem of its own. In contrast to this position, I wish to point out that reasoning from introspective sense data to common-sense realism is in perfect fit with the pattern of common-cause abduction [7.53, p. 98]. The hypothesis of external objects that cause our sensual experience yields a common-cause explanation of a huge set of intercorrelations between our introspective experiences.

*First*, there are the *intra-sensual* intercorrelations, in particular those within our system of visual perceptions. There are potentially infinitely many 2-D visual images of a perceptual object, but all these 2-D images are strictly correlated with the position and angle at which we look at that object; so these cor-

relations have a common-cause explanation in terms of three-dimensional external objects by the laws of the perspectival projection. To be sure, these common-cause abductions are mainly *unconscious* and rely on inborn computations performed by the visual cortex of our brains. What we consciously experience are the *abducted* three-dimensional objects that make up the mind of the *naive realist*. However, certain situations – for example, the case of visual illusions caused by 3-D pictures – make it plain that what underlies our three-dimensional visual appearances is a complicated abductive computational process [7.80]. Moreover, since in our ordinary visual perceptions some objects partly conceal other objects that are behind them, our visual abductions always include the task of Gestalt complementation. Identification of three-dimensional objects based on two-dimensional projective images is an important abductive task in the AI field of visual object recognition [7.81, Ch. 24.4]. Scientifically advanced versions of visual abduction where one abducts the shape of entire objects from sparse fragments have been analyzed in the field of archeology [7.82].

The *inter-sensual* correlation between different sensual experiences, in particular between visual perceptions and tactile perceptions, is the *second* important

basis for the unconscious abduction to an outer reality – in fact, these correlations seem even to be the major fundament of our naive belief in the outer reality. If you have a visual appearance of an object, but you are unsure whether it is a mere visual illusion or not, then you will probably go to the object and try touch it – and if you can, then your realistic desires are satisfied. On the other hand, visual appearances that do not correspond to tactile ones, so-called *ghosts*, have frightened the naively realistic mind and occupied its fantasy since the earliest times.

This concludes my analysis of patterns of abduction. Instead of a conclusion, I refer to the classification of abduction patterns in Fig. 7.1, and to my main theses and results as explained in Sect. 7.1, which are densely supported by the details of my analysis. As a final conclusion, I propose the following: As Peirce once remarked [7.20, CP 6.500], the success of scientists at finding true hypotheses among myriads of possible hypotheses seems to be a sheer miracle. I think that this success becomes much less miraculous if one understands the strategic role of patterns of abduction. In the concluding section, I present applications of abductive reasoning in two neighboring fields: belief revision and instrumental or technological reasoning.

## 7.8 Further Applications of Abductive Inference

### 7.8.1 Abductive Belief Revision

The theory of belief revision formulates rules for the rational change of a given belief system (*knowledge*)  $K$  upon receiving new evidence.  $K$  is understood as a set of (believed) sentences that is closed under deductive consequence ( $K = Cn(K)$ ) and the pieces of evidence  $E_i$  are usually (though not always) taken as certainly true (the so-called *axiom of success*). According to the well-known AGM-theory of belief revision (after Alchourrón, Gärdenfors and Makinson [7.83, 84]), the rational change of a belief system  $K$  upon receiving new evidence  $E$  is characterized as follows:

1. If  $E$  is consistent with  $K$ , this change is called the *expansion* of  $K$  by  $E$ , abbreviated as  $K + E$ , and defined as  $K + E =_{\text{def}} Cn(K \cup \{E\})$ , i. e., the logical closure of the union of  $K$  and  $\{E\}$ .
2. If  $E$  is inconsistent with  $K$  (i. e.,  $K$  entails  $\neg E$ ), this change is called the *revision* of  $K$  by  $E$ , abbreviated as  $K * E$  and defined as  $K * E =_{\text{def}} Cn((K - \neg E) + E)$ , where  $K - \neg E$  is called the *contraction* of  $K$  by  $\neg E$  and intuitively characterized as a *minimal* yet *reasonable* subset of  $K$  that is consistent with  $E$ .

Thus,  $K * E$  is the closure of the expansion of  $K$ 's contraction by  $\neg E$  with  $E$ ; this definition is called the *Levi identity*. There is no consensus about a *most reasonable* or *right* contraction operation in the literature.

A general deficiency of standard definitions of belief expansion and revision is their failure to represent learning on the basis of evidence. This is a consequence of the idea that the expansion or revision should always be as *minimal* as possible [7.85, p. 80]. An alternative is *abductive* belief expansion and revision. It rests on the idea that the expansion or revision of  $K$  by new evidence  $E$  should be the result of adding  $E$  to  $K$  and abducting a suitable explanation of  $E$  (assuming that such an explanation is not already present in  $K$ ).

In what follows, the abductive belief expansion or revision of a belief system  $K$  by new evidence  $E$  is abbreviated as  $K ++ E$  or  $K * * E$ , respectively. A first approach of this sort was initiated by Pagnucco [7.86], who characterized the space of abductible explanations in a maximally liberal way: an abduction (explanation) of  $E$  given  $K$  may be *any* sentence  $S$  such that  $S$  entails  $E$  within  $K$ ; in the most trivial case,  $S$  is identical with  $E$ . Thus, Pagnucco defines an abductive belief

expansion operation as any operation  $++$  satisfying  $K ++ E = Cn(K \cup \{S\})$  for some sentence  $S$  such that  $K \cup \{S\}$  is consistent and entails  $E$  (provided  $K \cup \{E\}$  is consistent). Belief revision is then defined by the Levi identity  $K * * E =_{\text{def}} (K - \neg E) ++ E$ . A similar approach to abductive belief revision is suggested in *Aliseda* [7.7, pp. 184].

Schurz [7.85, pp. 88] argues that from the viewpoint of philosophy of science, Pagnucco's notion of abduction is too weak, since not just any sentence that logically entails  $E$  constitutes a scientific explanation of  $E$ . Schurz [7.85] utilizes the abduction patterns classified in Fig. 7.1 to explicate corresponding operations of abductive belief expansion and revision. He defines abductive belief expansion as  $K ++ E =_{\text{def}} K \cup \{E\} \cup \text{abd}(K, E)$ , where the triple  $(E, \text{abd}(E, K), K)$  expresses one of the abduction situations classified in Fig. 7.1:  $E$  is the evidence to be explained,  $\text{abd}(E, K)$  is the abductive conjecture, and  $K$  is the given background belief system that drives the abduction [7.85, p. 93]. Next, Schurz [7.85, pp. 94–6] discovers that an appropriate definition of abductive belief revision fails to meet the Levi identity for two reasons, which he calls the problems of *old evidence* and *incremental belief revision*. He defines abductive belief revision based on a suitable notion of the abductive revision of an explanatory hypothesis by contradicting evidence [7.85, p. 96]. Operations of intelligent abductive belief revision that are congenial in spirit have been implemented in computer programs by Bharathan and Josephson [7.87].

A related account to abductive belief revision has been developed by Cevolani [7.88]. Cevolani agrees with Schurz that the characterization of an explanation as any sentences that entails the explanandum is too weak. He suggests that the abductive hypothesis  $S$  that in the given belief system  $K$  explains  $E$  should be such that the *expected verisimilitude* of the resulting belief systems  $K ++ E$  or  $K * * E$ , respectively, increases. Similar to Schurz, Cevolani observes that his so-defined notion of abductive belief revision fails to satisfy the Levi identity [7.88, p. 011].

## 7.8.2 Instrumental Abduction and Technological Reasoning

Abductions in the standard meaning of this word are *explanatory* in the sense that it is the task of the abductive hypothesis to *explain* a given phenomenon. All patterns of abductive inference that are classified in Fig. 7.1 and discussed in Sects. 7.2–7.7 are explanatory abductions. Tomiyama et al. [7.89, 90] and Tuzet [7.91, p. 152] have proposed to extend the meaning of the notion of *abduction* so that it also includes technological or, more generally, any sort of instrumental reasoning.

In instrumental *abduction*, the proposition that the abductive hypothesis entails in the given background system is not yet true, but rather represents a *goal*, i. e., something that one wishes to realize, and the abductive hypothesis (*conclusion*) expresses a conjectured *means* to *realize* this goal. Referring to the patterns of abductions classified in a predecessor paper of Schurz [7.1], Tomiyama et al. [7.89] show how abductive reasoning can be applied to create the design of a refrigerator. For Tuzet [7.91, p. 152], the reasoning schema *We want E. If C then E. Therefore, we should try to bring about C* expresses the basic form of instrumental abduction, constrained by the restriction that  $C$  should be practically *appropriate*: for example  $C$  must be practically realizable and must not have unwanted side-effects (etc.).

Generally speaking, often – though not always – instrumental reasoning proceeds by similar cognitive operations as abductive reasoning, the only difference being that the *abductandum* is not yet realized but expresses a goal. Therefore I propose to call this sort of reasoning *instrumental abduction*, provided one is aware that this notion *extends* the proper meaning of abduction to a different domain of application. (Note that Tuzet [7.91] speaks of *epistemic* versus *projectual* abduction; I prefer the designations *explanatory* versus *instrumental* abduction because they are more specific.) The distinction between explanatory and instrumental abduction is summarized in Fig. 7.7.

In Fig. 7.7 the superordinate concept that covers explanatory as well as instrumental abduction is called

*Generalized abduction:*

$C$ : Abductandum, conclusion to be inferred

$K$ : System of background beliefs

$P$ : Abductans, abducted conjecture such that  $\{P\} \cup K$  entails  $C$

*Ordinary explanatory abduction*

$C$  is an observed (true) phenomenon

$P$  is an optimal explanation of  $C$  given  $K$ .

*Instrumental abduction*

$C$  expresses a goal to be realized

$P$  expresses an optimal means for realizing  $P$  given  $K$ .

**Fig. 7.7** Generalized, explanatory and instrumental abduction

*generalized abduction*. What is common to both forms of abduction is a process that searches for missing premises  $P$  for a given conclusion  $C$ . Gabbay and Woods [7.17, p. 191] and Woods [7.92, p. 153] go so far as to call every cognitive process an abduction so long as it generates a premise  $P$  from which a given sentence  $C$  can be derived or obtained in the given background system  $K$  (thereby the authors generalize the notion of *consequence* to an arbitrary *closure relation*  $R$ ). According to this view, a process that *confirms*  $C$ , or that *predicts*  $C$  (via finding suitable premises), would also be called an abduction. From the viewpoint of philosophy

of science, I am inclined to think that this generalization overstretches the notion of abduction. On the other hand, from a logical viewpoint it seems to make sense to call any process that searches for premises in order to infer a given *inference goal* an abduction in the *logically generalized* sense.

## 8. Forms of Abduction and an Inferential Taxonomy

Gerhard Minnameier

In recent years, the Peircean concept of *abduction* has been differentiated into different forms and made fruitful in a variety of contexts. However, the very notion of abduction still seems to be in need of clarification. The present contribution takes very seriously Peirce's claim (1) that there are only three kinds of reasoning, that is, abduction, deduction, and induction, and (2) that these are mutually distinct. Therefore, the fundamental features of the three inferences canvassed, in particular as regards inferential subprocesses and the validity of each kind of reasoning. It is also argued that forms of abduction have to be distinguished along two dimensions: one concerns *levels* of abstraction (from elementary embodied and perceptual levels to high-level scientific theorizing). The other concerns *domains* of reasoning such as explanatory, instrumental, and moral reasoning. Moreover, Peirce's notion of *theorematic deduction* is taken up and reconstructed as *inverse deduction*. Based on this, *inverse abduction* and *inverse induction* are introduced as complements of the ordinary forms. All in all, the contribution suggests a taxonomy of inferential reasoning, in which different forms of abduction (as well as deduction and induction) can be systematically accommodated. The chapter ends with a discussion on forms of abduction found in the current literature.

For Peirce, not the proverbial misfortune comes in threes, but rather does *fortune*, not least with respect to his inferential triad of abduction, deduction, and induction. On the one hand, they are thought to cover the whole process of scientific reasoning from problem statement to the final adoption of a hypothesis [8.1, CP 5.171 (1903)]. On the other hand, he claimed that there are but these three elementary types of inferences so that all kinds of reasoning must belong to either abduction, deduction, or induction [8.2, CP 8.209 (c. 1905)]. Moreover, and this may sound strange, he explains in

the same place that even his earlier classification of inferences dating from 1867 can be understood in the same way, that is, in the sense of the mature Peirce's conception of the three inferences.

Peirce [8.2, CP 8.209 (c. 1905)]:

"I say that these three are the only elementary modes of reasoning there are. I am convinced of it both a priori and a posteriori. The a priori reasoning is contained in my paper in the Proceedings of the American Academy of Arts and Sciences for

April 9, 1867. I will not repeat it. But I will mention that it turns in part upon the fact that induction is, as Aristotle says, the inference of the truth of the major premiss of a syllogism of which the minor premiss is made to be true and the conclusion is found to be true, while abduction is the inference of the truth of the minor premiss of a syllogism of which the major premiss is selected as known already to be true while the conclusion is found to be true. Abduction furnishes all our ideas concerning real things, beyond what are given in perception, but is mere conjecture, without probative force. Deduction is certain but relates only to ideal objects. Induction gives us the only approach to certainty concerning the real that we can have. In forty years diligent study of arguments, I have never found one which did not consist of those elements.”

This is puzzling, if one considers Peirce’s own discussion of his earlier conception in his later work where he states explicitly that [8.2, CP 8.221 (1910)]:

“in almost everything I printed before the beginning of this century I more or less mixed up Hypothesis and Induction (i. e., abduction and induction according to his later terminology, G.M.).”

Thus, if he is not contradicting himself, both statements must be true, however, each in a specific respect.

This is one riddle I will try to solve in this chapter, but it is not the only one. I take it as one specific stumbling stone on the way to a full understanding of the very notion and logic of abduction. In order to achieve a comprehensive account of abduction, however, it is also necessary to accommodate a whole host of different concepts of abduction that have been suggested in recent years. *Magnani*, for instance, not only distinguishes between creative and selective abduction [8.3], but also between sentential and model-based abduction, theoretical and manipulative abduction, explanatory and nonexplanatory abduction [8.4]. The latter distinction is drawn from *Gabbay and Woods* [8.5], who maintain that abduction be extended to cover not merely explanatory, but also nonexplanatory abduction, although they remain diffident qualifying their differentiation “as a loose and contextually flexible distinction” [8.5, p. 115].

Another classification is proposed by *Schurz* [8.6] who distinguishes between *factual abduction*, *law-abduction*, *theoretical-model-abduction*, and *second order existential-abduction*, with the first and last being further divided into subclasses. Building on this classification and extending it, *Hoffmann* [8.7] produces a 3 × 5 matrix containing 15 types. Most importantly, he amends *Schurz*’s main categories by a form focusing

on *theoric transformations* that generate or select a new system of representation. However, the idea of theoric transformations relates to Peirce’s distinction between theorematism and corollary *deduction*, which raises the question of whether theoric transformations really belong to the realm of *abductive* reasoning (note that *Hoffmann* discusses Peirce’s analysis of Desargues’ theorem in [8.8, NEM III/2, 870–871 (1909)]. Here, another Peircean puzzle enters the scene, because he himself has claimed that theorematism deduction “is very plainly allied to retroduction (i. e., abduction, G.M.), from which it only differs as far as I now see in being indisputable” [8.9, MS 754 (1907)].

Thus, while there seem to be many different forms of abduction, it is unclear how many distinctive forms there really are. However, what is much more important is that the scientific community still seems to grapple with the very notion of abduction, that is, what are the central features of abduction as such or of its specific forms. Above, I started citing Peirce with his claim that there be only three basic and distinct kinds of inferences. However, apart from what has already been mentioned above, a persistent problem seems to be to distinguish between abduction and induction, inasmuch as *inference to the best explanation* (henceforth IBE) has to be understood as a form of induction in the Peircean sense. In [8.10], I have tried to disentangle abduction and IBE, and I have not been alone with this view [8.11]. However, *Gabbay and Woods* mention *inference-to-the-best-explanation abductions* [8.5, p. 44], and their schema for abduction [8.5, p. 47] seems to capture both abduction and IBE. *Magnani* [8.3, p. 19], [8.4, pp. 18–22] and *Schurz* [8.6, pp. 201–203] equally subsume IBE to abductive reasoning. I reckon that this has to do with similarities between their notion of *selective abduction* on the one hand and IBE on the other.

In my view, Peirce was right to claim that there are but three kinds of reasoning and that there are clear lines of demarcation between them. Accordingly, I think there is reason to *tighten the Peirce-strings* by integrating different forms of abduction (as well as deduction and induction) within a clear and coherent taxonomy. In Sect. 8.1, I will first point out that abduction and IBE are distinct (Sect. 8.1.1), then show how abduction, deduction, and induction hang together to form a productive inferential cycle from a pragmatist point of view (Sect. 8.1.2), and finally explain how this productivity enables us to construct a hierarchy of conceptual levels (Sect. 8.1.3). Within this context, different forms of abductions can be distinguished in terms of the cognitive levels at which they are located, and in terms of whether *new concepts are invented* or *existing ones applied*.

In Sect. 8.2, I explicate the logic of each of the three inferential types. This is done in two steps. First

(Sect. 8.2.1), the inferences will be analyzed in terms of three characteristic subprocesses that Peirce assumes for inferences in general, that is, (1) *colligation*, (2) *observation*, and (3) *judgment* ([8.12, CP 2.442–244 (c. 1893)], see also *Kapitan* [8.13, p. 479]). Next, the validity of each inference will be discussed in Sect. 8.2.2.

Based on this analysis, Peirce’s notion of *theore-matic reasoning* is explored in Sect. 8.3. In Sect. 8.3.1, theore-matic deduction is explicated as *inverse deduc-tion*, leading from the result of corollarial deduction to the premise of corollarial deduction, that is, the theoret-ical point of view from which the result can be deduced. An instructive example is given in Sect. 8.3.2, and in Sect. 8.3.3 the idea of inverse inferences is extended to inverse abduction and induction. As a result, we end up with three ordinary and three inverse forms of *pure* inferential types (note that Peirce has also introduced *analogy* as a compound inference conjoining abduction and induction [8.14, CP 1.65]; see also [8.15] on this issue).

## 8.1 Abduction in the Overall Inferential Context

### 8.1.1 Disentangling Abduction and IBE

In a recent overview of Peirce’s theory of abduction, Psillos stresses that abduction, deduction, and induction “constitute the three ultimate, basic and independent modes of reasoning. This is a view that runs through the corpus of the Peircean work” [8.16, p. 121]. So, the task of defining and distinguishing these three kinds of inferences might be assumed to be easy. However, reality is different, not least because [8.16, pp. 136–137]

“[t]he picture of abduction that Peirce has painted is quite complex. On the face of it, there may be a question of its coherence. Abduction is an inference by means of which explanatory hypotheses are admitted, but it is not clear what this admission amounts to.”

Why is abduction so hard to grasp? To my mind, the main reason is that it is often confounded with (aspects of) induction or IBE and that Peirce himself has given rise to such confusion. At first, he came up with a syl-logistic account of this inferential triad [8.12, CP 2.623 (1878)], but told us later that “in almost everything I printed before the beginning of this century I more or less mixed up Hypothesis and Induction” [8.2, CP 8.221 (1910)]. As already quoted above, however, he also maintained that in some sense the early Peirce’s concept of *hypothesis* and the mature Peirce’s *abduction* were still equivalent. What’s more, the passage quoted

In Sect. 8.4, I will discuss three important distinc-tions among forms of abductive reasoning: *creative* versus *selective* abduction (Sect. 8.4.1), *factual* versus *theoretical* abduction (Sect. 8.4.2), and *explanatory* ver-sus *nonexplanatory* abduction (Sect. 8.4.3). It turns out that abductions (and other inferences) are to be dis-tinguished in terms of knowledge generation (creative) versus knowledge application (selective) and along two cognitive dimensions: one concerns *levels* of abstrac-tion (from elementary embodied and perceptual levels to high-level scientific theorizing). The other concerns *domains* of reasoning such as explanatory, instrumental, and moral reasoning. In the concluding Sect. 8.5, the main results of my analysis are summarized and routes for further research indicated.

Although I consider my argumentation coherent and in line with Peirce, I do not claim to deliver an exegesis of what Peirce himself might have thought, especially since parts of my inferential taxonomy are clearly not contained in his works.

in the introduction makes explicit that the purpose of abduction is twofold (1) to generate new hypotheses and (2) to select hypotheses for further examination (see also [8.13, p. 477]; [8.17, p. 503]). The same is true for the following passage [8.18, CP 6.525 (1901)]:

“The first starting of a hypothesis and the enter-taining of it, whether as a simple interrogation or with any degree of confidence, is an inferen-tial step which I propose to call abduction. This will include a preference for any one hypothesis over others which would equally explain the facts, so long as this preference is not based upon any previous knowledge bearing upon the truth of the hypotheses, nor on any testing of any of the hypotheses, after having admitted them on probation. I call all such inference by the peculiar name, abduction, because its legitimacy depends upon altogether different principles from those of other kinds of inference.”

Thus, the question remains as to whether abduction is associated with IBE at least in some sense, and if so, whether abduction as such bears this feature or whether there are two different basic kinds of abduction – creative and selective – as *Magnani* [8.3, 4] and *Schurz* [8.6] hold. In the succeeding passages, Peirce writes on the testing of hypotheses and explains his concept of induction, in particular as a means to determine which of a number, or even a multitude, of hypotheses

is the best explanation and ought to be adopted as true or likely to be true [8.18, CP 6.526–536 (1901)]. Within this elaboration, he is careful to make sure that the selective aspect of abduction is something different [8.18, CP 6.528 (1901)]:

“These distinctions (among forms of induction, G.M.) are perfectly clear in principle, which is all that is necessary, although it might sometimes be a nice question to say to which class a given inference belongs. It is to be remarked that, in pure abduction, it can never be justifiable to accept the hypothesis otherwise than as an interrogation. But as long as that condition is observed, no positive falsity is to be feared; and therefore the whole question of what one out of a number of possible hypotheses ought to be entertained becomes purely a question of economy.”

Elsewhere, Peirce points out that the abductive selection of hypotheses is usually guided by criteria like simplicity and breadth [8.19, CP 7.220–222 (c. 1901)], and his main idea is that we do not consider just any possible hypothesis, but those hypotheses that make most sense to us from the outset (i. e., those with the highest subjective prior probabilities; see also [8.20]). However, this is no IBE, since it is merely a question of economy, and Peirce clearly states that no sound judgment could be based on this kind of selection, for it is “the most deceptive thing in the world” [8.12, CP 2.101 (1902)]. The further course of inquiry, and whether an originally neglected possibility will have to be taken up at a later stage, depends entirely on induction. For when the selected hypothesis is finally evaluated in the light of empirical data it has to be judged [8.12, CP 2.759 (1905)]:

“whether the hypothesis should be regarded as proved, or as well on the way toward being proved, or as unworthy of further attention, or whether it ought to receive a definite modification in the light of the new experiments and be inductively reexamined ab ovo, or whether finally, that while not true it probably presents some analogy to the truth, and that the results of the induction may help to suggest a better hypothesis.”

If the hypothesis is *regarded as proved*, then this is IBE. However, it could not possibly be regarded as proved if there were yet another hypothesis around that could not be excluded based on the evidence gathered so far. Hence, selection in the context of abduction and selection in the context of induction are quite different. In the former case, its role is merely practical, not logical; that is, one hypothesis is tried first, and if it testifies to be beyond any doubt, other alternatives would not

have to be considered anymore (however, this implies that by the same token all possible alternatives must, in fact, be refuted). Or if it is to be conceived as *logical*, then the hypothesis to be rejected at this stage has either to be conceived as abductively (here: explanatorily) invalid (see Sect. 8.2.2), or the rejection has to follow from an *inductive* evaluation of the competing hypotheses. From such an inductive evaluation it might follow that the hypothesis currently countenanced is *well on the way of being proved* in the above-quoted sense, in that it is better than a number of other hypotheses, although further testing or further reflection about novel approaches seems appropriate.

Anyhow, it has to be admitted that Peirce is imprecise in this respect. However, in order not to confuse abductive and inductive logic, I would suggest the rigid interpretation just stated. Moreover, I would like to refer to *Aliseda*, who has pointed out very clearly the difficulties of coming to grips with the selection of a *best* or *preferred* inference as an abductive task [8.21, pp. 72–74], even though she herself endorses hypothesis selection as an abductive task [8.21, p. 33].

On this background, let us now consider *Gabbay* and *Woods*’ reconstruction of abductive reasoning [8.5, p. 47]. According to them, it starts with a cognitive target  $T$  (e.g., to explain a certain phenomenon) that cannot be met based on the reasoner’s background knowledge  $K$ , and that the reasoner wants to attain (hence  $T$ ).  $R$  denotes the attainment relation on  $T$ , and  $R^{\text{pres}}$  the presumptive attainment relation on  $T$ . If  $R(K, T)$  is not possible, the reasoner aims at an enhanced successor knowledge base  $K^*$  so that  $R(K^*, T)$  holds.  $H$  denotes a hypothesis, and  $K(H)$  a knowledge base revised by  $H$ . Furthermore, there is  $C(H)$ , which means that it is “justified (or reasonable) to conjecture that  $H$ ” [8.5]. And finally, “ $H^c$  denotes the discharge of  $H$ .  $H$  is discharged when it is forwarded assertively and labelled in ways that reflect its conjectural origins” [8.5]. Based on these definitions they suggest the following schema [8.5, p. 47]:

- |   |                       |
|---|-----------------------|
| 1. $T!$   | [declaration of $T$ ] |
| 2. $\neg(R(K, T))$                                | [fact]                |
| 3. $\neg(R(K^*, T))$                              | [fact]                |
| 4. $R^{\text{pres}}(K(H), T)$                     | [fact]                |
| 5. $H$ meets further conditions $S_1, \dots, S_n$ | [fact]                |
| 6. Therefore, $C(H)$                              | [conclusion]          |
| 7. Therefore, $H^c$                               | [conclusion]          |

As I try to explain also in Sect. 8.3, the reach of abduction ought to be limited to steps 1 through 4, with (4) establishing a valid abductive inference, that is, that  $R^{\text{pres}}(K(H), T)$  holds. This establishes abductive validity in that  $H$  is capable of explaining the surprising facts. And this is precisely what  $R^{\text{pres}}(K(H), T)$  cap-

tures. Steps 5 through 7 ought, to my mind, be attributed to induction, in this case a rather tentative induction that Peirce has labeled “*abductive induction*” [8.18, CP 6.526 (c. 1901)], because it only qualifies a hypothesis  $H$  as better than possible alternative hypotheses, but not in the sense of a full-fledged inductive judgment to the truth of  $H$ . Further conditions  $S_1, \dots, S_n$  may exist in the form of background knowledge pertaining to Peirce’s criteria of simplicity or breadth (see above) or additional empirical evidence in favor of  $H$ . However, these further pieces of information clearly go beyond the abductive task; they may be produced by *deductive* reasoning about what certain hypotheses imply (because how do  $S_1, \dots, S_n$  become conscious?), and are finally considered in *inductive* reasoning. Therefore, I propose to repatriate steps 5 through 7 to the realm of *induction*, and to take very seriously the following statement [8.2, CP 8.218 (c. 1901)]:

“Nothing has so much contributed to present chaotic or erroneous ideas of the logic of science as failure to distinguish the essentially different characters of different elements of scientific reasoning; and one of the worst of these confusions, as well as one of the commonest, consists in regarding abduction and induction taken together (often mixed also with deduction) as a simple argument. Abduction and induction have, to be sure, this common feature, that both lead to the acceptance of a hypothesis because observed facts are such as would necessarily or probably result as consequences of that hypothesis. But for all that, they are the opposite poles of reason [...].”

Recently, *McKaughan* [8.20], *Campos* [8.22], and *Mackonis* [8.23] have argued in favor of a wide notion of IBE, including abduction, although they endorse the sharp distinction others and myself have made. However, in the light of the subtle, but nonetheless important, distinctions I have tried to highlight in this section, I think there is not much use fitting it all in one global concept of IBE.

### 8.1.2 The Dynamical Interaction of Abduction, Deduction, and Induction

By the end of the nineteenth century, Peirce rejected his original syllogistic approach and said “I was too much taken up in considering syllogistic forms [...], which I made more fundamental than they really are” [8.12, CP 2.102 (1902)]. However, even more to the point, Peirce realized that induction “never can originate any idea whatever. Nor can deduction. All the ideas of science come to it by the way of Abduction” [8.1, CP 5.145

(1903)]. The crucial point here is that induction can only operate with concepts that are already at hand. On top of this, even simple regularities like  $\forall x(Fx \rightarrow Gx)$  do not suggest themselves, but have to be considered by an active mind, before they can be tested and eventually accepted or rejected (see Sect. 8.1.3, relating to Carnap’s disposition predicates). This is why the mature Peirce suggests that abduction is the process by which new concepts, laws, and theories are first conceived, before they are investigated further by deductive and inductive processes [8.1, CP 5.171 (1903)]:

“Abduction is the process of forming an explanatory hypothesis. It is the only logical operation which introduces any new idea; for induction does nothing but determine a value, and deduction merely evolves the necessary consequences of a pure hypothesis. Deduction proves that something *must* be; Induction shows that something *actually* is operative; Abduction merely suggests that something *may be*. Its only justification is that from its suggestion deduction can draw a prediction which can be tested by induction, and that, if we are ever to learn anything or to understand phenomena at all, it must be by abduction that this is to be brought about.”

Abduction is most important in our overall reasoning, because without it we could not possibly acquire any idea of the world, not even elementary perceptions of objects, let alone scientific theories. Hence, “no new truth can come from induction or from deduction” [8.2, CP 8.219 (c. 1901)]. Whereas abduction is very powerful in terms of the generation of fruitful new ideas, however, it is very weak in terms of empirical validity, as Peirce often stresses. He even says that his discovering the true nature of abduction so late was “owing to the extreme weakness of this kind of inference” [8.12, CP 2.102 (1902)]. Empirical validity is gained by deducing necessary consequences from the abduced hypotheses, especially predictions that can be tested empirically, and the inductive evaluation of the experimental results (or other suitable evidence). Figure 8.1 illustrates the dynamical interaction of the three inferential types.

So far, the role of abduction and deduction seems self-evident. However, an explanation should be given for the role of induction in this triad, in particular why it points back to where abduction starts in Fig. 8.1. After all, induction is typically understood as the inference to the truth (or falsity) of the theory in question, and as a consequence it should point back to the theory itself, like for example in *Magnani’s* ST-Model [8.4, p. 16]; also [8.3, p. 23].

However, induction in the Peircean sense is tied back to his pragmatism, which, again, rests on the logic

**Fig. 8.1** The dynamical interaction of abduction, deduction, and induction

of abduction (cf. also [8.15, pp. 207–212]). Peirce [8.1, CP 5.196 (1903)]:

“That is, pragmatism proposes a certain maxim which, if sound, must render needless any further rule as to the admissibility of hypotheses to rank as hypotheses, that is to say, as explanations of phenomena held as hopeful suggestions.”

In other words, all we need in the first place is the confidence that abduction may enable us, by the construction of concepts and hypotheses, to acquire objective knowledge at all. Otherwise, all deductive and inductive examination were futile. However, since abduction is based on experience, induction cannot go beyond that level to infer some kind of “absolute truth” [8.24–27]. Therefore, all that induction can do is to establish habits of expectation and action based on theories.

Peirce [8.1, CP 5.197 (1903)]:

“What, then, is the end of an explanatory hypothesis? Its end is, through subjection to the test of experiment, to lead to the avoidance of all surprise and to the establishment of a habit of positive expectation that shall not be disappointed.”

To be sure, theories in this sense are understood realistically, not as psychological contrivances [8.24, pp. 201–203]. However, finally adopting a theory means to project its content onto all its cases, observed and unobserved, in the past, present, and future. And only in this sense can a theory still be revised or eventually rejected in the future. It is important, therefore, that a circle closes in this very sense of creating habits of expectation and action so that these habits can, in principle, always be broken up again in the future (see also [8.26, pp. 51–57]).

Peirce [8.2, CP 8.270 (1902)] (see also [8.1, CP 5.524 (c. 1905)]):

“The question is what passes in consciousness, especially what emotional and irritational states of feeling, in the course of forming a new belief. The

man has some belief at the outset. This belief is, as to its principal constituent, a habit of expectation. Some experience which this habit leads him to expect turns out differently; and the emotion of *surprise* suddenly appears.”

Thus, when an accepted theory is subsequently applied to relevant cases, it is *not only* being applied, but also reassessed over and over. In this very sense, knowledge acquisition and knowledge application are fundamentally tied together and follow the same inferential principles. That is, every application of previously acquired knowledge has to be understood as:

1. Abducing from a certain situational configuration to a suitable interpretation, then
2. Deducing a certain course of action or expectation, and
3. Inducing whether one’s actions or expectations were confirmed by experience.

Furthermore, if every application of knowledge constitutes a chance to strengthen or weaken the underlying belief, then by the same token, all failures and situation-specificities in the application of knowledge [8.28] and action-guiding principles, in particular moral principles [8.29, 30], can also be addressed and analyzed within this very frame of reference.

### 8.1.3 Abduction and Abstraction

As we have seen in the previous sections, the key feature of abduction is to construct new explanatory concepts to accommodate the surprising facts that give rise to them. “By its very definition abduction leads to a hypothesis which is entirely foreign to the data” [8.31, MS 692 (1901)]. Abductive hypotheses are typically of a higher degree of complexity in the sense that phenomena are not just explained by other phenomena that might have brought them about, but by a *theory* of the phenomena. Such theories constitute higher cognitive levels, and this entails that theoretical entities are not observable in the same way as the phenomena they are meant to explain. Of course, *Hanson’s* principle of theory-ladenness of experience [8.32] states that no experience (at least no description of experiences) is theory-free. Nonetheless, there are levels of cognitive architectures building on each other. This has been clear ever since *Carnap* discovered that not even simple disposition predicates could be reduced to observation sentences [8.33, 34].

When *Schurz* [8.6] differentiates between variants like *fact-abduction*, *law-abduction*, or *theoretical abduction*, he also distinguishes such levels, however, without making this aspect of successive theory-

building fully explicit. I think it would be a fruitful endeavor to reconstruct how conceptual (or theoretical) levels are built onto one another by successive abductions. For instance, when a simple disposition is discovered (that sugar dissolves in water), this constitutes an empirical law, which is itself a concept of a regularity in nature. It can also be used to explain why someone else does not see the sugar in her drink. We could say that it is very well in there, but cannot be seen, because it has dissolved.

What this simple example shows is that even in simple fact-abduction, we do not just infer to the fact, but to the law from which it then follows that sugar might be in a liquid, even if no sugar can be seen. Thus, dispositional laws and simple action schemes (*When the switch is pushed, the light will go on*) constitute an elementary theory level, that is, regularities in terms of observation language. However, these regularities are themselves phenomena that one may wish to explain, especially when one starts wondering, *how* the switch is causally connected with the light. At first, it was established *that* a natural regularity exists. Now, as the regularity is established as a matter of fact, it becomes the object of theoretical reflection and represents the fact to be explained.

This is what Hintikka highlights when he discusses the difference between abduction and IBE. He says that [8.32, p. 509]:

“when a dependence law telling us how the observed variable depends on the controlled one the law does not *explain* the result of the experiment. It is the *result* of the experiment, nature’s answer to the experimental investigator’s question.”

*Earnan McMullin* has made the same point concerning the role of laws in explanation: “Laws are the explananda; they are the questions, not the answers” [8.35, p. 90]. And he continues [8.35, p. 91]:

“To explain a law, one does not simply have recourse to a higher law from which the original law can be deduced. One calls instead upon a *theory*, using this term in a specific and restricted sense. Taking the observed regularity as effect, one seeks by abduction a causal hypothesis which will explain the regularity. To explain why a particular sort of thing acts in a particular way, one postulates an underlying structure of entities, processes, relationships, which would account for such a regularity. What is ampliative about this, what enables one to speak of this as a strong form of understanding, is that if successful, it opens up a domain that was previously unknown, or less known.”

I consider this a strong and important point (see also [8.36, 37] on explanatory hierarchies and explanatory coherence). Laws, in this view, are not the solutions (the explanations) but the problems (the facts to be explained). However, I would not go so far as to deny laws, even simple empirical laws, any explanatory function. It just depends on the point of view and the theoretical level, which is needed and appropriate to solve a particular explanatory problem. If one is looking for causal relationships between events, one is in fact searching for law-like explanations. And this not only applies to children in their early cognitive development. Most adults are content with knowing what keys to press in order to use certain functions of a software; in such cases the question is how a certain result is brought about, and the explanation consists in functional relations between the keys or menu options and the results visible on the screen. The same applies to cookbooks and manuals for technical appliances in which it is explained, how things work or why something I tried did not work. I assume that, for example, *Schurz’s* account of explanation as unification applies not only to scientific theories, but also to such simple forms of explanation [8.10, 38].

Thus, there seems to be an order of theory-levels or levels of abstraction, where the higher ones explain the lower ones, and where abduction is the process that takes the reasoner from a lower level to a higher one. Such a hierarchy of levels may also be the clue to understanding how (intuitive) cognition works below explicit sentential reasoning and how the latter comes about in ontogenetic development.

Peirce famously argued that perceptual judgments are no abductions. However, he seems to have been too strict or narrow-minded in this context (see also [8.3, pp. 42–43], [8.4, pp. 268–276]). While he clearly admits that perceptual judgment “is plainly nothing but the extremest case of Abductive Judgements” [8.1, CP 5.185 (1903)] and that “abductive inference shades into perceptual judgment without any sharp line of demarcation between them” [8.1, CP 5.181 (1903)], he maintains that they are nonetheless distinct, because unlike abductive inferences, perceptual judgments were “absolutely beyond criticism” [8.1, CP 5.181 (1903)]. Peirce points out repeatedly that abduction as an inference requires control and that this misses in perceptual judgment [8.1, CP 5.157, 181, 183, 194 (1903)]. He therefore holds that perceptual judgment is the “starting point or first premiss of all critical and controlled thinking” [8.1, CP 5.181 (1903)], hence something on which abduction is based, but which does not belong to abduction itself.

However, Peirce fails to consider two aspects of perceptual judgments: first, they might be conceivable as

established facts in the sense of a complete triad of abduction, deduction, and induction. This would explain why we are (normally) certain of our perceptions. Second, and more importantly, Peirce fails to consider that abductions are well-controlled, not by conscious thought, but by action. Perceptions can be understood as habits of action, that is, of categorization and behavior in accordance with what we perceive. And finally, the abductive or conjectural part of this process is that with every new perception the individual literally *makes sense* of what enters into the sensory system. Sometimes these *creations* are fallacious or even foolish, but this puts them fully in line with abduction in general.

At least, this is what I suggest at this point, and it would certainly have to be examined in more detail. However, *Magnani's* [8.4] and *Park's* [8.39] reflections on animal, visual, and manipulative abduction point in the very same direction and could be accommodated as basic forms, not only of abduction, but also of inferential functioning in general. Moreover, reconstructing *the formation* of perceptual judgments in this way makes the pragmatist epistemology even more stronger, because there is no specific level of consciousness, where epistemic processes start (see [8.40] for a discussion of this link between abduction and pragmatism). As for perceptual judgments, they are at this basic level not controlled by conscious reflection, but nonetheless controlled in an embodied and enacted manner [8.41]. Epistemology, then, would rather be embedded in life and would not have to resort to any a priori forms of cognition whatsoever. It also constitutes, to my mind, a sound basis for nonreliabilist epistemological externalism.

Without being able to explain my main point here in detail, I just assume that there are levels over levels of understanding and interaction with one's environment. And even though Peirce has never developed a theory of successive abstraction in this overarching sense, he had a clear idea of the basic principle, which he calls *hypostatic abstraction*. To explain his ideas, Peirce relates to Molière's *Malade imaginaire*, where a medical student takes his oral examination in the last scene. He is asked why opium puts people to sleep and he confidently replies that opium had a dormitive virtue whose nature was to lull the senses to sleep [8.1, CP 5.534 (c. 1905)]:

“Quia est in eo  
Virtus dormitiva,  
Cujus est natura  
Sensus assoupire.

Whereupon the chorus bursts out,  
Bene, bene, bene, bene, responde:  
Dignus, dignus est entrare,  
In nostro docto corpore.”

Peirce explains [8.1, CP 5.534 (c. 1905)]:

“Even in this burlesque instance, this operation of hypostatic abstraction is not quite utterly futile. For it does say that there is some peculiarity in the opium to which the sleep must be due; and this is not suggested in merely saying that opium puts people to sleep.”

Elsewhere, he discusses the same idea, but speaks of *subjectal abstraction* as opposed to *precisive abstraction* (see also [8.42]).

Peirce [8.8, NEM III/2, p. 917 (1904)]:

“There are two entirely different things that are often confused from no cause that I can see except that the words *abstract* and *abstraction* are applied to both. One is *αφαίρεσις* leaving something out of account in order to attend to something else. That is *precisive* abstraction. The other consists in making a subject out of a predicate. Instead of saying, Opium puts people to sleep, you say it has dormitive virtue. This is an important proceeding in mathematics. For example, take all *symbolic* methods, in which operations are operated upon. This may be called *subjectal abstraction*.”

By *subjectal abstraction* Peirce means that “a transitive element of thought is made substantive, as in the grammatical change of an adjective into an abstract noun” [8.12, CP 2.364 (1901)]. Even though *dormitive virtue* does not explain why opium puts people to sleep, it states an explanatory problem in the sense that a general law (with opium as cause and putting people to sleep as effect) has to be explained at a higher, more abstract level. In this very sense, *dormitive virtue* goes beyond stating a mere disposition of opium (see also *Schurz's* discussion on this issue [8.6, pp. 219–221]).

Forms of abductive reasoning could, therefore, be distinguished according to levels of abstraction in the sense in which Jean Piaget discusses constructive development and cognitive architectures [8.43]. Among the forms that *Schurz* [8.6] differentiates, some are at the same level, while others belong to different levels. *Factual abduction* and *law abduction* all concern simple empirical laws, the latter establishing them, the former applying them. Higher level abduction is what he calls *theoretical-model abduction*: “The explanandum of a theoretical-model abduction is typically a well-confirmed and reproducible empirical phenomenon expressed by an *empirical law*” [8.6, p. 213].

However, the distinction between empirical laws, on the one hand, and theoretical models, on the other hand, seems to be still rather crude (again, if this is compared to the fine-grained, but highly systematic, distinctions

made by *Piaget* and *Garcia* [8.43]). To date, research on cognitive architectures has primarily focused on the lower end of the cognitive hierarchy, i. e., how relative simple conceptual and action schemata are built and grounded in the brain's modal systems for perception, emotions, and actions [8.41, 44, 45]. However, since ab-

duction is the process that leads to successively more abstract cognitions in the sense of hierarchical complexity, there is a promising route for further research and a systematic differentiation of types of abductions according to the cognitive levels, to which they apply (as for moral cognition see [8.46] as an example).

## 8.2 The Logicity of Abduction, Deduction, and Induction

### 8.2.1 Inferential Subprocesses and Abduction as Inferential Reasoning

As already mentioned above, Peirce regarded abduction as an extremely weak kind of inference. This raises the question of whether it is an inference at all. On top of this, he says that abduction is “nothing but guessing” [8.19, CP 7.219 (1901)] and its results merely “the spontaneous conjectures of instinctive reason” [8.18, CP 6.475 (1908)]. However, abduction is also said to “cover all the operations by which theories and conceptions are engendered” [8.1, CP 5.590 (1903)], and since it takes us to novel concepts and theories, he cannot mean *guesses* in the ordinary sense of picking out something at random from a range of existing objects of choice. However, the question remains whether abduction is an inference or merely an instinct. In a way, both seems to be true [8.47], but for the present purpose it suffices to stress that abduction has an inferential aspect [8.32, 47, 48]. So, let us try to track this inferential aspect of abduction.

In this respect it may be instructive to consider Peirce's thoughts on inference in general. On his view, all inferences are mental acts of reasoning and as such describe a process with a definite beginning and a definite end. Any inference begins with a question that requires an answer in the form of the respective conclusion. Abduction aims at possible explanations, deduction at necessary consequences following from certain premises, and induction aims at determining whether to accept or reject a hypothesis. Whatever the inference, however, the process of answering these questions contains three distinctive steps, which Peirce calls *colligation*, *observation*, and *judgment*.

Peirce [8.12, CP 2.442 (c. 1893)]:

“The first step of inference usually consists in bringing together certain propositions which we believe to be true, but which, supposing the inference to be a new one, we have hitherto not considered together, or not as united in the same way. This step is called *colligation*.”

Peirce [8.12, CP 2.443–444 (c. 1893)]:

“The next step of inference to be considered consists in the contemplation of that complex icon . . . so as to produce a new icon. [. . .] It thus appears that all knowledge comes to us by observation. A part is forced upon us from without and seems to result from Nature's mind; a part comes from the depths of the mind as seen from within [. . .].”

Peirce [8.12, CP 2.444]:

“A few mental experiments – or even a single one [. . .] – satisfy the mind that the one icon would at all times involve the other, that is, suggest it in a special way [. . .] Hence the mind is not only led from believing the premiss to judge the conclusion true, but it further attaches to this judgment another – that *every* proposition *like* the premiss, that is having an icon like it, *would* involve, and compel acceptance of, a proposition related to it as the conclusion then drawn is related to that premiss.”

He concludes that “[t]he three steps of inference are, then, colligation, observation, and the judgment that what we observe in the colligated data follows a rule” [8.12, CP 2.444]. The step of colligation is consistently used and explained and thus seems to be rather clear [8.1, CP 5.163 (1903)], [8.1, CP 5.579 (1898)]. However, Peirce is less precise about the other two. In particular, his differentiation, in this context, between a *plan* and the *steps* of reasoning may cause some confusion [8.1, CP 5.158–166 (1903)]. As for the *plan* he says that [8.1, CP 5.162 (1903)]:

“we construct an icon of our hypothetical state of things and proceed to observe it. This observation leads us to suspect that something is true, which we may or may not be able to formulate with precision, and we proceed to inquire whether it is true or not.”

Thus, we observe what is colligated in the premise in order to produce a result. Even though this observation may be guided by strategies and other background knowledge the result will first come about in a spontaneous act as the reasoner becomes conscious of it.

When discussing observation in the context of abduction, he goes on to a general description of observation that brings out this main feature very plainly [8.1, CP 5.581 (1898)]:

“And then comes an Observation. Not, however, an External observation of the objects as in Induction, nor yet an observation made upon the parts of a diagram, as in Deduction; but for all that just as truly an observation. For what is observation? What is experience? It is the enforced element in the history of our lives. It is that which we are constrained to be conscious of by an occult force residing in an object which we contemplate. The act of observation is the deliberate yielding of ourselves to that *force majeure* – an early surrender at discretion, due to our foreseeing that we must, whatever we do, be borne down by that power, at last.”

Thus, the observed result is forced upon us in a rather uncontrolled manner. We just see it and can't help seeing it. However, in order to come to a conclusion as the last step of inference, we have to evaluate whether the result is valid in terms of the respective inference. This constitutes the judgmental step that finalizes each inference (see [8.49] for this matter).

### 8.2.2 The Validity of Abduction, Deduction, and Induction

Peirce is explicit concerning the validity of an abductive judgment [8.1, CP 5.197 (1903)]:

“What is good abduction? What should an explanatory hypothesis be to be worthy to rank as a hypothesis? Of course, it must explain the facts. But what other conditions ought it to fulfill to be good? The question of the goodness of anything is whether that thing fulfills its end. What, then, is the end of an explanatory hypothesis? Its end is, through subjection to the test of experiment, to lead to the avoidance of all surprise and to the establishment of a habit of positive expectation that shall not be disappointed. Any hypothesis, therefore, may be admissible, in the absence of any special reasons to the contrary, provided it be capable of experimental verification, and only insofar as it is capable of such verification. This is approximately the doctrine of pragmatism.”

Valid *abduction* thus has to satisfy two criteria:

1. It has to *explain the facts*, meaning that the initial surprise be eliminated, and
2. The explanation has to be *capable of experimental verification* in the pragmatist sense.

Any abductively observed result that does not meet these criteria will have to be rejected. If the criteria are met, however, the hypothesis will have to be accepted as a valid abductive conclusion (see also my reflections in Sect. 8.1.1). From this point of view, we can now understand Peirce's famous statement of the abductive inference [8.1, CP 5.189 (1903)]:

“The surprising fact, C, is observed;  
But if A were true, C would be a matter of course,  
Hence, there is reason to suspect that A is true.”

This only relates the *final* subprocess of abduction, the judgmental part. However, it is not to be confused with abduction as an inferential cognitive process as a whole [8.50]. *Kapitan* has famously criticized Peirce's concept of abduction, claiming that it was essentially a deductive argument [8.51]. However, he fails to see that the above statement does not describe the entire process of abductive reasoning. And, as far as this *deductive* aspect of the abductive judgment is concerned, Peirce himself expresses this clearly [8.1, CP 5.146 (1903)], [8.40, p. 168]. However, this does not turn the abductive judgment into a deductive inference, because it is not the primary task to derive C, since C is already known and constitutes the premise, whereas A constitutes the conclusion.

*Kapitan's* later account of abduction [8.51] is largely adequate, but still there is one widespread problem. Like many others, he conflates the abductive judgment with the selective aspect that I have argued above (Sect. 8.1.1) should be excluded. *Hintikka* [8.52, pp. 44–52] grapples with the notion of abductive inference for just the same reason. In my view, this makes it all the more important to drive a deep wedge between accommodating the facts as *the* abductive task, and evaluating abductively valid hypotheses as an inductive task.

The validity of *deduction* seems to be unproblematic. So, let us move straight to *induction*. It has already been pointed out above that induction is the inference that yields factual knowledge, constituting factual truth. However, what is the precise relation between knowledge and truth? The classical notion of knowledge as *justified true belief* requires that a proposition be true in order to be known. However, a main theorem from the point of view of pragmatism is that knowledge is logically prior, that is, knowledge establishes truth rather than requiring it as a condition. After all, this is the basic idea of disquotationalism [8.26, pp. 57–64].

As regards the validity of induction, I adopt an analysis of knowledge and its formation proposed by *Suppe* [8.53] within the framework of a possible-worlds semantics. He suggests a nonreliabilistic externalist approach to knowledge. On this view, we know *p* if it is not causally possible that we perceive the evidence

as it is unless the suggested hypothesis is true. This is indicated by a causal possibility operator  $\diamond$ , where *causal possibility* refers to all logically possible worlds that are consistent with the natural laws of our world (i. e., our current background knowledge regarding natural laws). According to Suppe’s approach, the truth of a proposition results from knowing it, and knowing results from the condition stated in (iv), below, being satisfied. Furthermore, “satisfying (iv) entails the satisfaction of condition (iii)” [8.53, p. 402], since  $R$  and/or  $K$  function as decisive indicators for  $\Phi$ .

*S propositionally knows that  $\theta$  if and only if*

- (i) *S* undergoes a cognitive process  $R$ , or *S* has prior knowledge that  $K$
- (ii) *S*, knowing how to use  $\Phi$  and knowing how to use  $\theta$  with the same propositional intent, as a result of undergoing  $R$  or having prior knowledge that  $K$  entertains the proposition  $\Phi$  with that propositional intent as being factually true or false
- (iii)  $\Phi$  is factually true
- (iv) there exists a conjunction  $C$  of partial world state descriptions and probability spaces such that  $C \ \& \ \sim \diamond \Phi \ (C \ \& \ R \ \& \ K \ \& \ \sim \Phi) \ \& \ \diamond \Phi \ (C \ \& \ \sim \Phi) \ \& \ R \ \& \ \diamond \ (R \ \& \ \sim \Phi)$
- (v) as a result of undergoing  $R$  or  $K$ , *S* believes that  $\Phi$  [8.53, p. 405].

As a result, induction can be conceived in terms of an elaborate eliminative inductivism in the sense of Earman [8.54]. A theory is to be adopted, if all that has been observed so far supports it and that no alternative hypothesis is conceivable (at the current state of knowledge).

The results of my analysis are condensed in Fig. 8.2 (which is reduced to the essential features). Note that the diagram shows steps in the inferential processes. They are not to be misread as syllogisms.

### 8.3 Inverse Inferences

#### 8.3.1 Theorematic Deduction as Inverse Deduction

Writing about mathematical reasoning, Peirce says: “My first real discovery about mathematical procedure was that there are two kinds of necessary reasoning, which I call the Corollarial and the Theorematic” [8.55, NEM IV, p. 49 (1902)]. However, scholars disagree on what is the content of this discovery. For Hintikka, “a valid deductive step is theorematic, if it increases the number of layers of quantifiers in the proposition” [8.56, p. 307]. Ketter claims that Hintikka fails to see “the true importance of Peirce’s corollar-

	Abduction	Deduction	Induction
Colligation	$C$	$H \wedge P$	$\Box((H \wedge P) \rightarrow E) \wedge E$
Observation	$H \rightarrow \diamond C$	$(H \wedge P) \rightarrow E$	$E \wedge \neg \diamond(E \wedge \neg H)$
Judgement	$\diamond H$	$\Box((H \wedge P) \rightarrow E)$	$\Box H$

Fig. 8.2 A formal model of inferential (sub)processes

In abduction we colligate the relevant aspects of a given explanatory problem, that is, what happens to be the case, hence  $C$ .  $C$  is observed with the intention to find a theoretical hypothesis  $H$  that would, if true, explain  $C$ , that is, render the previously surprising phenomenon causally possible. As one hits on an idea, one has to make sure that  $H$  would really explain  $C$ . This is the abductive judgement  $\diamond H$ .

This result gained from abduction is then used as input for the following deduction, together with suitable premises  $P$  available from background knowledge. These are observed so as to generate necessary consequences, in particular empirical hypotheses  $E$ . The judgment  $\Box((H \wedge P) \rightarrow E)$  states that  $E$  follows with necessity from  $(H \wedge P)$ .

Again, the deductive conclusion is input into induction, where it is colligated with the actual experiment, which are then observed. This observation is more than just recording what happens; in fact, such recording would have to be understood as the main part of the inductive colligation. Observation in the context of induction means to look at these results (maybe at the time when they are actually produced) under the aspect of whether they confirm the tested hypothesis and disconfirm its rivals. If the final outcome is positive,  $H$  is accepted as causally necessary, hence  $\Box H$ .

ial/theorematic reasoning distinction” [8.57, p. 409], which, according to Ketter, is that “it makes significant contributions toward showing that mathematics and logic are observational, experimental, hypothesis-confirming sciences” [8.57, p. 409]. Ketter also maintains that the “production of experiments within theorematic reasoning, on Peirce’s view, is done through abduction” [8.57, p. 411]. Referring to this argument, Hoffmann says he had “spent some effort to find in Peirce’s writings hints at such a connection between abduction and theorematic reasoning, but without much success” [8.48, p. 293]. However, Hoffmann acknowledges and discusses obvious similarities between the-

orematic deduction and abduction and comes to the following result: “It is one thing *to prove* a theorem and another to *formulate* it” and continues that “it would make sense to describe the first task as theorematic deduction and the second task as abduction” [8.48, p. 294].

In view of this puzzlement concerning the proper understanding of theorematic deduction and its relation to abduction, my suggestion is not to subdivide theorematic deduction into abductive and deductive aspects, but to reconstruct theorematic deduction as a form of reasoning of its own, albeit similar to abduction in an important respect. As for the similarity between abduction and theorematic deduction, Peirce himself remarks that “[i]t is very plainly allied to retrodution, from which it only differs as far as I now see in being indisputable” [MS 754 (1907), quoted from [8.48, p. 293]]. And the commonality apparently lies in the creative act of introducing a new idea not present in the premises from which one starts [8.58, p. 97].

Peirce [8.55, NEM IV, 42 (1902)]:

“What I call the theorematic reasoning of mathematics consists in so introducing a foreign idea, using it, and finally deducing a conclusion from which it is eliminated. Every such proof rests, however, upon judgments in which the foreign idea is first introduced, and which are simply self-evident. As such, they are exempt from criticism.”

Peirce [8.55, NEM IV, 49 (1902)]:

“The peculiarity of theorematic reasoning is that it considers something not implied at all in the conceptions so far gained, which neither the definition of the object of research nor anything yet known about could of themselves suggest, although they give room for it.”

Again, the *foreign idea* is what alludes to abduction, and once it is gained, *self-evident* judgments can be taken in order to prove a theorem. Elsewhere in the same text, Peirce has made clear that these self-evident judgments are, in fact, corollarial deductions [8.55, NEM IV, 38 (1902)]:

“*Theorematic deduction* is deduction in which it is necessary to experiment in the imagination upon the image of the premiss in order from the result of such experiment to make corollarial deductions to the truth of the conclusion.”

All these explanations by Peirce can be accommodated, if theorematic abduction is conceived of as an inverse deduction that infers from the result of corollar-

ial deduction to the premises from which the result can be deductively derived. The similarity with abduction results from the fact that theorematic deduction takes the reasoner to a theoretical point of view, which is the point in the above diagram on inferential reasoning (Fig. 8.1) where abduction would take her. Thus, abduction and theorematic deduction both aim at the same point (Fig. 8.3).

Within this frame of reference, it also becomes clear why Peirce thinks that theorematic deduction is *ampliative*. He just did not call it *ampliative deduction*, because he feared that this labeling would have been considered as unacceptable [8.55, NEM IV, 1 (1901)]:

“It now appears that there are two kinds of deductive reasoning, which might, perhaps, be called *explicative* and *ampliative*. However, the latter term might be misunderstood; for no mathematical reasoning is what would be commonly understood by *ampliative*, although much of it is not what is commonly understood as *explicative*. It is better to resort to new words to express new ideas. All readers of mathematics must have felt the great difference between *corollaries* and *major theorems*.”

The overall process of theorematic deduction can then be analyzed based on the three inferential subprocesses discussed in Sect. 8.2.1, only that the process runs in the inverse direction, starting from a proposition to be proved, say whether  $p$  or  $\neg p$  is logically true (colligation). This is the premise of theorematic deduction, which is then observed in order to find a conceptual point of view from where to derive either  $p$  or  $\neg p$  (observation). Once a candidate for this is found, it has to be established by a corollarial deduction to  $p$  or  $\neg p$ , which is equivalent to *judgment* in the context of theorematic deduction. This is how I understand Peirce when he says [8.55, NEM IV, p. 38 (1902)] (see also [8.12, CP 2.267 (c. 1903)]; [8.59, CP 4.233 (1902)]):

“*Theorematic deduction* is deduction in which it is necessary to experiment in the imagination upon the

Fig. 8.3 Theorematic deduction in relation to the inferential triad

**Fig. 8.4** The seven bridges of Königsberg

image of the premiss in order from the result of such experiment to make corollarial deductions to the truth of the conclusion.”

Hoffmann, too, stresses that theorematic reasoning (he uses the notion of *theoric transformations*) essentially consists in “looking at facts from a novel point of view” – a phrase taken from [8.60, MS 318] ([8.7, p. 581], [8.48, p. 291], [8.4, p. 181]). And the fact that attaining this novel point of view is first of all the result of *observation* that subsequently has to be subjected to a corollarial deduction as judgment within theorematic deduction may also explain the following passage.

Peirce [8.61, NEM III, p. 869 (1909)]:

“To the Diagram of the truth of the Premisses something else has to be added, which is usually a mere *May-be*, and then the conclusion appears. I call this *Theorematic* reasoning because all the most important theorems are of this nature.”

Ketner [8.57, p. 408] refers to this passage to underpin his view that theorematic deduction is a kind of abduction. However, on my account theorematic deduction is a *May-be*, firstly, in the sense of introducing a theoretical point of view, and secondly, because it is spontaneously generated by *observation* and still has to be submitted to *judgment*. This is my reconstruction of theorematic deduction as inverse deduction. Further refinements might be necessary, in particular analyzing the variants that Levy discusses in [8.58, pp. 98–103]. However, this must be left to a separate analysis. Here, I prefer to provide an instructive example and extend the idea of inverse inferences to include inverse abduction and inverse induction.

**Fig. 8.5** Graph of the state sequence in seven bridges problem

### 8.3.2 An Example for Theorematic Deduction

In addition to Peirce’s examples like Desargues’ theorem (discussed in [8.7, pp. 581–584]), I suggest Leonhard Euler’s solution of the Königsberg bridge problem as a case in point. In Euler’s time, the river Pregel formed the topological shape shown in Fig. 8.4. The question is whether it is possible to pass all seven bridges on a walk while passing each bridge only once.

To solve this problem, Euler used a graph in which the state sequence is shown as transitions from region to region. Figure 8.5 shows how this looks like, if one starts in region A and passes the first five bridges in numerical order. Accordingly, the number of regions in this diagram will always be  $N + 1$ , where  $N$  is the number of all bridges. Moreover, with the five bridges connected to region A, this region is mentioned three times. A so-called *uneven region*, that is, one with an uneven number of bridges, will always appear  $(n + 1)/2$  times in the graph, independently from whether one starts in this very region or in another region. This is different for even regions. If we only consider regions A and B, there are only two bridges. If one starts in A, A is mentioned twice and B only once. If one starts in B, it is the other way round. In general, the region is mentioned  $n/2$  times if one starts outside this region, and  $n/2 + 1$  times if one starts from within.

However, all regions in the seven bridges problem are uneven so that the solution is rather simple. A walk on which one passes each bridge only once encompasses seven transitions between eight states. However, each region must appear  $(n + 1)/2$  times in the diagram, which means three times for region A and two for regions B through D, that is, nine altogether. Hence, the desired walk is impossible.

This example shows that from an abstract topological point of view it is possible to formulate principles from which the impossibility of the specified walk can be deduced. The diagram in Fig. 8.4, together with the question, represents the *colligated* premiss, which

is then observed. The result of this *observation* is the approach represented in the graph in Fig. 8.5 and the further reflections based on it. The final *judgment* consists in deriving the solution, that is, the proof as such.

### 8.3.3 Inverse Abduction and Inverse Induction

Based on the reconstruction of theorematic deduction as an inverse deduction, it follows naturally that there could be two other forms of reasoning: inverse abduction and inverse induction (Fig. 8.6). Moreover, since inverse (theorematic) deduction is similar to abduction in that it aims at the same point in Fig. 8.6, inverse abduction should be similar to induction, and inverse induction should be similar to deduction.

Inverse abduction starts from some theory or abstract concept and searches, for examples, possible instantiations. For instance, the economist *Nicholas Kaldor* [8.62] suggested the cobweb model, which explains how supply (S) and demand (D) develop if time lags are assumed for the reaction of the supply side to a change in demand and vice versa (see Fig. 8.7). If the supply curve is steeper than the demand curve, prices (P) and quantities (Q) will gradually converge to the equilibrium. However, if the slope is the same, supply and demand will fluctuate cyclically.

If it is asked what would be a case in point of such a persistently fluctuating supply and demand, this would require what I call *inverse abduction*. The theoretical model has to be understood on the abstract level, but it is unclear whether there is a concrete case at all to it. An example would be the so-called *pork cycle* that was observed in the 1920s in the United States and in Europe. Kaldor's theoretical model provides a possible explanation for such phenomena, but in this case the argument runs in the opposite direction, from the theory to the case. The similarity to induction consists in the fact that inverse abduction projects a possible explanation onto a case (and

**Fig. 8.7a,b** The cobweb model: (a) successive adjustment of supply and demand; (b) cyclical fluctuations of supply and demand

all other relevant cases one might think of or encounter). The difference is that it is only a provisional projection (if the theory is true), whereas in induction factual truth in the pragmatist sense is established.

The difference can also be stated in this way: inverse abduction starts from the *colligation* of a theoretical model of some sort, which has a meaning but as yet no reference. This theoretical model is *observed* in order to be able to project it onto some case to which it refers (here is the similarity to induction). Finally, it has to be *judged* (abductively) whether the case that suggested itself can really be subsumed to the theoretical model.

Other examples for inverse abduction are riddles that we give children to solve, once they can use concepts independently from concrete references, for example, *What has a face and two hands, but no arms or legs? A clock.* The task is to find something concrete that satisfies this abstract definition. Again, the definition is first colligated, then observed in order to project it onto some concrete object, and the final part consists in the judgment as to whether the definition really applies to the object and whether this inference is thus abductively valid (in this case, as a *possible* circumscription of a clock).

Turning to *inverse induction*, this inference starts from the purported truth (or falsity) of a theory and tries to infer back to a crucial experiment that determines whether the theory would have to be accepted or rejected. This form of reasoning typically applies when two competing approaches stand against each other, in particular when both are well-confirmed by ordinary induction, but are mutually incompatible. One famous example are Bell's inequalities based on the Einstein–Podolsky–Rosen (EPR) Gedankenexperiment. The EPR assumptions entail the fulfilment of Bell's inequalities, quantum theory entails their violation. Hence, the inequalities did not prove anything in themselves, but were the basis for a decisive empirical test, eventually carried out by Alain Aspect, which

**Fig. 8.6** Inverse inferences

established the validity of quantum theory and refuted Einstein in his attempt to save classical physics.

Inverse induction is similar to deduction because it essentially involves deductive steps to derive the decisive experimental conditions. However, as opposed to Peirce's thematic deduction, it does not prove anything, and unlike corollary deduction it does not just derive what follows from a certain theory, but starts from competing theories and the intention to determine which one is true and which one false. From this *col-ligated* premise, the theories are *observed* in order to find the decisive experimental conditions, and the final *judgment* does not concern the deductive validity but whether the test would really be decisive.

Another, much simpler, example is the so-called *Wason* selection task [8.63], one of the most investigated experimental paradigms. This task consists in determining which two of four cards one has to turn over in order to know whether a certain rule is true or false. There are cards with a yellow or a red back, and on their front-sides they have a number, even or odd. Now, there are four cards showing (1) a 3, (2) an 8, (3) a red back, and (4) a yellow back. The rule says that if a card shows an even number on one face, then its op-

posite face is red. So, which two cards have to be turned over to see whether this rule is violated? The solution is the two cards showing the 8 and the yellow back.

Not even 10% get this right (at least in this rather formal context). The reason may be that they fail to see that they need to use modus ponens (*even number*  $\rightarrow$  *red back*) and modus tollens ( $\neg$  (*red back*)  $\rightarrow$   $\neg$  (*even number*)). However, the task is not just to use modus ponens and modus tollens correctly, and therefore it is not just about deduction, as is usually thought. Rather is it the most important part of this reasoning task to *find out* (through *observation*) that these deductive rules allow you to determine which two cards have to be turned over. Moreover, strictly speaking, there are also two competing hypotheses involved: the rule and its negation.

To sum up, all inverse inferences contain elements of its predecessor in the ordinary order, and these elements are important in the *observational* subprocesses. Here, inverse abduction relates to induction, inverse deduction to abduction, and inverse induction to deduction. However, the final judgments are abductive in inverse abduction, deductive in inverse deduction, and inductive in inverse induction.

## 8.4 Discussion of Two Important Distinctions Between Types of Abduction

### 8.4.1 Creative Versus Selective Abduction

In this section, some of the important and/or controversial distinctions between abductions shall be discussed starting with the one between creative and selective abduction (see also [8.64]). Most scholars endorse the view that abduction has to fulfil these two purposes, but *Magnani* [8.3, 4] and *Schurz* [8.6], in particular, discuss them even as separate forms of abduction. However, I oppose this view and think that (1) there is no separate form of abduction that is selective, and (2) that the ways in which abduction might be rightly called *selective* are specific forms of one and the same basic form of abduction. As I have pointed out already in Sects. 8.1.1 and 8.2.1 all other candidates for selective abduction would have to be reinterpreted as forms of induction.

*Selective abduction* is an elusive concept, not only because it is easily confused with IBE, but also because different authors understand it in different ways. In particular, I see a difference in the usage by *Magnani* and *Schurz*, on the one hand, and by *Kapitan* and *Hintikka* on the other hand. As for the latter, *Hintikka* [8.17, p. 503] cites *Kapitan*, who claims that “[t]he purpose of *scientific* abduction is both (i) to gen-

erate new hypotheses and (ii) to select hypotheses for further examination” [8.13, p. 477]. They state this with particular reference to [8.18, CP 6.525], where *creation* and *selection* do not appear as two different kinds of abduction, but as two aspects of one and the same notion of abduction [8.18, CP 6.525 (c. 1901)]:

“The first starting of a hypothesis and the entertaining of it, whether as a simple interrogation or with any degree of confidence, is an inferential step which I propose to call *abduction*. This will include a preference for any one hypothesis over others which would equally explain the facts, so long as this preference is not based upon any previous knowledge bearing upon the truth of the hypotheses, nor on any testing of any of the hypotheses, after having admitted them on probation.”

The last part of the passage ensures that the selective aspect is not confused with induction. Furthermore, Peirce makes clear that selection does not mean separating stupid ideas from sensible ones, because they all have to *explain the facts*, that is, have to be valid abductions. Thus, selection does not refer to the abduc-

tive judgment by which stupid ideas are sorted out. The hypotheses among which to select have already passed this test. However, elsewhere Peirce makes clear that “the whole question of what one out of a number of possible hypotheses ought to be entertained becomes purely a question of economy” [8.18, CP 6.528 (1901)]. Hence, this aspect of selection concerns abduction only from a practical point of view, not from a logical one, as I have argued above in Sect. 8.1.1.

Turning to *Magnani* and *Schurz*, the latter writes [8.6, p. 202]:

“Following *Magnani* (2001, p. 20) I call abductions which introduce new concepts or models *creative*, in contrast to *selective* abductions whose task is to choose the best candidate among a given multitude of possible explanations.”

This sounds as if IBE were included in this notion of selective abduction. However, *Magnani* is careful to distinguish between these, when he discusses what he calls the “two main epistemological meanings of the word abduction” [8.4, p. 10], that is, *creative* and *selective* abduction on the one hand, and IBE on the other hand. Then, he goes on to differentiate between *creative* and *selective* abduction [8.4, p. 10]; see also [8.3, p. 19]:

“An illustration from the field of medical knowledge is represented by the discovery of a new disease and the manifestations of causes which can be considered as the result of a *creative* abductive inference. Therefore, *creative* abduction deals with the whole field of the growth of scientific knowledge. This is irrelevant in medical diagnosis where instead the task is to *select* from an encyclopedia of prestored diagnostic entities.”

As it turns out, *selective abduction* in *Magnani*’s sense is nothing else than the application of previously established knowledge. In this sense, some suitable background knowledge is activated or *selected* vis-à-vis a certain problem. As I understand it, medical diagnosis is only one example; such *selective* abductions seem to be part of everybody’s daily routines. I have discussed abduction as knowledge application above in Sect. 8.1.2, so there is nothing more to add here. On this account, *selective abduction* is to be reconstructed as the abductive step of knowledge application, in particular in the sense that:

1. Specific (explanatory) concepts or theories are activated (selected) from one’s background knowledge, triggered by the initial problem at hand.
2. Accepted as the result of abductive judgment (whereas other spontaneously generated ideas may be rejected as abductively invalid).

3. And, if there are more than one abductively valid ideas, ranked in order of a priori plausibility, however, only for economical reasons.

To be sure, the latter aspect is clearly the least central one, since it is merely of practical importance. And it should be noted that *Magnani* does not attribute it to *selective abduction* when he writes: “Once hypotheses have been selected, they need to be ranked [...] so as to plan the evaluation phase by first testing a certain preferred hypothesis” [8.3, p. 73]. As also *Peirce* warns in [8.18, CP 6.525, see above], it should by no means be confused with inductive reasoning.

This reconstruction of *selective abduction* as the abductive step in knowledge application allows us, finally, to solve the riddle highlighted in the introduction. It concerns what *Peirce* calls *a priori reasoning* in the passage quoted there, and which he associates with his earlier, syllogistic, concept of abduction (i. e., hypothetical reasoning). When *Peirce* explains that this kind of [8.2, CP 8.209 (c. 1905)]:

“abduction is the inference of the truth of the minor premiss of a syllogism of which the major premiss is selected as known already to be true while the conclusion is found to be true,”

1. The major premiss to be *selected* is the theory to which one abduces (e.g.,  $\forall x(Fx \rightarrow Gx)$ ).
2. Based on the conclusion (of the syllogism), *Ga*, which is found to be true and which needs to be explained.
3. And *Fa* results from the assumption that the occurrence of *Ga* is a case of  $\forall x(Fx \rightarrow Gx)$ .

With respect to (3), the only question remaining is whether the abduction runs from *Ga* to  $\forall x(Fx \rightarrow Gx)$ , as I have suggested, or from *Ga* to *Fa*, as *Schurz* [8.6] might perhaps argue based on his notion of *factual abduction*. This is discussed in the following section.

### 8.4.2 Factual Versus Theoretical Abduction

This is how *Schurz* formalizes the basic form of *factual abduction* [8.6, p. 206]:

“*Known Law*: If *Cx*, then *Ex*  
*Known Evidence*: *Ea* has occurred  

---

---

*Abduced Conjecture*: *Ca* could be the reason.”

Let us take an example that *Aliseda* uses in [8.21]. I wake up in the morning in a hotel, look out of the window, and see that the lawn is wet (*w*). Wondering about why it is wet, I think that it might have rained (*r*) or that the sprinklers were on (*s*) last night. Hence, there

are two possible causes,  $r$  and  $s$ . However, the question is whether I abduce to  $r$  and  $s$  or to  $r \rightarrow w$  and  $s \rightarrow w$ , respectively. In my view, both is true in a certain way, which becomes clear if we distinguish inferential subprocesses.

Of course, as we look out of the window and wonder about  $w$  (*colligation*), either  $r$  or  $s$  or both spring to our minds (*observation*). However, since we are looking for an explanation of  $w$ , we are not interested in  $r$  or  $s$  as such, but whether  $w$  because of  $r$  ( $r \rightarrow w$ ) or whether  $w$  because of  $s$  ( $s \rightarrow w$ ). In other words, the law must be implicit in observing the fact, because the fact only makes sense as part of the law. What's more, a spontaneous idea is no valid abduction (not yet). In order to abduce that  $r$  or that  $s$  we have to perform a judgment (explicitly or implicitly) of the type of Schurz's schema. Thus, Schurz's schema fleshes out the abductive judgment in the case of factual abduction. And even though  $r$  or  $s$  may be our spontaneous ideas they are engendered not as such, but as the antecedents of  $r \rightarrow w$  and  $s \rightarrow w$ , respectively.

This may all appear self-evident. However, since factual abduction is basically abduction to known laws and theories (rather than to facts pure and simple), we can unify Schurz's subforms of factual abduction, namely *observable-fact abduction*, *first-order existential abduction*, and *unobservable-fact abduction* [8.6, pp. 27–210]. Moreover, it reveals that Schurz's distinction between factual abduction, on the one hand, and law abduction, on the other hand, does not refer to entirely different forms of abductive inference. The only difference is that law abduction relates to the *creative* abduction of new laws, whereas factual abduction relates to *selective* abduction as the abductive step of the application of known laws. Schurz sanctions this view when he writes [8.6, p. 207]:

“In the setting of factual abduction, the problem consists in the *combinatorial explosion* of the search space of possible causes in the presence of a rich background store of laws but in the *absence* of a rich factual knowledge. Thus, factual abductions are primarily *selective* in the sense of Magnani.”

However, I see yet another problem with this description. It assumes that there is a multitude of possible hypotheses from which one or a few plausible ones have to be chosen. In the very same sense he explains that [8.6, p. 204]:

“in abduction problems we are often confronted with thousands of possible explanatory conjectures (or conclusions) – everyone in the village might be the murderer.”

To my mind, this misrepresents (factual) abduction. For on the one hand, if we take each of the village's inhabitants as a hypothetical candidate for the murderer, and intend to boil down their number by some kind of inference, this would have to be *induction*. On the other hand, if the problem really is to reduce the search space, then we are not dealing with a multitude of conjectures as abductive solutions to some abductive problem (finding the murderer), but we are dealing with a *problem*. The fact that there is a multitude of possibilities changes the situation. The task is not simply to select one of those *hypotheses*, but to come up with a *theory* that explains the murder and identifies particular individuals as suspects.

The deeper truth is that instead of merely selecting we move to higher level of reasoning, just in the sense that I have described in Sect. 8.1.3. The very first level, in the example of the murderer, is that one understands that the very concept of a murder implies that the victim has been killed by someone. Given that there are certain objective restrictions, not every human being can possibly have committed the crime, but just the set of the villagers. The next step is to move to the level of narratives in the sense of a coherent description of what might have happened. However, there might be still too many possibilities, or also none. Yet another step could consist in applying theoretical knowledge as professional profilers do.

As already expounded in Sect. 8.1.3, my suggestion is to reconstruct different forms of abduction in the dimension of theoretical abstraction. Since factual abduction comes out as applied law or theory abduction, there is no fundamental difference between factual and theoretical abduction. However, what should be distinguished systematically are cognitive levels in reasoning, down from elementary cognitive levels captured by forms like *visual* (or *iconic*) and *manipulative* abduction [8.3, 4], and up to high-level abductions like *theoretical model abduction*, *common cause abduction* [8.6], or *trans-paradigmatic abduction* [8.65]. Magnani, Schurz, Hoffmann, and others have done pioneering work explicating abductive inferences at both ends concrete versus abstract cognition, a dimension which I prefer to call hierarchical complexity. However, the precise structures of hierarchical complexity have yet to be revealed (cf. Sect. 8.1.3, above).

One also has to be careful to distinguish forms that do not fit entirely in this order. This seems to apply, for example, to Schurz's notions of (extrapolational) *micropart abduction* and *analogical abduction* [8.6, pp. 216–219]. The former consists, for example, in extrapolating from the behavior of observable macroobjects to assume that unobservable microparts like atoms behave in the same (or a similar) way. However, this is

equivalent to an analogical inference from macro to micro, and as such both do not indicate a certain level of abstraction or complexity, but, following also Peirce, are to be reconstructed as compound inferences (including an abductive and an inductive step to hit the abductive target), as I have tried to reveal in [8.15]. Moreover, Schurz's concept of *hypothetical (common) cause abduction* [8.6, pp. 219–222], where he draws to the *dormitive virtue* example (see Sect. 8.1.3), is, to my mind, no valid form of abduction, since this kind of reasoning establishes a problem (*Why does opium put people to sleep? or What does its dormitive virtue consist of?*), not the solution. It yields the premise of an abductive inference, but not more.

### 8.4.3 Explanatory Versus Nonexplanatory Abduction

However, Schurz [8.6] points to yet another interesting form of abduction, when he discusses “statistical factor analysis” as a kind of “probabilistic common cause abduction” [8.6, pp. 228–231]. He believes that [8.6, p. 228]:

“factor analysis is a certain generalization of hypothetical common cause abduction, although sometimes it may better be interpreted in a purely instrumentalistic way.”

As I have argued a few lines above, hypothetical common cause abduction is no abduction. However, I fully endorse Schurz's interpretation of factor analysis (to be sure, he thinks of *exploratory factor analysis*, not *confirmatory factor analysis*, which also exists). Exploratory factor analysis is a method to reveal correlative structures among numerical representations of empirical items and thus give us a clue as to possible common causes for certain types of effects (the dependent variables). However, factor analyses do not explain anything. *Factors*, once extracted, have to be interpreted, and this is where they are used as hints toward a possible explanation. Hence, their value consists in being instrumental to find interesting patterns in a dataset, but they do not explain anything as such.

Throughout this chapter, I have focused on (forms of) explanatory abduction as the basic purposive context, because this is the received understanding of abduction in general and because most concepts of abductions fall into this category. However, Gabbay and Woods [8.5] have made the point that there are types of reasoning that do not have an explanatory purpose. In particular, they point to abductions that do not aim at a plausible explanation, because they, in fact, “advance propositionally implausible hypotheses” [8.5, p. 115]. The purpose of such abductions cannot be ex-

planatory, but they can serve to fulfil some other kind of purpose.

As an example, Gabbay and Woods discuss Newton's action-at-a-distance theorem, which was never conceived of as an explanatory hypothesis by Newton, since he thought that such an action was causally impossible [8.5, p. 116]. From that point of view, it is clear that in the explanatory context an *action at a distance* poses a problem, that is, that of explaining gravitation, not a solution (like Schurz's hypothetical cause abduction discussed above). However, Gabbay and Woods point out that [8.5, p. 118–119]:

“[t]he action-at-a-distance equation serves Newton's theory in a wholly instrumental sense. It allows the gravitational theory to predict observations that it would not otherwise be able to predict.”

Thus, there are hypotheses that are not set forth in order to explain something, but to serve some practical purpose. Newton used the action-at-a-distance equation as a tool to predict phenomena. Psychologists have used factor analysis as a tool to find basic personality traits (pioneered by [8.66]).

However, technological sciences in general – mechanical, electronic, medical engineering and the like – do not aim at explanations. They aim at practical, though principled, solutions to practical problems. They may be built on explanatory theories, but what they develop does not have to be *true*; it has to be *effective*. Sometimes, technologies have been invented, before the mechanisms that they employed were sufficiently understood (as for instance in the case of x-rays). Moreover, although technological theories are typically based on explanatory theories, the latter ones are *input* in this context and appear in the *colligation* of abductive inferences to technological theories.

For instance, laser technology employs physics in many ways, but the technology itself is *abducted* from these background theories. Before the laser was invented, Charles Townes and Arthur Schawlow developed the *maser* (microwave amplification by stimulated emission of radiation) in 1954 to amplify radio signals. A few years later, the first optical laser was invented. The technological aim was to *produce* focused light, not to explain anything. And even though it was unclear, at the outset, what practical purposes the technology could be used for, it was effective in producing what it was invented for. On top of this, searches for practical applications – of which we know many today – can be easily accommodated as inverse abductions (as suggested in Sect. 8.3.3), from technological theories (here: laser technology) to concrete practical problems which might be solved, either in principle or better than without the technology. Based on technologies, the practical

problems and further background knowledge, the functioning of machines and appliances can be deductively derived, and the machines or prototypes so constructed are then evaluated in terms of effectiveness and efficiency.

Hence, there seems to exist (at least) a second kind of cognitive architecture parallel to the explanatory architecture (and, accordingly, Magnani [8.4, p. 71] is right to claim that Gabbay and Woods' [8.5] notion of instrumental abduction is orthogonal to the forms he distinguishes). On the one hand, explanatory concepts and theories aim at true accounts, and truth is the evaluative criterion for induction. On the other hand, there

are technological theories, which are inductively evaluated in terms of effectiveness and – as far as economic aspects are concerned – efficiency.

However, technological theories seem to be just one domain of reasoning among others to complement explanatory reasoning. At least moral concepts and ethical theories could be a third domain [8.26, pp. 90–101], [8.30], and they are evaluated neither in terms of truth nor effectiveness, but in terms of *justice*. I can only allude to these domains, here, and a separate paper will be necessary to expound these ideas. However, what seems obvious is that there are distinct realms of abduction and of reasoning in general.

## 8.5 Conclusion

To sum up, I have argued (as Peirce did) that there are precisely three basic kinds of inferences: abduction, deduction, and induction. I have distinguished three inferential subprocesses and introduced three inverse types of inference, based on the analysis of inferential subprocesses. My claim is that all kinds of real reasoning ought to be reducible to one of these three basic forms, its inverse forms, or a particular subprocesses within one inferential type. However, I also mentioned analogical reasoning as a special compound form of inferential reasoning and referred the reader to my [8.15].

Moreover, I have tried to point out that apart from these fundamental kinds of reasoning, inferences can be distinguished along two dimensions. One is the dimension of hierarchical complexity so that concepts and theories are built upon one another across cognitive levels, from elementary perception and action to high-

level scientific theories. The other dimension, discussed in the previous section, is that of *domains*. By a *domain* I do not mean, in this context, issues of content to which one and the same theory is applied, but domains of reasoning. In this respect I distinguished explanatory, technological, and moral/ethical concepts and theories.

This framework opens up a taxonomical system that might be able to accommodate the various forms of reasoning in general, and of abduction in particular, that have been suggested so far. I have discussed a few of them, but by far not all. However, my hope is that this taxonomy allows us to account for all a multitude of varieties of abduction, deduction, and induction, while recognizing them in their particular place and function in an overall system and help us to a distinctive understanding of similarities and differences between these individual forms.

# Magnani's M

## 9. Magnani's Manipulative Abduction

Woosuk Park

Despite the extensive research in logic, cognitive science, artificial intelligence, semiotics, and philosophy of science, there is no sure proof that we have better or deeper understanding of abduction than its modern founder, Charles S. Peirce. In this sense, one of the most important developments in recent studies on abduction is Lorenzo Magnani's discovery of manipulative abduction. In this paper, I shall examine in what ways Magnani goes with and beyond Peirce in his views on manipulative abduction. After briefly introducing his distinction between theoretical and manipulative abduction (Sect. 9.1), I shall discuss how and why Magnani counts diagrammatic reasoning in geometry as the prime example of manipulative abduction (Sect. 9.2). Though we can witness an increasing interest in the role of abduction and manipulation in what Peirce calls theorematic reasoning, Magnani is unique in equating theorematic reasoning itself as abduction. Then, I shall discuss what he counts as some common characteristics of manipulative abductions (Sect. 9.3), and how and why Magnani views manipulative abduction as a form of practical reasoning (Sect. 9.4). Ultimately, I shall argue that it is manipulative abduction that enables Magnani to extend abduction to all directions to develop the eco-cognitive model of abduction. For this purpose, fallacies and animal abduction will be used as examples (Sect. 9.5).

### 9.1 Magnani's Distinction Between Theoretical and Manipulative Abduction

It is certainly worthwhile to take a view of Magnani's multiple distinctions of abduction:

1. Selective/creative
2. Theoretical/manipulative
3. Sentential/model based.

Above all, our focal interest lies in understanding the relationships between these three distinctions. The

most revealing seems to be the following text [9.1, p. 11]:

“What I call *theoretical abduction* certainly illustrates much of what is important in creative abductive reasoning, in humans and in computational programs, especially the objective of selecting and creating a set of hypotheses (diagnoses, causes, hy-

potheses) that are able to dispense good (preferred) explanations of data (observations), but fails to account for many cases of explanations occurring in science and in everyday reasoning when the exploitation of environment is crucial. [...] I maintain that there are two kinds of theoretical abduction, *sentential*, related to logic and to verbal/symbolic inferences, and *model based*, related to the exploitation of internalized models of diagrams, pictures, etc.”

This text is important because it presents a tentative definition of theoretical abduction and the subdivision of theoretical abduction into sentential and model-based abductions. The passage above says that theoretical abduction can be a kind of creative reasoning (not only selective, as in diagnosis).

Insofar as Magnani views theoretical abduction also as a kind of creative abduction, and again insofar as he tries to distinguish between theoretical and manipulative abductions, he must also view manipulative abduction as a kind of creative abduction. *Magnani* introduces the concept of manipulative abduction as follows [9.1, p. 12] (cf. [9.2, pp. 15,16,43]):

“The concept of *manipulative abduction* captures a large part of scientific thinking where the role of action is central, and where the features of this action are implicit and hard to be elicited: Action can provide otherwise unavailable information that enables the agent to solve problems by starting and by performing a suitable abductive process of generation or selection of hypotheses.”

For my present purpose, the following text is more informative [9.1, p. 39] (cf. [9.2, p. 53]):

“*Manipulative abduction* [9.2] – contrasted with theoretical abduction – happens when we are thinking through doing and not only, in a pragmatic sense, about doing. [...] Manipulative abduction

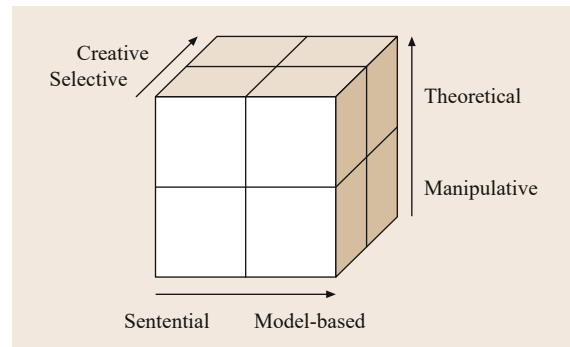

Fig. 9.1 Magnani’s classification of abduction: Cubic model

refers to an extra-theoretical behavior that aims at creating communicable accounts of new experiences to integrate them into previously existing systems of experimental and linguistic (theoretical) practices.”

As is clear from this quote, manipulative abduction is contrasted with theoretical abduction by Magnani.

Further, in *Magnani*’s writings it is also stressed that manipulative abduction is occurring taking advantage of those model-based (e.g., iconic) aspects that are embedded in external models [9.1, p. 58]:

“We have seen that manipulative abduction is a kind of abduction, usually model based and so intrinsically *iconic*, that exploits external models endowed with delegated (and often implicit) cognitive and semiotic roles and attributes.”

This line of thought clearly indicates a possibility that Magnani’s multiple distinctions of abduction may work in such a way that each distinction represents a different dimension in our understanding of abduction. What I have in mind might be presented crudely as in the cubic model of Magnani’s classification of abduction (Fig. 9.1).

## 9.2 Manipulative Abduction in Diagrammatic Reasoning

### 9.2.1 Abductive and Manipulative Aspects of Diagrammatic Reasoning

In Peirce’s distinction between corollarial and theorematic reasoning, there are some typical texts in Peirce’s writings frequently invoked by the commentators. For example, Hoffmann cites [9.3, NEM 4:38] in [9.4, p. 290] (cf. [9.5, CP 2.267], [9.6, CP 7.204] and [9.3, NEM 4:288]):

“Corollarial deduction is where it is only necessary to imagine any case in which the premises are true in order to perceive immediately that the conclusion holds in that case [...] Theorematic deduction is deduction in which it is necessary to experiment in the imagination upon the image of the premiss in order from the result of such experiment to make corollarial deductions to the truth of the conclusions.”

Marietti cites the following texts as “the classic description given by Peirce of the two types of deduction” [9.7, CP 2.267]:

“A corollarial deduction is one that represents the conditions of the conclusion in a diagram and finds from the observation of this diagram, as it is, the truth of the conclusion. A Theorematic Deduction is one which, having represented the conditions of the conclusion in a diagram, performs an ingenious experiment upon the diagram, and by the observation of the diagram, so modified, ascertains the truth of the conclusion.”

Marietti [9.7, p. 120, NEM 4:42]:

“What I call the *theorematic* reasoning of mathematics consists in so introducing a foreign idea, using it, and finally deducing a conclusion from which it is eliminated.”

CP 4.233 seems, however, the most extensive text pertinent to Peirce's distinction between corollarial/theorematic distinction in broader perspective. I discussed this text rather extensively in [9.8].

In their treatment of these typical Peircean texts, recently many commentators have discussed diagrammatic reasoning in connection with abduction. For example, Hoffmann [9.4, p. 411] writes (cf. [9.9, p. 337], [9.10, p. 69], [9.11, p. 465] and [9.4, pp. 292–293]):

“The creativity of theorematic reasoning and the role of observation in it support the interpretation that there must be, for Peirce, a connection between this form of deductive reasoning and abduction. Both, at least, seem to fulfill the same task. What theorematic deduction is for mathematics, abduction seems to be for scientific discoveries in general. Thus, Ketner (1985) maintained ‘that production of experiments within theorematic reasoning, on Peirce's view, is done through abduction’.”

It is interesting to note that, while Ketner clearly invokes abduction in the “experiments within theorematic reasoning”, Hoffmann himself is merely making an analogy between theorematic deduction in mathematics and abduction in science. Campos [9.12] is also somewhat similar to Hoffmann's case [9.12, p. 135]:

“In mathematical reasoning, the imagination creates experimental diagrams that function as signs that are then perceived, interpreted, judged, often transformed, re-imagined, re-interpreted, and so on, in a continuous process. Experimental hypotheses are imaginative suggestions that become subject to logical scrutiny as possible keys to the solution of a theorematic deduction. Once conceived, the

experimental diagrams act like objects for observation; they now resist the mind, as it were, and must be evaluated as solutions to the mathematical problem. In this respect, this process is akin to abduction in the natural sciences.”

Marietti [9.7] seems to go one step further in this regard, for she explicitly mentions the necessity of abduction in theorematic demonstration in mathematics [9.7, p. 124]:

“In my view, it is possible to identify an operation in thought – it takes place essentially above the diagram and involves precisely the perceptual relations organized by it – which forms the core of the abductive inference that makes the demonstration synthetic, theorematic, creative. This is the point: There has to be an abductive inference in every informative demonstration given that a connecting thread running through Peirce's thoughts on the logic of science is that ‘[a]ll the ideas of science come to it by the way of abduction’ (CP 5.145). In a theorematic demonstration – that is in a demonstration introducing new knowledge into our mathematical system – it is necessary to carry out an abductive passage.”

However, Marietti leaves it unclear how it is possible to have “synthetic, theorematic, creative” mathematical demonstration. So, one might say that Marietti is here detecting the indispensability of abduction in theorematic reasoning.

Stjernfelt [9.13] is clearly much more informative as to how abduction takes place in theorematic reasoning [9.13, p. 276]:

“An important issue here – both related to the *addition of new elements or foreign ideas* and to the *experiment* aspects – is the relation between theorematic reasoning and abduction. A finished piece of theorematic reasoning, of course, is deductive – the conclusion follows with necessity from the the premises. But in the course of conducting the experiment, an abductive phase appears when investigating which experimental procedure, among many, to follow; *which* new elements or foreign ideas to introduce. This may require repeated, trial-and-error abductive guessing, until the final structure of the proof is found – maybe after years or centuries. Exactly the fact that neither premises nor theorems need to contain any mentioning of the experiment or the introduction of new elements makes the abductive character of experimentation clear. Of course, once the right step has been found, abductive searching may cease and the deductive character of the final proof stands out.”

Here, Stjernfelt makes it exactly clear when and where abduction intervenes in theorematic reasoning. When conducting the experiments with diagrams, “an abductive phase appears”. He is also quite explicit about what are abduced at that phase: i.e., “which experimental procedure to follow”, and “*which* new elements or foreign ideas to introduce”. His view seems attractive in that at least it rather persuasively appeasing the apparent conflict between theorematic deduction and abduction. Though “a finished piece of theorematic reasoning, of course, is deductive”, abductive phase appears in doing experiments with diagrams. At the same time, he also explains why it has been difficult to notice abductive phase in theorematic reasoning, for “once the right step has been found, abductive searching may cease and the deductive character of the final proof stands out”. He is perceptive enough to point out that [9.13, p. 276]:

“Exactly the fact that neither premises nor theorems need to contain any mentioning of the experiment or the introduction of new elements makes the abductive character of experimentation clear.”

A few recent commentators are also to be congratulated for their discussion of manipulation in diagrammatic reasoning. After pointing out that “for Peirce mathematics is a science of observation and experimentation upon diagrams akin to the physical sciences”, for example, Campos draws our attention to the following text [9.12, p. 129] (cf. [9.14, CP 4.530]):

“One can make experiments upon uniform diagrams, and when one does so, one must keep a bright lookout for unintended and unexpected changes thereby brought about in the relations of different significant parts of the diagram to one another. Such operations upon diagrams, whether external or imaginary, take the place of the experiments upon real things that one performs in chemical and physical research. Chemists have ere now, I need not say, described experimentation as the putting of questions to Nature. Just so, experiments upon diagrams are questions put to the Nature of the relations concerned.”

In case of experiments on diagrams, it may be hard not to notice the manipulative character, for in experimenting on diagrams by doing certain operations we are doing nothing but manipulations. Indeed, Campos is able to locate a text, in which Peirce actually uses the language of *manipulation* extensively [9.15, CP 3.363, emphasis is mine]:

“As for algebra, the very idea of the art is that it presents formulae which can be *manipulated*, and

that by observing the effects of such *manipulation* we find properties not to be otherwise discerned. In such *manipulation*, we are guided by precious discoveries which are embodied in general formulae. These are the patterns which we have the right to imitate in our procedure, and are the icons par excellence of algebra [Emphasis is mine].”

Among the commentators of Peirce, Marietti seems to be the one who highlights *manipulation on diagrams* in more detail. She is rather explicit in presenting *manipulation on diagrams* as the core of mathematical proofs, and thereby mathematics itself [9.16, p. 166]:

“Manipulation and observation of diagrammatic signs characterize Peirce’s idea of mathematical reasoning. The more that such reasoning leads to relevant conclusions, the more manipulation and observation play a key role in it.”

Marietti [9.7, p. 112]:

“It is well known that Peirce conceived mathematics as a semiotic activity using particular kinds of signs, which he called diagrams. In his view, the work of a mathematician consists entirely in observing and manipulating these diagrammatic signs.”

Marietti’s commentaries are quite recommendable in that they enable us to understand not only that manipulation on diagrams is everywhere in mathematics, but also why it has such an important role in mathematics. For example, she writes [9.16, p. 151]:

“In order to experiment on a diagram, in fact, we must face a single instance of it, that is to say, a spatial and temporal object, be it actually drawn on a blackboard or rather only scribed in our mind. To look for a suitable strategy of demonstration (to look for the *foreign idea* required in order to get to the conclusion) means to manipulate a concrete, individual diagram according to established rules, until the new cognition, whatever it might be, appears on it. Manipulation, action, concrete experimentation: this is what a mathematical proof consists in.”

Here, Marietti painstakingly elaborates what is involved in diagrammatic reasoning. Experiment on diagrams is nothing but manipulation on them, which requires “to manipulate a concrete, individual diagram”. Indeed, both equations, that is, *experimenting is manipulating*, and *manipulation is manipulation on individual diagrams* are emphasized by Marietti, as is clear from the following [9.7, p. 121]:

“It is even more understandable, however, in the case of the most fertile type of deduction, theore-

matic deduction, in which it is not only a question of observing the relations that emerge but also to *carry out* some operations on this single model, on the individual *token*. What is to be done is to manipulate this sign, to implement a series of ingenious experiments – hence creative and not mechanical – aimed at finding the correct modification so as to cause to emerge the new relations that we then observe. Such concrete work presupposes the concrete quality of a material sign.”

*Marietti* further hints at what is involved in *manipulation on individual diagrams*. *Sun-Joo Shin* seems to be another important contributor to the research on Peircean diagrammatic reasoning, who emphasizes the aspect of individuality in diagrams [9.17, 18]. [9.16, p. 153]:

“The second step of the demonstration introduces that spatiotemporal level which is indispensable in view of the manipulation of the diagram. The *ekthesis* consists in the individualization of the initial proposition, the *protasis*, which is expressed in general terms.”

*Marietti* [9.16, p. 154]:

“Demonstrating means manipulating individual diagrams. In order to experiment on a diagram, as we said above, we must face a single instance of it. Deduction cannot work on general signs alone.”

*Marietti* [9.16, p. 155]:

“The individual diagrammatic sign really acts upon us. We manipulate it, and it reacts on us concretely showing some new relations that impose themselves upon our understanding, escaping any doubt.”

In sum, some commentators of Peirce's distinction between corollarial and theorematic reasoning indeed detect abductive and manipulative aspects of diagrammatic reasoning in geometry. None of them, however, invokes *manipulative abduction* in diagrammatic reasoning.

### 9.2.2 Magnani on Manipulative Abduction in Diagrammatic Reasoning

Magnani already dealt with the role of model based and manipulative abductions in geometrical reasoning in several places [9.1, 2, 19, 20]. Since there have been many attempts to understand Peirce's philosophy of mathematics focusing on his distinction between corollarial and theorematic reasoning, as we saw earlier, Magnani's results in model based and manipulative abduction can be easily combined with previous results

in diagrammatic reasoning in geometry. For example, Peircean corollarial reasoning would be model based, theoretical, and visual abduction. On the other hand, Peircean theorematic reasoning would be model based, manipulative, and visual abduction [9.1, pp. 117–118, 176–178].

In assimilating Magnani's views of manipulative abduction to Peirce's theory of diagrammatic reasoning in geometry, the most difficult point would be that Peircean corollarial and theorematic reasonings are usually counted as deductions. *Magnani* claims that “theorematic deduction can be easily interpreted in terms of manipulative abduction” [9.1, p. 178]. However, it is not clear what he has in mind. Probably, further hints can be secured from the following quote from *Magnani* [9.1, p. 181]:

“As I have already indicated Peirce further distinguished a *corollarial* and a *theoric* part within *theorematic reasoning*, and connected theoric aspects to abduction [Hoffmann, 1999, p. 293]: *Théoric reasoning* [...] is very plainly allied to what is normally called abduction [Peirce, 1966, 754, ISP, p. 8].”

As Hoffmann points out, however, there can be different possible interpretations of what Peirce says “either he identified abduction/retroduction and theoric reasoning here or he claimed that there is abduction in mathematics beyond theoric deduction” [9.4, p. 293].

Though extremely interesting and significant, it is not my present concern to answer whether we can safely understand Peirce's theoric reasoning as abduction, as *Magnani* claims. What is at stake is rather how and why *Magnani* views diagrammatic reasoning in geometry as the prime example of manipulative abduction. If so, by assuming that we now understand the basics of *Magnani*'s notion of manipulative abduction, we need to raise the following further questions. Why does he appeal to diagrammatic reasoning in geometry whenever he has to give an example of manipulative abduction? What exactly does *Magnani* mean by manipulative abduction in geometrical reasoning? What exactly do mathematicians do when they experiment on diagrams? What kind of things could be manipulated in mathematicians' manipulative abduction? What is it for to do manipulative abduction?

*Magnani* uses Fig. 9.2 as an example of cognitive manipulating in diagrammatic demonstration. According to him, this example, taken from the field of elementary geometry, shows how [9.1, p. 176]:

“a simple manipulation of the triangle in Fig. 9.2a gives rise to an external configuration – Fig. 9.2b – that carries relevant semiotic information about the

**Fig. 9.2a,b** Diagrammatic demonstration that the sum of the internal angles of any triangle is 180. (a) Triangle (b) diagrammatic manipulation/construction (after [9.1, p. 176])

internal angles of a triangle *anchoring* new meanings”

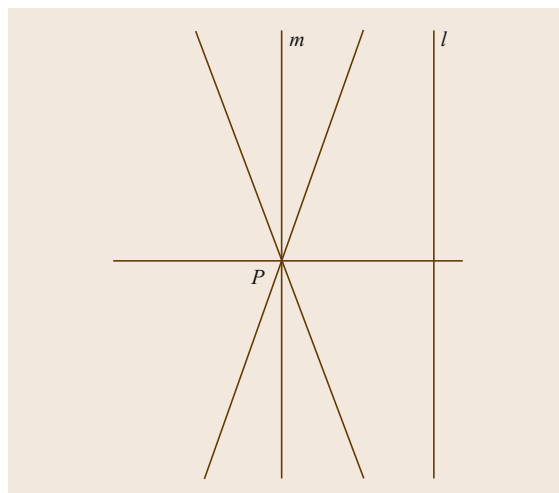

What Magnani counts as cognitive manipulating here is “the entire process through which an agent arrives at a physical action”. And he claims that the very process can be understood by means of the concept of manipulative abduction. He continues [9.1]:

“In this perspective manipulative abduction is a specific case of cognitive manipulating in which an agent, when faced with an external situations from which it is hard or impossible to extract new meaningful features of an object, elects or creates an action that structures the environment in such a way that it gives new information which would be otherwise unavailable and which is used specifically to infer explanatory hypotheses.”

The reason why diagrammatic reasoning in geometry is instrumental for Magnani to introduce *manipulative abduction* is not hard to understand. From his point of view, it is important to first note that “mathematical diagrams play various roles in a typical abductive way”. Secondly, they are external representations that provide both explanatory and nonexplanatory abductive results [9.1, pp. 118–119]. The first point can be elaborated by the following [9.1, p. 118]:

“Following the approach in cognitive science related to the studies in distributed cognition, I contend that in the construction of mathematical concepts many external representations are exploited, both in terms of diagrams and of symbols. I have been interested in my research in diagrams which play an *optical* role – microscopes (that look at the infinitesimally small details), telescopes (that look at infinity), windows (that look at a particular situation), a *mirror* role (to externalize rough mental models), and an *unveiling* role (to help create new and interesting mathematical concepts, theories, and structures).”

Also, the second point is further explained by Magnani as follows.

**Fig. 9.3** Euclidean parallel line (after [9.1, p. 120])

Two of them are central [9.1, pp. 118–119]:

- They provide an intuitive and mathematical *explanation* able to help the understanding of concepts difficult to grasp or that appear obscure and/or epistemologically unjustified. I will present in the following section some mirror diagrams which provided new mental representations of the concept of parallel lines.
- They help abductively *create* new previously unknown concepts that are *nonexplanatory*, as illustrated in the case of the discovery of the non-Euclidean geometry.

As we can infer from the passage just quoted, the discovery of non-Euclidean geometry provides Magnani an ideal springboard to elaborate his views on manipulative abduction in diagrammatic reasoning. In fact, *Magnani* [9.1] uses Lobachevsky’s discovery of non-Euclidean geometry as an example, in which manipulative abduction played a crucial role. After briefly narrating what happened to the parallel postulate of Euclidean geometry throughout the history, he explains Lobachevsky’s strategy to face the problem situation as follows [9.1, p. 123]:

“Lobachevsky’s strategy for resolving the anomaly of the fifth postulate was first of all to manipulate the symbols, second to rebuild the principles, and then to derive new proofs and provide a new mathematical apparatus; of course his analysis depended on some of the previous mathematical attempts to demonstrate the fifth postulate. The failure of the demonstrations – of the fifth postulate from the other four – that was present to the attention of Lobachevsky, lead him to believe that the difficulties that had to be overcome were due to causes

Fig. 9.4 Non-Euclidean parallel lines (after [9.1, p. 131])

traceable at the level of the first principles of geometry.”

According to Magnani, we can detect the anomaly of the fifth postulate from Fig. 9.3, for, unlike other four postulates, “we cannot verify empirically whether two lines meet, since we can draw only segments, not lines” [9.1, p. 121].

In contrast to the diagram of Fig. 9.3, as Magnani explains, the diagram of Fig. 9.4 introduces a new definition of parallelism [9.1, p. 13]:

“All straight lines which in a plane go out from a point can, with reference to a given straight line in the same plane, be divided in two classes – into *cutting* and *not-cutting*. The boundary lines of the one and the other class of those lines will be called *parallel to the given lines*.”

See Magnani [9.1, p. 131] for further details:

“The external representation is easily constructed like in of [Lobachevsky, Figure 2.11, Prop. 16, p. 13], where the angle  $HAD$  between the parallel  $HA$  and the perpendicular  $AD$  is called the angle of parallelism, designated by  $\Pi(p)$  for  $AD = p$ . If  $\Pi(p)$  is  $< 12\pi$ , then upon the other side of  $AD$ , making the same angle  $DAK = \Pi(p)$  will lie also a line  $AK$ , parallel to the prolongation  $DB$  of the line  $DC$ , so that under this assumption we must also make a distinction of sides in parallelisms”

Magnani explicitly claims that Lobachevsky’s inference here “to rebuild the first principles of geometry is prevalently a kind of *manipulative* and *model-based* abduction” [9.1, 127]. As Magnani aptly points out, “Lobachevsky’s target is to perform a geometrical abductive process able to create the new and very abstract concept of non-Euclidean parallel lines”, and what is remarkable is that “the whole epistemic process is mediated by interesting manipulations of external mirror diagrams” [9.1, p. 123].

### 9.3 When Does Manipulative Abduction Take Place?

Earlier we saw how Magnani introduces the distinction between theoretical and manipulative abduction, and how he counts diagrammatical reasoning in geometry as an example of manipulative abduction. In order to capture the essence of manipulative abduction, however, we may need a bit more systematic desiderata. In other words, one might want an individually necessary but jointly sufficient set of conditions for manipulative abduction. Does Magnani present some such things in addition to his frequently invoked claim that “*manipulative* abduction happens when we are thinking *through* doing and not only, in a pragmatic sense, about doing?” [9.1, p. 46].

The answer seems to be positive, for, at least Magnani presents what he calls “some common features of the tacit templates of manipulative abduction [...] that enable us to manipulate things and experiments in science are related to” [9.1, pp. 47–48]:

“1. sensibility toward the aspects of the phenomenon which can be regarded as *curious* or *ano-*

*malous*; manipulations have to be able to introduce potential inconsistencies in the received knowledge [...]; 2. preliminary sensibility toward the *dynamical* character of the phenomenon, and not to entities and their properties, common aim of manipulations is to practically reorder the dynamic sequence of events into a static spatial one that should promote a subsequent bird’s eye view [...]; 3. referral to experimental manipulations that exploit *artificial apparatus* to free new possibly stable and repeatable sources of information about hidden knowledge and constraints [...]; 4. various contingent ways of epistemic acting: *looking* from different perspectives, checking the different information available, comparing subsequent events, *choosing*, *discarding*, *imaging* further manipulations [...].”

Further, Magnani finds it interesting that manipulative abductions are present in mathematics in the sense that geometrical constructions indeed satisfy all these requirements [9.1, p. 49].

However, it would be prudent not to conclude so fast, for it is not clear which comes first. In a lengthy paragraph just quoted selectively, Magnani uses the well-known history of electromagnetism in the nineteenth century in order to make sense of many requirements for manipulative abduction. Magnani uses Oersted's report of his experiment about electromagnetism as an example of 1, for it described some anomalous aspects. Also, he uses Davy's setup of using an artificial tower of needles as an example of 3. *Magnani* seems indebted here to *Gooding's* views of the roles of construals in science [9.1, pp. 48–51] and [9.21, pp. 29–69]. But, in order for the episodes in that history to be examples of manipulative abduction, should not there be first pre-established set of requirements for manipulative abduction? Magnani seems delighted to find geometrical constructions satisfy all these requirements. But he does not first discover manipulative abduction in geometrical constructions, and sort out the commonalities of manipulative abductions, and not the other way around? There is some suspicion as to possible circularity in Magnani's way of thinking. Furthermore, not to mention the fact that it is by no means clear what relations hold between these requirements, there is room for doubt whether each of the requirements is evidently an individually necessary condition for manipulative abduction.

Some such worries make us wonder whether Magnani simply enumerates some interesting traits that appear in cases of manipulative abduction. Magnani

seems still collecting interesting cases that deserve to be characterized as manipulative abductions, and identifying their interesting traits. In other words, he has just drawn our attention to when and by what manipulative abductions occur. What is interesting is, if we are on the right track, such a search to find cases of manipulative abduction and their typical characteristics might result in a disjunctive property, whose extension could be rather huge. Though it might be interesting and meaningful to pursue such a property, it is definitely not necessary and sufficient for manipulative abduction. Contrary to what one might believe Magnani is doing, he may be after entirely different target. Roughly speaking, Magnani seems to aim at demonstrating the ubiquity or pervasiveness of manipulative abduction. What I have in mind could become clearer by “the example discussed above”. It is rather impressive that Magnani is able to uncover all the various iconic roles in geometrical diagrams, such as optical, mirror, unveiling roles. These different iconic roles are related to different types of representations. Further, there is no end to the synthesis or multiplication of these representations, for [9.1, p. 49]:

“[t]he various procedures for manipulating objects, instruments and experiences will be in their turn reinterpreted in terms of procedures for manipulating concepts, models, propositions, and formalisms”

## 9.4 Manipulative Abduction as a Form of Practical Reasoning

In order to sharpen the notion of manipulative abduction in contrast to theoretical abduction, we need some defining characteristics that appropriately capture the essence of manipulative abduction. But we by no means have exhausted the possible cases of manipulative abduction. We seem to rather find the ubiquity or pervasiveness of manipulative abduction. So, we seem to face a dilemma or at least an essential tension: If we stop somewhere satisfied with a set of conditions that fits with some typical common characteristics of manipulative abductions, we might run the risk of ignoring or neglecting some interesting cases of manipulative abduction; On the other hand, if we indefinitely continue our search for all different types of manipulative abduction, and try to subsume all of them under the general rubric of manipulative abduction, it could become difficult to find any that is definitely not a case of manipulative abduction.

I believe that Magnani is also well aware of such a dilemma or an essential tension in his investigations

into manipulative abduction. He seems to make a decision to do an inductive search for important cases of manipulative abduction first, thereby postponing to give a rigorous definition or a necessary and sufficient conditions for manipulative abduction. My hunch may be supported by Magnani's two interesting moves. First, in Chapter 7, “Abduction in human and logical agents: Hasty generalizers, hybrid abducers, fallacies” of his book on abductive cognition, he introduces an illuminating new perspective on manipulative abduction, according to which we can view manipulative abduction “as a form of practical reasoning” [9.1, p. 362; see also p. 384]:

“What has been called manipulative abduction in the previous chapters will be re-interpreted as a form of practical reasoning, a better understanding of which can furnish a description of human beings as hybrid reasoners in so far they are users of ideal (logical) and computational agents.”

There are several interesting points to note regarding Magnani's new perspective of manipulative abduction as a form of practical reasoning. For convenience's sake, let us distinguish between scientific contexts and the contexts of ordinary life. As is clear from our discussion earlier, manipulative abduction plays important roles in scientific contexts. But with this new perspective, we may deepen our understanding of some of the characteristics of manipulative abduction in science. According to Magnani, for example, the first three among the new characteristics of manipulative abduction are also found in geometrical constructions. It may not be irrelevant to invoke, in this regard, *John Woods'* apt characterization of Magnani [9.22, p.240]:

“At the centre of Magnani's investigations is the reasoning of the *practical agent*, of the individual agent operating *on the ground*, that is, in the circumstances of real life. In all its contexts, from the most abstractly mathematical to the most muckily empirical, Magnani emphasizes the cognitive nature of abduction.”

If Woods is right, then it is not a small matter that manipulative abduction can be interpreted as a form of practical reasoning. Magnani is shifting our focus from more theoretical and abstract aspects of science to more practical and experimental aspects of science by his emphasis on manipulative abduction. Now, if we turn to the world of everyday reasoning with the new perspective of manipulative abduction as a form of practical reasoning, we may realize how indispensable manipulative abduction is for individual agents in virtually every moments and situations in real life. Again, *Woods'* succinct summary of the pages 363–384 of *Magnani* [9.1] is to the point [9.22]:

“In an original thrust, he identifies the practical agent as a cognitive system whose resources are comparatively scant and who sets his cognitive targets with due regard (and respect) for these resource-limitations.”

Magnani's second move is also impressive. In addition to the common characteristics of manipulative abduction discussed earlier, Magnani identifies some other common characteristics of manipulative abduction from the perspective of manipulative abduction as a form of practical reasoning [9.1, pp. 51–52]:

“5. Action elaborates a *simplification* of the reasoning task and a redistribution of effort across time [9.23], when we need to manipulate concrete things in order to understand structures which are otherwise too abstract [9.24], or when we are in presence of *redundant* and unmanageable information;

6. Action can be useful in presence of incomplete or inconsistent information – not only from the *perceptual* point of view – or of a diminished capacity to act upon the world: it is used to get more data to restore coherence and to improve deficient knowledge;
7. Action enables us to build *external artifactual models* of task mechanisms instead of the corresponding internal ones, that are adequate to adapt the environment to the agent's needs: Experimental manipulations exploit *artificial apparatus* to free new possible stable and repeatable sources of information about hidden knowledge and constraints.
8. Action as a *control of sense data* illustrates how we can change the position of our body (and/or of the external objects) and how to exploit various kinds of prostheses (Galileo's telescope, technological instruments and interfaces) to get various new kinds of stimulation: action provides some tactile and visual information (e.g., in surgery), otherwise unavailable.”

As individual agents with scant resources to manage and survive in complicated and unfriendly environments, we can understand without much difficulty what Magnani is talking about in this quote. Furthermore, as I shall show by some examples in the next section, Magnani's recent research, including not only those works directly concern abduction (such as *Magnani* [9.1]) but also virtually all other works apparently dealing with other subject matters (such as *Magnani* [9.25–27]) can be interpreted as examining the roles of manipulative abduction in all the different areas. Before turning to examples, let us briefly examine what new aspects of manipulative abduction are introduced by the characteristics 5 through 8 in addition to characteristics 1 through 4. The most salient point would be that *action-based* character of these characteristics are emphasized by Magnani. In some sense, there seems to be one–one correspondence between the new characteristics 5 through 8 and the old characteristics 5 through 8. For example, in both 3 and 7, *artificial apparatus* is invoked. The only difference is that in the latter externality of artifactual models is emphasized. Likewise, in both 4 and 8, some contingent ways of acting are invoked. The only difference is that, unlike epistemic acting in the former (e.g., looking from different perspective), real acting is done in the latter (e.g., control of sense-data by changing the position of the body). In other words, Magnani seems to be insinuating that, when we interpret manipulative abduction as a form of practical reasoning, thereby exploiting some action, we can find the new characteristics that were in some sense already pregnant in the old characteristics.

The following quote from *Magnani* [9.1] seems perfectly supports my understanding by clearly combining his two moves [9.1, p. 397]:

“Human beings spontaneously (and also animals, like already Peirce maintained) perform more or less rudimentary abductive and inductive reasoning. Starting from the low-level inferential performances of the kid’s hasty generalization that is a strategic success and a cognitive failure human beings arrive to the externalization of *theoretical* inductive and abductive agents as *ideal agents*, logical and

computational. It is in this way that *merely successful strategies* are replaced with successful strategies that also tell the *more precise truth* about things. Human informal nondemonstrative inferential processes of abduction (and of induction) are more and more externalized and objectified: These external representations can be usefully rerepresented in our brains (if this is useful and possible), and they can originate new improved organic (mentally internal) ways of inferring or suitably exploited in a hybrid manipulative interplay, as I have said above.”

## 9.5 The Ubiquity of Manipulative Abduction

In order to fathom Magnani’s mind in expanding the scope of manipulative abduction by treating it as a form of practical reasoning, the distinction between linguistic and prelinguistic agent could be at least equally fruitful as the distinction between scientific and everyday context. As he wants to find manipulative abduction in everyday as well as scientific contexts, he also wants to find it in prelinguistic as well as linguistic agents. How does Magnani expand manipulative abduction in science to manipulative abduction in everyday context? How does Magnani expand manipulative abduction in linguistic agents to manipulative abduction in prelinguistic agents? A nice strategic point to get an overview of both lines of expanding the scope of manipulative abduction may be secured in Chapter 7 of Magnani [9.1] entitled “Abduction in human and logical agents: Hasty generalizers, hybrid abducers, fallacies”. On the one hand, this chapter provides us with a clear example of nonexplanatory abduction, thereby representing the shift from the scientific to the practical. On the other hand, it presents us a foil for the search of manipulative abduction in nonhuman, prelinguistic agents. In both respects, interestingly, Magnani seems to be strongly influenced by and responding to *Gabbay* and *Woods* [9.28] and *Woods* [9.29].

### 9.5.1 Manipulative Abduction in Fallacies

As pointed out by *Park* [9.30], we can witness the recent surge of interest in classifying different patterns or types of abduction. Many philosophers, including *Thagard*, *Magnani*, *Gabbay* and *Woods*, *Schurz*, and *Hoffmann*, have suggested their own classifications emphasizing different aspects of abduction [9.1, 2, 28, 31–33]. Such a development is remarkable, in view of the fact that until quite recently the focus of the research on Peircean abduction was basically to identify its log-

ical form [9.34]. Among these contributions, *Gabbay* and *Woods* [9.28] seem most instrumental in expanding our purview by introducing nonexplanatory abductions. This is important, for as is clear from *Schurz* [9.32] and *Hoffmann* [9.33], attempts at classifying abduction is still largely focusing on the problem of classifying explanatory abduction in science. Not to mention nonexplanatory abduction in science, such as instrumental abduction, *Gabbay* and *Woods* [9.28] covers abduction in nonscientific context, such as legal abduction. *Magnani* welcomes *Gabbay* and *Woods*’ distinction between explanatory and nonexplanatory abduction as follows [9.1, p. 71]:

“In my previous book on abduction [9.2] I made some examples of abductive reasoning that basically are nonexplanatory and/or instrumentalist without clearly acknowledging it. The contribution of *Gabbay* and *Woods* to the analysis of abduction has the logical and epistemological merit of having clarified these basic aspects of abduction, until now disregarded in the literature. Their distinction between explanatory, nonexplanatory and instrumental abduction is orthogonal to mine in terms of the theoretical and manipulative (including the subclasses of sentential and model based) and further allows us to explore fundamental features of abductive cognition.”

*Magnani* is also strongly influenced by *Woods*’ extensive and revolutionary study of fallacies. Above all, *Magnani* is fully sympathetic with *Woods*’ project of the naturalization of logic, the official core topic of which is the one of logical fallacies [9.35, p. 20]. What is needed here is just to understand how *Magnani* adopts and appropriates *Woods*’ views of fallacies for his own eco-cognitive project. *Woods* contends, and *Magnani* confirms that fallacy has been counted as “a mistake in

reasoning, a mistake which occurs with some frequency in real arguments and which is characteristically deceptive" [9.1, p. 404] and [9.29]. However, Magnani points out that [9.1, pp. 404–405]:

“when they are used by actual reasoners, *beings like us*, that is in an eco-logical and not merely logical – ideal and abstract – way, they are *no longer* necessarily fallacies.”

Magnani agrees with Woods' conviction that from Aristotle onward logic has irremediably mismanaged the fallacies project. And he concurs with Woods' belief that naturalization of logic is appropriate to the task of “an account of fallacious reasoning – and of its detection, avoidance, and repair” [9.35, 36]. What Woods calls *EAUI-conception* of fallacies is the traditional perspective of fallacies that “fallacies are *Errors of Reasoning*, Attractive, Universal, and Incorrigible” [9.36, p. 135], [9.35, p. 21]. Now, Magnani reports Woods' views of fallacies as follows [9.35, p. 22]:

“According to Woods' last and more recent observations the traditional fallacies – hasty generalization included – do not really instantiate the traditional concept of fallacy (the EAUI-conception). In this perspective it is not that it is sometimes strategically justified to commit fallacies (a perfectly sound principle, by the way), but rather that in the case of the *Gang of Eighteen* traditional fallacies they simply are not fallacies. The distinction is subtle, and I can add that I agree with it in the following sense: The traditional conception of fallacies adopts – so to say – an *aristocratic* (ideal) perspective on human thinking that disregards its profound eco-cognitive character. Errors, in an eco-cognitive perspective, certainly are not the exclusive fruit of the so-called fallacies, and in this wide sense, a fallacy is an error – in Woods' words – ‘that virtually everyone is disposed to commit with a frequency that, while comparatively low, is nontrivially greater than the frequency of their errors in general’.”

By the term *Gang of Eighteen*, Woods refers to following typical fallacies [9.36, p. 5]:

“*ad baculum*, *ad hominem*, *ad populum*, *ad verecundiam*, *ad ignorantiam*, *ad misericordiam*, affirming the consequent, denying the antecedent, begging the question, gambler's fallacy, *post hoc, ergo propter hoc*, composition and division (of which *secundum quid* is a special case), faulty analogy, and *ignoratio elenchi* (of which straw man is a special case).”

Magnani's eco-cognitive perspective draws a rather sharp distinction between strategic and cognitive ra-

tionality, and he explicitly claims that “many of the traditional fallacies – hasty generalization for example – call for an equivocal treatment” [9.35, p. 21] and [9.1]. What he means by “an equivocal treatment” is that the so-called fallacies [9.1]:

“are sometimes cognitive mistakes and strategic successes, and in at least some of those cases, it is more rational to proceed strategically, even at the cost of cognitive error.”

Magnani also claims that his general agreement with Woods' views of fallacies can be further strongly motivated by his emphasis on what he calls the general *military* nature of language, that is:

1. Human language possesses a *pregnance-mirroring* function.
2. In this sense we can say that vocal and written language is a tool exactly like a knife.
3. The so-called fallacies, are certainly linked to that efficacious *military intelligence*, which relates to the problem of the role of language in the so-called *coalition enforcement*, which characterizes all the various kinds of groups and collectives of humans [9.35, p. 22].

Indeed Magnani contends that in this perspective language is basically rooted in a kind of *military intelligence*, a term coined by the mathematician *René Thom* [9.37], the creator of the so-called catastrophe theory. See Chap. 8 of *Magnani* [9.1] for more in-depth study of military intelligence and the notion of coalition enforcement.

Certainly most people would believe that communication is the primary function of language. Also, when broadly understood, communication might include the manipulation of other human beings by language. One possible danger is that whenever we talk about communicative function as the primary function of language, we tend to ignore or neglect the manipulative function of language. Clever and sometimes malicious uses of fallacies in order to manipulate other human beings, definitely there is military intelligence involved. In a word, we may say that manipulative abduction is crucial in understanding the role of fallacies in military intelligence.

## 9.5.2 Manipulative Abduction in Animals

I emphasized the central importance of animal abduction in Magnani's thought in a series of papers [9.30, 38, 39]. This section draws extensively from these, especially [9.38]. Unlike these previous articles, this time I want to highlight the role of manipulative abduction in animal cognition. One of the most pressing issues in

understanding abduction is whether it is an instinct or an inference. For many commentators find it paradoxical “that new ideas and hypotheses are products of an instinct (or an insight), and products of an inference at the same time” [9.40, p. 131]. Paavola refers to [9.41–46]. As Paavola points out, we seem to face a dilemma: “If abduction relies on instinct, it is not a form of reasoning, and if it is a form of reasoning, it does not rely on instinct” [9.40, p. 131]. Fortunately, Lorenzo Magnani’s recent discussion of animal abduction sheds light on both instinctual and inferential character of Peircean abduction (Magnani [9.1, especially Chapter 5], “Animal abduction: From mindless organisms to artifactual mediators”, which was originally published in Magnani *an Li* [9.25]). Contrary to many commentators, who find conflicts between abduction as instinct and abduction as inference, he claims that they simply co-exist.

In order to overcome the conflict between abduction as an instinct and abduction as an inference, it is not enough to draw attention to some relevant texts from Peirce and to provide insightful interpretation of them. Magnani needs to indicate exactly where he is going beyond Peirce, thereby pointing out wherein lies the limitation of Peirce’s views on abduction. It is of course an important matter for Magnani himself whether he is going *beyond* Peirce or not [9.1, p. 221]. Magnani finds such a clear example from Peirce’s different treatments of practical reasoning and scientific thinking [9.1, pp. 278–279]:

“Elsewhere Peirce seems to maintain that instinct is not really relevant in scientific reasoning but that it is typical of just the reasoning of practical men about every day affairs. So as to say, we can perform instinctive abduction (that is not controlled, not *reasoned*) in practical reasoning, but this is not typical of scientific thinking.”

Here Magnani quotes extensively from Peirce’s Carnegie application of 1902 (MS L75) (cf. Arisbe Website [9.47].) We should note that Magnani is fully aware of the fact that we can find many instances where Peirce allowed abductive instinct to humans even in scientific reasoning. For example, hypothesis selection is a largely instinctual endowment of human beings which Peirce thinks is given by God or related to a kind of Galilean *lume naturale* [9.1, p. 277] and [9.6, CP 7.220]:

“It is a primary hypothesis underlying all abduction that the human mind is akin to the truth in the sense that in a finite number of guesses it will light upon the correct hypothesis.”

Magnani counts commentators like [9.4, 40, 48] as maintaining that “instinct [...] *does not* operate at the

level of conscious inferences like for example in the case of scientific reasoning” [9.1, p. 279]. And he implicitly blames their assumption of instinct “as a kind of mysterious, not analyzed, guessing power” for such a claim [9.1]. Indeed Magnani distances himself from those commentators and Peirce himself as follows [9.1]:

“I think a better interpretation is the following that I am proposing here: Certainly instinct, which I consider a simple and not a mysterious endowment of human beings, is at the basis of both *practical* and scientific reasoning, in turn instinct shows the obvious origin of both in natural evolution.”

But on what ground does Magnani claim superiority of his interpretation? How could he be so sure that instinct is at the basis of both practical and scientific reasoning? Even though Magnani does not formulate an argument that proves his claim once and for all, there seem to be enough clues for fathoming his mind. In addition to his reliance on the naturalistic ground for abductive instinct in humans, Magnani is also attracted to the so-called synechism of Peirce. Further, he seems encouraged by two intriguing points from Peirce: (1) that “thought is not necessarily connected with brain”, and (2) that “instincts themselves can undergo modifications through evolution” [9.1, p. 278]. For the first point, Magnani actually quotes from Peirce [9.14, CP 4.551]:

“Thought is not necessarily connected with brain. It appears in the work of bees, of crystals, and throughout the purely physical world; and one can no more deny that it is really there, than that the colours, the shapes, etc. of objects are really there.”

On the other hand, for the second point, he again quotes from Peirce: [instincts are] “inherited habits, or in a more accurate language, inherited dispositions” [9.1, p. 278] and [9.5, CP 2.170].

In other words, Magnani seems to assimilate abduction as an instinct and abduction as an inference form both directions. This interpretation of Magnani’s strategy seems to be supported strongly by his explicit announcement [9.1, p. 267]:

“I can conclude that instinct versus inference represents a conflict we can overcome simply by observing that the work of abduction is partly explicable as a biological phenomenon and partly as a more or less *logical* operation related to *plastic* cognitive endowments of all organisms.”

To those who would allow abductive instinct to nonhuman animals but not to humans, he tries to emphasize the instinctual elements in human abductive reasoning. On the other hand, to those who would allow

abduction as inference to humans but not to nonhuman animals, he suggests to broaden the concept of inference, and thereby that of thinking. For the former project, Magnani cites hypothesis generation in scientific reasoning as a weighty evidence for abductive instinct in humans: From this Peircean perspective, hypothesis generation is a largely instinctual and non-linguistic endowment of human beings and, of course, also of animals. It is clear that for Peirce abduction is rooted in the instinct and that many basically instinctually rooted cognitive performances, like emotions, provide examples of abduction available to both human and nonhuman animals [9.1, p. 286]. Here, of course, Magnani's claim about *hypothesis generation* as instinctual must be still controversial. Someone may object that it should be able to work out what might explain a phenomenon. For further discussion of this complicated issue, please see [9.1, pp. 18–19]. In this regard, Magnani distinguishes between “(1) abduction that only generates plausible hypothesis (*selective or creative*)” and “(2) abduction considered as *inference to the best explanation*, that also evaluates hypotheses by induction” [9.1, p. 18, Magnani's emphasis]. And, he makes it explicit that the first meaning of abduction is what he accepts in his epistemological model. Though inconclusive, Magnani's claim about *hypothesis generation* as instinctual is more defensible under the first meaning of abduction. Even after having noted these supportive points, however, it is still unclear how abduction could be rooted in instinctual-rooted cognitive performances like emotion.

As for the latter project, Magnani wants to secure inferential character of animal abduction from sign activity and semiotic processes found in nonhuman animals. He frequently appeals to Peirce [9.49, CP 5.283]:

“all thinking is in signs, and signs can be icons, indices or symbols. Moreover, all inferences are a form of sign activity, where the word sign includes feeling, image, conception, and other representation.”

Here is a lengthy quote from Magnani that makes this point crystal clear [9.1, p. 288] and [9.5, 14, CP 5.283]:

“Many forms of thinking, such as imagistic, emphatic, trial and error, and analogical reasoning, and cognitive activities performed through complex bodily skills, appear to be basically model based and manipulative. They are usually described in terms of living beings that adjust themselves to the environment rather than in terms of beings that acquire information from the environment. In this sense these kinds of thinking would produce

responses that do not seem to involve sentential aspects but rather merely *noninferential* ways of cognition. If we adopt the semiotic perspective above, which does not reduce the term *inference* to its sentential level, but which includes the whole arena of sign activity – in the light of Peircean tradition – these kinds of thinking promptly appear full, inferential forms of thought. Let me recall that Peirce stated that all thinking is in signs, and signs can be icons, indices, or symbols, and, moreover, all inference is a form of sign activity, where the word sign includes *feeling, image, conception, and other representation.*”

Magnani is well aware of the fact animals have been widely considered as mindless organisms for a long time. So, based on the cornerstone laid by Peirce, this semiotic perspective needs further extension. But how is it possible? According to Magnani, that is possible thanks to the recent results in cognitive science and ethology about animals, and of developmental psychology and cognitive archeology of humans and infants. [9.1, p. 283]:

“Philosophy itself has for a long time disregarded the ways of thinking and knowing of animals, traditionally considered *mindless* organisms. Peircean insight regarding the role of abduction in animals was a good starting point, but only more recent results in the fields of cognitive science and ethology about animals, and of developmental psychology and cognitive archeology about humans and infants, have provided the actual intellectual awareness of the importance of the comparative studies.”

Magnani not only points out that inferences are not necessarily structured like a language, but also there are animal-like aspects in human thinking and feeling. [9.1, p. 283]:

“Sometimes philosophy has anthropocentrically condemned itself to partial results when reflecting upon human cognition because it lacked in appreciation of the more *animal-like* aspects of thinking and feeling, which are certainly in operation and are greatly important in human behavior.”

Encouraged by the discovery of “the ways of thinking in which the *sign activity* is of a nonlinguistic sort” [9.1, p. 189] in lower animals, Magnani claims that “a higher degree of abductive abilities has to be acknowledged” to them [9.1, pp. 290,291]:

“Chicken form separate representations faced with different events and they are affected by prior experiences (of food, for example). They are mainly

due to internally developed plastic capabilities to react to the environment, and can be thought of as the fruit of learning. In general this plasticity is often accompanied by the suitable reification of external artificial *pseudo representations* (for example landmarks, alarm calls, urine marks and roars, etc.) which artificially modify the environment, and/or by the referral to externalities already endowed with delegated cognitive values, made by the animals themselves or provided by humans.”

In fact, Magnani goes even farther in his ascription of pseudo thought to nonhuman animals in his discussion of *affordances*, *multimodal abduction*, *cognitive niches*, and *animal artifactual mediators*. It is exactly where we can find what Magnani believes to be a clear evidence that manipulative abduction plays a crucial role in animal sign activities.

As Magnani points out, we are now in a much better position than Peirce to understand the way of thinking and knowing of animals, thanks to [9.1, p. 283]:

“more recent results in the fields of cognitive science and ethology about animals, and of developmental psychology and cognitive archeology about humans and infants.”

But Magnani reminds us of the fact that Darwin already paved a way toward the appreciation of cognitive faculties of animals [9.1, pp. 284-285]:

“It is important to note that Darwin also paid great attention to those external structures built by worms and engineered for utility, comfort, and security. I will describe later on in this chapter the cognitive role of artifacts in both human and nonhuman animals. Artifacts can be illustrated as *cognitive mediators* [9.2] which are the building blocks that bring into existence what it is now called a *cognitive niche*: Darwin maintains that ‘We thus see that burrows are not mere excavations, but may rather be compared with tunnels lined with cement’ [9.50, p. 112]. Like humans, worms build external artifacts endowed with precise roles and functions, which strongly affect their lives in various ways, and of course their opportunity to know the environment.”

I would like to discuss a strong or active sense of learning abduction from animals. I do interpret Magnani’s ideas on perceiving affordance in human and nonhuman animals as an answer to the problem of how to learn abduction from animals in this sense. As far as the problem of perceiving affordances is concerned, we do not have to confess our inferiority to nonhuman animals. It is we humans who have perceived affordances in some highly creative ways. However, we cannot eas-

ily claim our superiority over nonhuman animals either. It is roaches not humans that turn out to demonstrate better ability for survival, which may imply superiority in perceiving affordances. In a word, I think we may safely and more profitably forget the issue of inferiority or superiority. Let it suffice to say that we humans, unlike nonhuman animals, seem to have very unique abductive instinct displayed by our perceiving affordances.

Magnani would be happy with my interpretation, for he himself claims that “cognitive niche construction can be considered as one of the most distinctive traits of human cognition” [9.2, p. 331]. According to Magnani, both human and nonhuman animals are chance seekers, and thereby ecological engineers. They “do not simply live their environment, but actively shape and change it looking for suitable chances” [9.1, p. 319]. Further, “in doing so, they construct cognitive niches” [9.1]. Then, in chance seeking ecological engineering in general, and in cognitive niche construction in particular, what exactly does differentiate humans from nonhuman animals?

In order to answer this question, we need to understand in what respects Magnani extends or goes beyond Gibson’s notion of affordance. In principle, it should not be too difficult, because Magnani himself indicates explicitly or implicitly some such respects of his own innovation. Magnani takes Gibson’s notion of affordance “as what the environment offers, provides, or furnishes” as his point of departure. He also notes that Gibson’s further definitions of affordance as [9.1, p. 333]:

- “1. Opportunities for action.
2. The values and meanings of things which can be directly perceived.
3. Ecological facts.
4. Implying the mutuality of perceiver and environment.”

may contribute to avoiding possible misunderstanding. Given this Gibsonian ecological perspective, Magnani appropriates some further extensions or modifications by recent scholars in order to establish his own extended framework for the notion of affordance. It is simply beyond my ability to do justice to all elements of Magnani’s extended framework for affordances. Let me just note one issue in which Magnani shows enormous interest, Gibsonian direct perception.

Magnani takes Donald Norman’s ambitious project of reconciling constructivist and ecological approaches to perception seriously [9.1, 6.4.3, p. 343]. Above all, Magnani notes that Norman “modifies the original Gibsonian notion of affordance also involving

mental/internal processing" [9.1, p. 337] based on a text, where *Norman* writes [9.51, p. 14]:

"I believe that affordances result from the mental interpretation of things, based on our past knowledge and experience applied to our perception of the things about us."

If Norman is right, we may safely infer, as Magnani does, that pace Gibson, "affordances depend on the organism's experience, learning, and full cognitive abilities" [9.1, p. 337]. Both Norman and *Magnani* are evidencing these ideas by formidable array of recent results in cognitive experimental psychology and neuroscience [9.1, p. 341].

Now, given this extended framework for that extends and modifies some aspects of the original Gibsonian notion of affordances, what exactly is Magnani's contribution? In some sense, this is an unnecessary stupid question, for everybody already knows the correct answer. By his expertise on abduction, and in particular his Peircean thesis of perception as abduction, Magnani contributes enormously to deepen our understanding of some truly big issues, such as how to reconcile constructivist and ecological theories of perception. So, my question aspires to understand more specifically how the Peirce–Magnani view of perception as abduction contributes in that regard. Let us suppose that the original Gibsonian notion of affordance has been extended and modified à la Norman. Would Magnani claim that such an extension or modification is impossible without abductive activities of organisms? Or, would he claim that such an extension or modification is still incomplete without abduction?

Be that as it may, the big picture *Magnani* presents is this [9.1, p. 348]:

"Organisms have at their disposal a standard endowment of affordances (for instance through their hardwired sensory system), but at the same time they can extend and modify the scope of what can afford them through the suitable cognitive abductive skills."

If we probe the question as to what exactly are involved in organisms' employment of cognitive abductive skills, *Magnani* would respond roughly as the following lines [9.1, p. 346]:

"in sum organism already have affordances available because of their instinctive gifts, but also they can dynamically abductively *extract* natural affordances through *affecting* and modifying perception

(which becomes semiencapsulated). Finally, organisms can also *create* affordances by building artifacts and cognitive niches."

There are several points that become clear from this quote, I think. First, in addition to the original Gibsonian framework for affordances, there is room for organisms to participate in perceiving affordances (in the broad sense). Secondly, abductive skills are performed by organisms in perceiving affordances. Thirdly, in such abductively perceiving affordances, perception and action are inseparably intertwined. Finally, organisms can even create affordance by abduction. Except for the first point, I think, all these seem to be due to Magnani.

At the beginning of this section, I introduced Paavola's dilemma: "If abduction relies on instinct, it is not a form of reasoning, and if it is a form of reasoning, it does not rely on instinct". Though I welcomed basically Magnani's way out of this dilemma, that is, they simply co-exist, it was not clear exactly what that solution means. After having improved our understanding of manipulative abduction in animals, now we may understand it better. Magnani claims that, from a semiotic point of view, the idea that there is a conflict between views of abduction in terms of heuristic strategies or in terms of instinct (insight, perception) [9.4, 40, 52], appears old fashioned. And he elaborates his claim that the two aspects simply coexist, by adding that that is so *at the level of the real organic agent* (Emphasis is mine). Depending upon the cognitive/semiotic perspective we adopt, he claims [9.1, pp. 281–282]:

- "1. We can see it as a practical agent that mainly takes advantage of its implicit endowments in terms of guessing right, wired by evolution, where of course instinct or hardwired programs are central.
2. We can see it as the user of explicit and more or less abstract semiotic devices internally stored or externally available – or hybrid – where heuristic plastic strategies (in some organism they are *conscious*) exploiting relevance and plausibility criteria – various and contextual – for guessing hypotheses are exploited."

Now we may underwrite the fact that the two aspects simply co-exist at the level of real organic agents, who are *manipulative abducers*, for it would be hard to find a better example of manipulative abduction than creating affordances. In other words, manipulative abduction is the key factor in Magnani's thought about animal abduction.

## 9.6 Concluding Remarks

Until quite recently abduction has been studied most extensively in scientific context. Even if we consider abduction in artificial intelligence and cognitive science, still the majority of the researches have been governed by theoretical concerns. With Magnani's discovery of manipulative abduction, everything changes. Insofar as manipulative abduction can be construed as a form of practical reasoning, the possibility of expanding the scope of abduction is wide open. As has been seen earlier, Magnani indeed applies manipulative abduction to an impressive array of areas, only a few of which have been examined in this chapter. We con-

firmed that manipulative abduction plays an important role in the use of fallacies in everyday life. Possibly more impressive would be the establishment of manipulative abduction in animals as a research field. Of course, there are many issues unsettled. Above all, there is a desperate need to sharpen our conception of manipulative abduction by deepening our understanding of the characteristics of manipulative abduction. In both expanding the scope and sharpening the conception of manipulative abduction, Magnani's pioneering achievement is simply overwhelming. We may expect rapid and fruitful progress in both directions in the near future.

This section, *The Logic of Hypothetical Reasoning, Abduction, and Models*, shall be concerned with reviewing some formal models for scientific inquiry. Scientific inquiry is a human enterprise to which we cannot deny a big success. It has been our intellectual instrument for achieving great endeavors, such as the arrival on the moon, the possibility of internet communication, the discovery of infections and the invention of vaccines, and many more. The inferential processes involved in scientific inquiry are an essential aspect to analyze when carrying out an enterprise like the one in this *Springer Handbook of Model-Based Science*. However, the field and the material are so vast that it would be impossible to review everything.

Therefore, the main concern within scientific reasoning will be *ampliative reasoning*, those inferential processes in which the conclusion *expands* the given information. This kind of reasoning manifests itself in inferences such as *induction* and *abduction*, and it is opposed to *deduction*, in which conclusions are certain but add nothing new to the given. A salient aspect of ampliative reasoning is the tentative epistemic status of the conclusions produced, something which makes them *defeasible*. That is, given additional information, it may no longer be warranted to draw a previously valid conclusion.

More particularly, the focus in this section will be precisely on the tentative status of the conclusion produced, of its being *hypothetical*. A hypothetical statement is, at the very best, potential knowledge. It is neither true nor false, but holds a hypothetical epistemic status, one that may be settled later as true (when the hypothesis is corroborated) or as false (when it is falsified). Hypothetical reasoning is understood here as a type of reasoning *for explanations*.

One case of hypothetical reasoning is *enumerative induction*, also known as *inductive generalization*, in which the inferential process that is at stake is one which obtains a universal statement (*all ravens are black*) from a set of individual ones (*the first raven is black, ..., the n-th raven is black*). A generalization from instances is a case of ampliative reasoning because it expands what is stated in the instances by advancing a defeasible prediction (*the next raven will be black*). That is, the generalization may fail when a further instance falsifies the conclusion. As is well known, inductive generalization is based on the assumption of the *uniformity of nature*; the world is uniform and, therefore, it seems safe to draw generalizations out of instances, although they may fail at some point.

Another case of hypothetical reasoning that shall be reviewed in depth is that of abduction. Broadly speak-

ing, abduction is a reasoning process *from a single observation to (plausible) explanations*. This characterization, which largely follows the original formulation of Charles Peirce (to be described in [Chap. 10](#)), still leaves ample room for several interpretations. To begin with, when talking about abduction, or any inferential process for that matter, we may refer to a finished product, in this case the *abductive explanation*, or to an activity, the *abductive process*. These two are closely related, for the abductive process produces an abductive explanation, but they are not the same. Moreover, for a given fact to be explained, there are often several abductive explanations to choose from, but only one that counts as the *best* one. Thus, abduction is connected to both hypotheses construction and hypotheses selection. Some authors consider these processes as two separate steps, construction dealing with the generation of plausible explanations according to some criteria of what counts as such, and selection with applying some preference criteria to select the *best* one among the plausible ones. Another issue to be settled in regard to abduction is the distinction from its closest neighbor, induction.

In this very broad map of hypothetical reasoning, two approaches to abduction are salient, one which interprets it as *argument* versus as *inference to the best explanation* (each case, in turn, may be seen either as a product or as a process). This is a familiar distinction in the philosophy of science, where abduction is closely connected with issues of scientific explanation. In a more in-depth view of logical abduction, three characterizations may be identified, namely as *logical inference*, as a *computational process*, and as a *process for epistemic change*. Each one of these views highlights one relevant aspect of abductive reasoning: its logical structure (under an interpretation as a product), its underlying computational mechanism (under an interpretation as a process), and its role in the dynamics of belief revision. Indeed, there are several ways to characterize this reasoning type, and it may be more appropriate to characterize *abductive patterns* rather than trying to define it as a single concept. These approaches and logical characterizations of abduction will be spelled out in detail in the introductory chapter, *The Logic Abduction: An Introduction*, together with an attempt to provide a proper distinction between induction and abduction.

In [Chap. 11](#) by Mathieu Beirlaen, *Qualitative Inductive Generalization and Confirmation*, the author offers a number of *adaptive logics* for inductive generalization, each of which is analyzed as a criterion of confirmation and confronted with Hempel's satisfaction criterion and the hypothetico-deductive model

of confirmation. The adaptive criteria proposed in this paper offer an interesting alternative perspective on (qualitative) confirmation theory in the philosophy of science.

Adaptive logics are a relatively new proof-theoretical framework designed to model ampliative reasoning and *dynamic* information. For the case of inductive generalization, the defeasibility of the conclusion is dealt with in two respects. On the one hand, each of these proposed logics uses a criterion to assert a generalization as a statement within the proof. On the other hand, each of these logics implements a *strategy*, a specific way by which a generalization is refuted and, therefore, *marked* in the proof, so that it is no longer considered as part of the derivation (until it is unmarked due to new information).

In **Chap. 12** by Tjerk Gauderis, *Modeling Hypothetical Reasoning by Formal logics*, the author offers an interesting discussion in regard to the feasibility of the project of modeling hypothetical reasoning by means of formal logics, exploring the assumptions one has to hold in order to accept or reject this endeavor. The author then puts forward four *patterns* of hypothetical reasoning, showing that not a single one can be easily modeled by formal means. *Abduction of a singular fact* is the one pattern that has received most attention in the logical literature; the author gives a review and a detailed description of two adaptive logics devised for this particular pattern, showing that although it is the simplest pattern of all four, there are already some challenges to model it formally.

These two chapters share the logical framework of adaptive logics as a formal model for scientific inquiry, one for inductive generalization, the other one for single fact abduction. Of the four patterns of hypothetical reasoning put forward by Gauderis, the second one, *abduction of a generalization*, is indeed a case of inductive generalization.

According to the previously mentioned classification of hypothetical reasoning, these two chapters fall into the argumentative approach of the type of reasoning modeled (inductive or abductive). However, the chapter by Gauderis highlights a distinction between *practical abduction* and *theoretical abduction*, which – to a certain extent – corresponds to the argumentative versus inference to the best explanation dichotomy of abduction found in the philosophical literature.

The next three chapters of this section belong to the epistemic approach to abduction of taking an agent-oriented stance, one in which the agent's perspective is

at the center of the formal modeling. However, each of these chapters is actually a combination of at least two abductive characterizations.

In **Chap. 13** by Angel Nepomuceno Fernández, Fernando Soler Toscano and Fernando R. Velázquez Quesada, *Abductive Reasoning in Dynamic Epistemic Logic*, the authors rely on the *dynamic epistemic logic* framework, which is largely based on a semantic perspective of modal logic and is an ideal tool to represent an agent's state of knowledge (and belief) together with the dynamics of epistemic change. Operations to upgrade, update and revise *plausibility models* are put forward to dynamically change both the content and the ordering of these models. Original characterizations of what is an abductive problem (solution) are put forward, not with respect to a background theory, as is the case in the classical approach to abduction (see introductory chapter), but rather with respect to an agent's information at a given state. Moreover, plausibility models provide an ordering among epistemic possibilities and accordingly, the *best abductive explanation* turns out to be the most plausible one. This chapter exhibits the inference to the best explanation approach and a combination of the inferential and epistemic characterizations of abduction.

In **Chap. 14** by Cristina Barés Gómez and Matthieu Fontaine, *Argumentation and Abduction in Dialogical Logic*, the authors offer an interesting discussion in favor of a reconciliation between argumentation theory and formal logic; one in which their selected logical framework, *dialogical logic*, is the formal model for scientific inquiry. More particularly, reasoning is modeled via a dialectical interaction in a game-like scenario between the proponent of a thesis and an opponent to it. The authors endorse the view of Dov Gabbay and John Woods, according to which abduction is a response to an *ignorance problem*. An agent has an ignorance problem with respect to a cognitive target when she lacks the knowledge to attain such a target, and abduction is but one type of solution to this kind of problem. The authors of this chapter propose an extension of the dialogical framework to account for abduction and put forward the notion of a *concession problem*, in order to do so. The chapter follows the argumentative approach to abduction, but extends this view with a dialectical interaction and combines aspects of the inferential and epistemic characterizations.

In the last chapter of this section, **Chap. 15** by Juliana Bueno Soler, Walter Carnielli, Marcelo Coniglio, and Abilio Rodrigues, *Formal (In)consistency, Abduction and Modalities*, the authors take a broader view of

scientific inquiry and deal with the problem of inconsistent information, as when there is conflicting evidence for a fact to be explained. In accordance with the focus on hypothetical reasoning taken in this section, the onset of conflicting information, as presented in this chapter, is just another case of a *tentative conclusion*, one which is taken in a sense *weaker* than true, with a provisional status and pending *further investigation*. Authors of this chapter are interested in reviewing the case when no *obvious* explanation is at hand, especially when contradictory information is involved, and a *meaningful* explanation can still be constructed (one that can not be produced in a classical setting). They develop their own formal framework, based on the classical tableaux systems. In respect to abduction, the authors apply a paraconsistent logic to deal with it, and even go further to draw connections between modalities and consistency. Their approach is focused on the process of hypothesis generation, making it attractive for computational implementation (not developed in the paper) and identified by the authors themselves as a case of *creative abduction*, one which contrasts with

*explicative abduction*, according to the distinction put forward by Lorenzo Magnani. The chapter mainly follows the argumentative approach to abduction and is a combination of the computational and epistemic characterizations.

By virtue of their being formal models of scientific reasoning, the chapters to follow are technical; each one of them offers an original contribution to the field, but at the same time, they all provide the intuition and rationale behind the notions presented. The diversity of formal frameworks displayed in this section shows the wide variety of formal tools for hypothetical reasoning modeling. These tools have proved useful to philosophers, logicians, and computer scientists alike and may also be so to anyone who would like to make use of the potential of formal tools to model scientific inquiry at large. This section, *The Logic of Hypothetical Reasoning, Abduction, and Models*, offers a thorough introduction and is an overview to some formal models for hypothetical reasoning found in the philosophy of science and logical literature.

# 10. The Logic of Abduction: An Introduction

Atocha Aliseda

In this chapter, the focus will be on formal models of hypothetical reasoning, in particular on those concerned with *abductive reasoning*.

In Sect. 10.1, the chapter offers a brief history of the notion of abduction, starting with an attempt to distinguish it from its closest neighbor, induction. Charles Peirce's original conception of abduction is then presented and followed by an overview of abduction in the cognitive sciences, together with some paradigmatic examples of the kind that will be dealt with in the chapters to follow. Sect. 10.2 presents two main approaches to abduction in philosophy, as *argument* and as *inference to the best explanation* (IBE), something which sets the ground to put forward a general logical taxonomy for abduction. Sect. 10.3 goes deeper into three logic-based *classical* characterizations of abduction found in the literature, namely as *logical inference*, as a *computational process*, and as a *process for epistemic change*.

Hypothetical reasoning is understood here as a type of reasoning to explanations. This type of

reasoning covers abductive as well as inductive inferences. As for the latter, in this handbook part, the concern will be limited to *enumerative induction* and will leave its full presentation to the corresponding chapter (Chap. 11).

## 10.1 Some History

### 10.1.1 Induction and Abduction

In this section, an attempt has been made to provide a clear distinction between inductive and abductive reasoning. As it turns out, diverse terminologies are being used.

On the one hand, for some, beyond deductive logic, there is only place for inductive logic. For others, abduction is another focus, and it is important, at least, to clarify its relationship to induction. For C.S. Peirce, to whom abduction owes its name, *deduction*, *induction* and *abduction* formed a natural triangle – but the literature in general shows many overlaps, and even confusions.

An example of the former view is given by *Russell* [10.1], when he claims:

“There are two sorts of logic: Deductive and inductive. A deductive inference, if it is logically correct, gives as much certainty to the conclusion as the premises, while an inductive inference, even when it obeys all the rules of logic, only makes the conclusion probable even when the premises are deemed certain.”

More recently, there is also a predominant view that identifies induction with ampliative reasoning. For *Paul Thagard*, who coined the field of *computational philos-*

ophy of science, induction is understood in the broad sense of any kind of inference that expands knowledge in the face of uncertainty [10.2].

Since the time of *John Stuart Mill* (1806–1873), the technical name given to all kinds of nondeductive reasoning has been *induction*, but several *methods for discovery and demonstration of causal relationships* [10.3] were recognized. These included generalizing from a sample to a general property, and reasoning from data to a causal hypothesis (the latter further divided into methods of agreement, difference, residues, and concomitant variation). A more refined and modern terminology is *enumerative induction* and *explanatory induction*, of which *inductive generalization*, *inductive projection*, *statistical syllogism*, and *concept formation* are some instances.

Another term for nondeductive reasoning is *statistical reasoning*, introducing a probabilistic flavor, in which explanations are not certain but only probable. Statistical reasoning exhibits the same diversity as abduction. First of all, just as the latter is strongly identified with *backward deduction* (as it will be shown later in this chapter), the former finds its *reverse notion* in probability (For those readers interested in quantitative approaches: the problem in probability is: Given an stochastic model, what can we say about the outcomes? The problem in statistics is the reverse: Given a set of outcomes, what can we say about the model?). Both abduction and statistical reasoning are closely linked with notions like confirmation (the testing of hypotheses) and likelihood (a measure for alternative hypotheses). The former will be reviewed later in this part of the handbook (Chap. 11).

On the other hand, some authors put forward abduction as the main category and take induction as one of its instances. Abduction as *IBE* is considered by *Harman* [10.4] as the basic form of nondeductive inference, which includes (enumerative) induction as a special case (this approach will be presented later in this chapter).

This confusion in terminology returns in artificial intelligence (AI). *Induction* is used for the process of learning from examples – but also for creating a theory to explain the observed facts [10.5], thus making abduction an instance of induction. Abduction is usually restricted to producing abductive explanations in the form of facts (predicates of some sort, as those used in computational implementations of abduction, to be later introduced). When explanations are rules, it is then regarded as part of induction. Indeed, the relationship between abduction and induction has been a distinguished topic of several workshops in AI mainstream conferences (European Conference on Artificial Intel-

ligence (ECAI) and International Joint Conference on Artificial intelligence (IJCAI)) as well as that of edited books [10.6].

With the sole purpose of providing a methodological distinction between abduction and induction, in this chapter, abduction will be understood as reasoning from a single observation to its explanations, and induction as *enumerative induction*, a reasoning kind from samples to general statements. Given these tentative characterizations, those aspects that distinguish them will be highlighted. While induction explains a set of observations, abduction explains a single one. Induction makes a prediction for further observations, abduction does not (directly) account for later observations. While induction needs no background theory per se, abduction relies on a background theory to construct and test its abductive explanations.

As for their similarities, induction and abduction are both ampliative and defeasible modes of reasoning. More precisely, they are *nonmonotonic* types of inference. A consequence  $\Rightarrow$  is labeled as nonmonotonic whenever  $T \Rightarrow b$  does not guarantee  $T, a \Rightarrow b$ . That is, the addition of a new premise (*a*) may invalidate a previous valid argument. In the terminology of philosophers of science, nonmonotonic inferences are not *erosion proof* [10.7]. Moreover, qua direction, both run in the opposite direction to standard deduction; they both run from evidence to explanation and the status of the produced explanation is hypothetical.

To clear up terminological conflicts, one might want to coin new terminology altogether. Some may argue for a new term of *explanatory reasoning* as done in [10.8] or even better as *hypothetical reasoning* trying to describe its fundamental aspects without having to decide if they are instances of either abduction or induction. In this broader perspective, it is also possible to capture explanation for more than one instance or for generalizations and introduce further fine-structure. Indeed, a classification in terms of *patterns of hypothetical reasoning* may be very appropriate, as will be found later on in this part of the handbook (Chap. 12. A key reference in the literature in terms of *patterns of abduction* is found in [10.9]).

### 10.1.2 The Founding Father: C.S. Peirce

The literature on abduction is so vast that makes impossible to undertake a complete survey here. But any history of abduction cannot fail to mention the founding father: Charles Sanders Peirce (1839–1914).

Peirce is the founder of American pragmatism and the first philosopher to give to abduction a logical form. However, his notion of abduction is a difficult one to un-

ravel. On the one hand, it is entangled with many other aspects of his philosophy, and on the other hand, several different conceptions of abduction evolved in his thought. The notions of logical inference and of validity that Peirce puts forward go beyond our present understanding of what logic is about. They are linked to his epistemology, a dynamic view of thought as logical inquiry, and correspond to a deep philosophical concern, that of studying the nature of synthetic reasoning. In what follows, a few general aspects of his later theory of abduction will be pointed out, to later concentrate on some of its more logical aspects (for a more elaborate analysis of the evolution of Peirce's abduction as well as its connection to his epistemology [10.10–12]).

For Peirce, three aspects determine whether a hypothesis is promising: it must be *explanatory*, *testable*, and *economic*. A hypothesis is an explanation if it accounts for the facts. Its status is that of a suggestion until it is verified, which explains the need for the second criterion.

Finally, the motivation for the economic criterion is twofold: A response to the practical problem of having innumerable explanatory hypotheses to test, as well as the need for a criterion to select the best explanation among the testable ones.

For the explanatory aspect, *Peirce* gave the following often-quoted logical formulation [10.13, CP 5.189]:

“The surprising fact, C, is observed.  
But if A were true, C would be a matter of course.  
Hence, there is reason to suspect that A is true.”

This formulation has played a fundamental role in Peirce scholarship, and it has been the point of departure of many classic studies on abductive reasoning in all fields that make up the cognitive sciences, mainly those in which the approach is argumentative-based. Nevertheless, these accounts have paid little attention to the elements of this formulation and practically none to what Peirce said elsewhere in his writings. This situation may be due to the fact that his philosophy is very complex and not easy to be implemented in the computational realm. The notions of logical inference and of validity that Peirce puts forward go beyond logical formulations but at the same time some of his ideas find a natural place in recent proposals, such as that found in *theories of belief revision* (to be reviewed later in this chapter).

The approach to abductive reasoning, in this handbook part, reflects this Peircean diversity in part, taking abduction as a style of logical reasoning that occurs at different levels and contexts and comes in several degrees.

### 10.1.3 The Cognitive Sciences

Research on abduction in AI dates back to the 1970s of the twentieth century [10.14], but it is only fairly recently that it has attracted great interest, in areas like logic programming, knowledge assimilation, and diagnosis, to name a few. Some publications, collective and individual alike, are found in [10.15–19], to name a few. In all these places, the discussion about the different aspects of abduction has been conceptually challenging but also shows a (terminological) confusion with its close neighbor, induction (similar to what has already been pointed out previously). Abduction has also been a distinguished topic of model-based reasoning (MBR) conferences (those linked to the editorial project of this handbook).

The importance of abduction has been recognized by leading researchers in nearly all fields that make up the cognitive sciences: philosophy, computer science, cognitive psychology, and linguistics. For *Jaakko Hintikka*, abduction is *the fundamental problem of contemporary epistemology*, in which *abductive inferences must be construed as answers to the inquirer's explicit or (usually) tacit question put to some definite source of answers (information)* [10.11, p.519]. For *Herbert Simon*, the nature of the *retroductive process* (Peirce's original term for abduction) is *the main subject of the theory of problem solving in both its positive and normative versions* [10.20, p.151]. For *Paul Thagard*, several kinds of abduction play a key role as heuristic strategies in the program PI (processes of induction), a working system devoted to explain – in computational terms – some of the main problems in philosophy of science, such as scientific discovery, explanation, and evaluation [10.2]. Finally, for *Noam Chomsky*, abduction plays a key role in language acquisition; for the child *abduces* the rules of grammar guided by her innate knowledge of language universals [10.21].

### 10.1.4 Some Examples

There are a variety of approaches that claim to capture the true nature of the notion of abduction. One reason for this diversity lies in the fact that abductive reasoning occurs in a multitude of contexts and aims to cover from the simplest selection of already existing hypotheses in a context of common sense reasoning to the generation of new concepts in science. Here are some examples illustrating this variety (examples are taken from [10.8]):

1. *Common sense: Explaining observations with simple facts.* All you know is that the lawn gets wet either when it rains, or when the sprinklers are on. You wake up in the morning and notice that the lawn

is wet. Therefore you hypothesize that it rained during the night or that the sprinklers had been on.

2. *Common sense: When something does not work.* You come into your house late at night, and notice that the light in your room, which is always left on, is off. It has been raining very heavily, and so you think some power line went down, but the lights in the rest of the house work fine. Then, you wonder if you left both heaters on, something which usually causes the breakers to cut off, so you check them: but they are OK. Finally, a simpler explanation crosses your mind. Maybe the light bulb of your lamp which you last saw working well, is worn out, and needs replacing.

These examples belong to a practical setting found in our day-to-day common sense reasoning. The first one is the paradigmatic example of abduction in AI and will be analyzed in full detail later in this part of the handbook, in Chap. 15. An extension of the second example will be presented in Chap. 13.

Some other instances of abductive reasoning, but in this case oriented to model the cognitive competence of health practitioners and of working scientists are the following:

3. *Statistical reasoning: Medical diagnosis.* Jane Jones recovered quite rapidly from a streptococci infection after she was given a dose of penicillin. Almost all streptococcus infections clear up quickly upon administration of penicillin, unless they are penicillin resistant, in which case the probability of quick recovery is rather small. The doctor knew that Jane's infection is of the penicillin-resistant type, and is puzzled by her recovery. Jane Jones then confesses that her grandmother had given her Bel-

ladonna, a homeopathic medicine that stimulates the immune system by strengthening the physiological resources of the patient to fight infectious diseases (This is an adaptation of Hempel's illustration of his inductive-statistical model of explanation as shown in [10.7]). The part about homeopathy is taken from [10.8])

4. *Scientific reasoning: Kepler's discovery.* It has been claimed that Johannes Kepler's great discovery that the orbit of the planets is elliptical rather than circular was a prime piece of abductive reasoning [10.13, CP 2.623]. What initially led to this discovery was his observation that the longitudes of Mars did not fit circular orbits, but before even dreaming that the best explanation involved ellipses instead of circles, he tried several other forms. Moreover, Kepler had to make some other assumptions about the planetary system, without which his discovery does not work. His heliocentric view allowed him to think that the sun, so near to the center of the planetary system, and so large, must somehow cause the planets to move as they do. In addition to this strong conjecture, he also had to generalize his findings for Mars to all planets, by assuming that the same physical conditions obtained throughout the solar system.

The third example is concerned with the construction of a diagnosis, in which based on a series of observations (symptoms and signs) and of causal relations linking those observations to pathologies, health professionals build their diagnoses in order to determine an illness. But abduction also occurs in theoretical scientific contexts, such as the one described in the fourth example, in which anomalous observations give rise to new ideas that force to revise knowledge found in existing theories.

## 10.2 Logical Abduction

In contemporary philosophy of science, logical approaches to abduction may be traced back to *Hempel's* models [10.8, 22–24] and are therefore related to a reasoning style connected to theories of explanation and empirical progress [10.25]. More recently, logical abduction found a place in computationally oriented theories of belief change in AI as well as in the field of *nonmonotonic logics* [10.18, 26–30].

In what follows, two approaches to abduction, as an argument and as inference to the best explanation, will be described. Later on, a general taxonomy for its logical analysis will be proposed.

### 10.2.1 Argument

In AI circles, Peirce's formulation has been generally interpreted as the following logical argument-schema

$$\begin{array}{c} C \\ \hline A \rightarrow C \\ A \end{array}$$

where the status of *A* is tentative (it does not follow as a logical consequence from the premises).

However intuitive, this interpretation certainly captures neither the fact that  $C$  is surprising nor the additional criteria Peirce proposed. Moreover, the interpretation of the second premise should not be committed to material implication (For a causal interpretation of this conditional [10.31]). But other interpretations are possible; any nonstandard form of logical entailment or even a computational process in which  $A$  is the input and  $C$  the output, are all feasible interpretations for *if  $C$  were true,  $A$  would be a matter of course*.

The additional Peircean requirements of testability and economy are not recognized as such in AI, but to some extent are nevertheless incorporated. The latter criterion is implemented as a further selection process to produce the *best explanation*, since there might be several formulae that satisfy the above formulation but are nevertheless inappropriate as explanations. Testability as understood by Peirce is an extra-logical empirical criterion.

### 10.2.2 Inference to the Best Explanation

Abduction as IBE was proposed by Gilbert Harman as the basic form of nondeductive inference, one which included enumerative induction as one of its instances. According to him [10.4, p.89]:

“Uses of the inference to the best explanation are manifold. When a detective puts the evidence together and decides that it must have been the butler, he is reasoning that no other explanation which accounts for all the facts is plausible enough or simple enough to be accepted.”

This idea may be put into an argumentative form as follows [10.32]:

“ $D$  is a collection of data  
(facts, observations, givens)  
 $H$  explains  $D$   
(would, if true, explain  $D$ )  
No other hypothesis explains  $D$  as well as  $H$  does  
Therefore,  $H$  is probably correct”

Given a fact to be explained, there are often several possible abductive explanations, but (hopefully) only one that counts as the best one. Pending subsequent testing, in the previous common sense example of light failure (2) several abductive explanations account for the unexpected darkness of the room (power line down, breakers cut off, bulb worn out). But only one may be considered as best explaining the event, namely the *true* one, the one that really happened. But other preference criteria may be appropriate, too, especially when there is no direct test available.

Under this approach, abduction may be regarded as a single process by which a single best explanation is constructed. And the focus is on finding selection criteria which allow to characterize a hypothesis as the best one (A key references for the interpretation of abduction as inference to the best explanation is found in [10.33]).

Thus, abduction is connected to both hypotheses construction and hypotheses selection. Some authors consider these processes as two separate steps: construction dealing with what counts as a possible abductive explanation, and selection with applying some preference criterion over possible abductive explanations to select the best one.

As it turns out, the notion of a *best abductive explanation* necessarily involves contextual aspects, varying from application to application. There is at least a new parameter of preference ranking here. There exists both a philosophical tradition on the logic of preference, and logical systems in AI for handling preferences that may be used to single out best explanations [10.34, 35]. A proposal to tackle this approach in the framework of *dynamic epistemic logic*, in which (an extension of) the light failure example is analyzed in full detail, will be presented later in this handbook part (Chap. 13).

### 10.2.3 A Taxonomy

What has been presented so far may be summarized as follows. Abduction is a process whose products are specific abductive explanations, with a certain inferential structure, making an (abductive) explanatory argument. As for the *logical form* of abduction – referring to the inference corresponding to the abductive process that takes a background theory ( $\Theta$ ) and a given observation ( $\varphi$ ) as inputs, and produces an abductive explanation ( $\alpha$ ) as its output – the proposal here is that at a very general level, the logical structure of abduction may be viewed as a threefold relation

$$\Theta, \varphi \Rightarrow \alpha .$$

Other parameters are possible here, such as a preference ranking, but these would rather concern the further selection process. This characterization aims to capture the direction (from evidence to abductive explanation) of this type of reasoning. In the end, however, the goal is to characterize an (abductive) explanatory argument, in its deductive forward fashion, that is, an inference from theory ( $\Theta$ ) and abductive explanation ( $\alpha$ ) to evidence ( $\varphi$ ) as follows

$$\Theta, \alpha \Rightarrow \varphi .$$

Against this background, three main parameters that determine types of explanatory arguments are put forward:

1. An *inferential parameter* ( $\Rightarrow$ ) sets some suitable logical relationship among explananda, background theory, and explanandum.
2. Next, *abductive triggers* determine what kind of abductive process is to be performed:  $\varphi$  may be a novel phenomenon, or it may be in conflict with the theory  $\Theta$ .
3. Finally, *abductive outcomes* ( $\alpha$ ) are the various products (abductive explanations) of an abductive process: facts, rules, or even new theories.

### Abductive Parameters

**Varieties of Inference.** In the above schema, the notion of explanatory inference  $\Rightarrow$  is not fixed. It can be classical derivability  $\vdash$  or semantic entailment  $\models$ , but it does not have to be. Instead, it is regarded as a parameter that can be set independently. It ranges over such diverse values as probable inference ( $\Theta, \alpha \Rightarrow_{\text{probable}} \varphi$ ), in which the explanans render the explanandum only highly probable, or as the inferential mechanism of logic programming ( $\Theta, \alpha \Rightarrow_{\text{LP}} \varphi$ ). Further interpretations include dynamic inference ( $\Theta, \alpha \Rightarrow_{\text{dynamic}} \varphi$ ), replacing truth by information change potential along the lines of belief update or belief revision (Later in the chapter, both the abductive mechanism in logical programming as well as the belief revision framework will be described further. The dynamic interpretation will be reviewed in Chap. 13). To be sure, the point here is that abduction is not one specific nonstandard logical inference mechanism, but rather a way of using any one of these.

**Two Triggers.** According to Peirce, as his logical formulation dictates, abductive reasoning is triggered by a *surprising phenomenon*. The notion of surprise, however, is a relative one, for a fact  $\varphi$  is surprising only with respect to some background theory  $\Theta$  providing expectations. What is surprising to someone (that the lights go on as I enter the copier room) might not be surprising to someone else. One way to interpret a surprising fact is as one in need of an explanation. From a logical point of view, this assumes that the fact is not already explained by the background theory  $\Theta$ :  $\Theta \not\Rightarrow \varphi$ .

Moreover, one may also consider the status of the negation of  $\varphi$ . Does the theory explain the negation of

observation instead ( $\Theta \Rightarrow \neg\varphi$ )? Thus, two triggers for abduction are identified: *novelty* and *anomaly*

**Definition 10.1 (Abductive Novelty:  $\Theta \not\Rightarrow \varphi$ ,  $\Theta \not\Rightarrow \neg\varphi$ )**

$\varphi$  is novel. It cannot be explained ( $\Theta \not\Rightarrow \varphi$ ), but it is consistent with the theory ( $\Theta \not\Rightarrow \neg\varphi$ )

**Definition 10.2 (Abductive Anomaly:  $\Theta \not\Rightarrow \varphi$ ,  $\Theta \Rightarrow \neg\varphi$ )**

$\varphi$  is anomalous. The theory explains rather its negation ( $\Theta \Rightarrow \neg\varphi$ ).

As it will be shown later on, in the computational literature on abduction, novelty is the condition for an *abductive problem*. Following Peirce, incorporating anomaly as a second basic type is put forward (See [10.8] for the proposal).

Of course, nonsurprising facts (where  $\Theta \Rightarrow \varphi$ ) should not be candidates for abductive explanations. Even so, one might speculate if facts which are merely probable on the basis of  $\Theta$  might still need an abductive explanation of some sort to further cement their status.

**Different Outcomes.** Abductive explanations themselves come in various forms: facts, rules, or even theories. Sometimes one simple fact suffices to explain a surprising phenomenon. In other cases, a rule establishing a causal connection might serve as an abductive explanation. And many cases of abduction in science provide new theories to explain surprising facts. These different options may sometimes exist for the same observation, depending on how complex one wants to take it. Later in this handbook part, patterns of hypothetical reasoning will be classified according to abductive outcomes types (Chap. 12).

Moreover, as well known in the history of science, genuine abductive explanations sometimes introduce new concepts, over and above the given vocabulary. For instance, the eventual explanation of planetary motion (example section in this chapter), was not given by Kepler, but by Newton, who introduced a new notion of *force* – and then derived elliptic motion via the law of gravity. Abduction via new concepts – broadly conceived – will be outside the scope of our analysis in this part of the handbook (however, see Chap. 12 for a special case of *conceptual abduction*).

## 10.3 Three Characterizations

This section offers a description of three logical characterizations of abduction found in the literature. Nowadays, there are plenty of logic-based papers on abduction, most of which fit into one of the following three characterizations:

1. Abduction as logical inference
2. Abduction as computation
3. Abduction as epistemic change.

While the first one aims at characterizing abduction as *backward deduction plus additional conditions* and (generally) has classical logical consequence as an underlying inference, the second one focuses on providing specific algorithms that produce abductive explanations, and it is therefore as varied as computational platforms allow for. The last one puts forward abductive operations to revise, expand and update and has close links both with theories of belief revision and of update in AI. These approaches may be labeled as the *classical characterizations of logical abduction*. These characterizations are classical in at least two respects. In the first place, they are classical because they emerged originally as logical models for abduction and capture at least one relevant aspect of abductive reasoning: Its logical structure, its underlying computational mechanism, and its role in the dynamics of belief revision. In another respect, they are classical – in so far as presented in this chapter – because they exhibit a very classical way for doing logic, computation, or formalizations of belief revision theories.

Interesting proposals in all three characterizations and of its combinations are to be found in special issues of the *Logic Journal of the IGPL* (most notably, in special issues on abduction, such as [10.36–38]). Some of the chapters to follow are good examples of these combinations as well.

### 10.3.1 Inferential

The *classical* characterization of abduction as logical inference is mainly a deductive classical logical account in which a background theory ( $\Theta$ ), together with an abductive explanation ( $\psi$ ), constitutes the explananda and do entail the explanandum ( $\varphi$ ). It puts forward the following logical schema.

Given a theory  $\Theta$  (a set of formulae) and a formula  $\varphi$  (an atomic formula),  $\psi$  is an abductive explanation if:

1.  $\Theta \cup \psi \models \varphi$
2.  $\psi$  is consistent with  $\Theta$
3.  $\psi \not\models \varphi$
4.  $\psi$  is *minimal*.

When  $\models$  is interpreted as classical logical consequence, conditions 1 and 2 go hand in hand and are clearly mandatory. The first one dictates the entailment condition while the second one imposes the abductive explanation to be consistent with the background theory, for the *principle of explosion* is valid in classical logic (Chap. 15). As for condition 3, it is necessary in order to avoid self-explanations or, more generally, explanations that are independent from the background theory. Condition 4 aims at capturing either a criterion of best explanation by which *minimal* may be interpreted as selecting the *weakest explanation* (e.g., not equal to  $\Theta \rightarrow \varphi$ ) or a *preferred explanation* (which requires a predefined preference ordering). Additionally, there is usually another requirement restricting the logical vocabulary as well as the syntactic form of the explanation  $\psi$ , such as being an atomic formula from the vocabulary in the logical language. This schema suggests a classification into *abductive inferential styles* (as done in [10.8]), one in which *plain, consistent, explanatory, minimal, and preferential* abductive styles correspond to above conditions.

A (pre) condition to the above schema – not always made explicit – is that the theory does not already entail neither the explanandum nor its negation ( $\Theta \not\models \varphi$  and  $\Theta \not\models \neg\varphi$ ). In many proposals, this condition constitutes an *abductive problem* (such as in Chap. 15). Given the previous taxonomy for abduction by which two abductive triggers were distinguished, the following definition of an *abductive problem* is put forward, one in which *novel* and *anomalous* problems are distinguished.

#### Definition 10.3 (Abductive problem)

Let  $\Theta$  and  $\varphi$  be a theory and a formula, respectively, in some language  $\mathcal{L}$ . Let  $\models$  be a consequence relation on  $\mathcal{L}$ :

- The pair  $(\Theta, \varphi)$  constitutes a (novel) abductive problem when neither  $\varphi$  nor  $\neg\varphi$  are consequences of  $\Theta$ . That is, when

$$\Theta \not\models \varphi \quad \text{and} \quad \Theta \not\models \neg\varphi .$$

- The pair  $(\Theta, \varphi)$  constitutes an *anomalous abductive problem* when  $\varphi$  is not a consequence of  $\Theta$ , but  $\neg\varphi$  is. That is, when

$$\Theta \not\models \varphi \quad \text{and} \quad \Theta \models \neg\varphi .$$

It is typically assumed that the theory  $\Theta$  is a set of formulas closed under logical consequence, and that  $\models$  is a truth-preserving consequence relation.

Given this definition, a (*novel*) *abductive solution* would then be any formula  $\psi$  which follows the logical schema above. It remains to be seen however, what would be an *anomalous abductive solution* for an *anomalous abductive problem*. To this end, several proposals exist in the literature (e.g., [10.39]), many of which acknowledge the possibility of theory revision, for some formula may be retracted from  $\Theta$  in order to maintain the consistency of the revised theory (in Chap. 13 a proposal is made in this direction in the framework of dynamic epistemic theories, one in which a three-way distinction of abductive problems is offered).

Going back to the logical schema above, it should be stressed that some authors are not committed to classical logical entailment but rely instead on some other form of nonclassical consequence, something that often has as a consequence that the conditions that make up the logical schema need not be imposed explicitly or are replaced instead by weaker ones. For example, in Chap. 15 in which abduction is modeled in *paraconsistent logics*, the consistency condition is replaced by a weaker one stating nontriviality ( $\Theta$  and  $\psi$  are nontrivial when there exists a  $B$  such that  $\Theta, \psi \not\vdash B$ ).

To be sure, while there are clear-cut characterizations of what is an *abductive problem (solution)*, there are several logical ways to make it precise. It should be clear by now that there is a significant way in which abduction is interpreted as a logical inference in its own right. This characterization does integrate the view of an otherwise varied group of scholars; *John Woods* has labeled it as the *AKM model*, according to the initial letters of its proponents surnames [10.40, p.305]:

“Thus, for example, for ‘A’ we have *Aliseda* [10.8]; for ‘K’ we have *Kowalski* [10.41], *Kuipers* [10.25], *Kakas* et al. [10.26] and *Flach* and *Kakas* [10.6]; and for ‘M’ there is *Magnani* [10.19] and *Meheus* et al. [10.30]. Needless to say, there are legions of AKM-proponents whose surnames are ungraced by any of these letters in first positions.”

### 10.3.2 Computational

Of the many computational approaches to abduction, *abductive logic programming* (ALP) is the selected one to be described in detail (see [10.26, 42–44] for an overview to the field). Logic programming works mostly within first-order logic, and it consists of *logic programs, queries*, and an underlying inferential mechanism known as *resolution*. Abduction emerges naturally in logic programming as a repair mechanism, that is, its result is an extension of a logic program with the facts needed for a query to succeed (a query does not

succeed when it is not derivable from the program). In actual ALP, for these facts to be counted as abductions, they have to belong to a predefined set of abducibles, and to be verified by additional conditions (so-called *integrity constraints*), in order to prevent a combinatorial explosion of possible explanations.

Therefore, logic programming does not use blind deduction; different control mechanisms for proof search determine how queries are processed and this is crucial to the efficiency of the enterprise. Hence, different control policies will vary in the abductions produced, their form and the order in which they appear.

In what follows, it will be illustrated how an ALP system works. A notation closer to logic than to logic programs is the one used in what follows. An *abductive logic program* has three components:

- *A set of rules.* Each rule has a head (a predicate) and a body (a set of predicates). A way to prove the head is to prove all predicates of its body. Rules without body are facts and are assumed to be true. Here is a very simple logic program

$$\text{eats}(X, Y) \leftarrow \text{vegetarian}(X), \text{vegetable}(Y) \quad (10.1)$$

$$\text{eats}(X, Y) \leftarrow \text{carnivore}(X), \text{meat}(Y) \quad (10.2)$$

$$\text{vegetarian}(\text{rabbit}). \quad (10.3)$$

There are two rules (10.1) and (10.2) for the predicate  $\text{eats}(X, Y)$ . The first rule, for example, states that a way to prove that  $X$  eats  $Y$  is to prove that  $X$  is vegetarian and  $Y$  is a vegetable. The fact (10.3) states that the rabbit is vegetarian:

- *A set of abducible predicates.* A common restriction is that abducible predicates cannot be in the head of any rule. In the example above, the following may be considered as abducible predicates:  $\text{vegetarian}(X)$ ,  $\text{carnivore}(X)$ ,  $\text{vegetable}(X)$  and  $\text{meat}(X)$ .
- *A set of integrity constraints.* These are rules with  $\perp$  (falsehood) as head. To be satisfied, they require that not all literals in the body are simultaneously true. In the example above, the following constraint may be added in order to avoid that an animal is considered both a vegetarian and a carnivore

$$\perp \leftarrow \text{vegetarian}(X), \text{carnivore}(X). \quad (10.4)$$

An *abductive problem* in ALP manifests itself when there is a query (an instance of some predicate) that cannot succeed with the rules of the logic program

(the query is not derivable from the program). In the example above, the query `eats(rabbit,banana)` is not successful with the program (10.1)–(10.3). An *abductive solution* in ALP is then a set of facts that, together with the program, entail the original query. In above example, there are two possible sets of these:

- {vegetable(banana)}
- {carnivore(rabbit), meat(banana)}.

But only the first one satisfies integrity constraint (10.4), because assuming `carnivore(rabbit)`, together with `vegetarian(rabbit)`, contradicts (10.4).

More technically, in ALP, *standard selective linear definite resolution* [10.45] is extended to build the abductive solutions and check the integrity constraints. Some modified resolution procedures and ALP systems have been developed since the pioneer work of *Bob Kowalski* [10.41], but the usual procedure remains the same: look for abductive solutions at the *dead ends* of the proofs. That is, when a resolution proof cannot be completed because there is no clause to prove some query, if the predicate of that query is abducible, then it is incorporated to the abductive solution. Other procedures use *well-founded semantics* and *stable models*. The overview of ALP is left here.

As already mentioned, there are indeed many computational approaches to abduction. To end this section, here are some final words in regard to the logical framework of *semantic tableaux*, which – when properly extended – allows for a combination of both approaches to abduction previously reviewed, that of abduction as a logical inference and abduction as computation.

As well known in the logical literature, semantic tableaux is a refutation method to test formulae validity. Roughly speaking, it works as follows (see [10.46] for an overview to the field):

“To test if a formula  $\varphi$  follows from a set of premises  $\Theta$ , a tableau tree for the sentences in  $\Theta \cup \{\neg\varphi\}$  is constructed, denoted by  $\mathcal{T}(\Theta \cup \{\neg\varphi\})$ . The tableau itself is a binary tree built from its initial set of sentences by using rules for each of the logical connectives that specify the ways in which the tree branches.

If the tableau closes (every branch contains an atomic formula  $\psi$  and its negation), the initial set is unsatisfiable and the entailment  $\Theta \models \varphi$  holds. Otherwise, if the resulting tableau has open branches, the formula  $\varphi$  is not a valid consequence of  $\Theta$ .”

Within this framework, abduction comes into play as an *extension* of the constructed tableau. When there are open branches, which indicates the condition for a *novel abductive problem* in this framework, the generation of abductive solutions consists in producing

those formulae, which close the open branches (in a consistent way). Abduction in semantic tableaux offers a way of implementing computationally the AKM model (for more details on abduction in semantic tableaux, see [10.27] for its original proposal and [10.8] for a further development). Moreover, abduction in semantic tableaux for a paraconsistent logical theory is to be found in Chap. 15, in which a detailed description of this framework will be offered.

### 10.3.3 Epistemic Change

Abduction has also been characterized as a process for epistemic change, and in this respect an obvious related territory is theories of belief revision in AI (see [10.8, 29, 47, 48] for an introduction and a more detailed account on this topic). These theories describe how to incorporate a new piece of information into a database, a scientific theory, or a set of common sense beliefs. More precisely, given a consistent theory  $\Theta$  closed under logical consequence, called the belief state, and a sentence  $\varphi$ , the incoming belief, there are three *epistemic attitudes* for  $\Theta$  with respect to  $\varphi$ :

1.  $\varphi$  is accepted ( $\varphi \in \Theta$ )
2.  $\varphi$  is rejected ( $\neg\varphi \in \Theta$ )
3.  $\varphi$  is undetermined ( $\varphi \notin \Theta, \neg\varphi \notin \Theta$ ).

Given these attitudes, the following operations characterize the kind of belief change  $\varphi$  brings into  $\Theta$ , thereby effecting an epistemic change in the agent’s currently held beliefs:

- *Expansion*. A new sentence is added to  $\Theta$  regardless of the consequences of the larger set to be formed. The belief system that results from expanding  $\Theta$  by a sentence  $\varphi$  together with the logical consequences is denoted by  $\Theta + \varphi$ .
- *Contraction*. Some sentence in  $\Theta$  is deleted without any addition of new facts. In order to guarantee the deductive closure of the resulting system, some other sentences of  $\Theta$  may be given up. The result of contracting  $\Theta$  with respect to sentence  $\varphi$  is denoted by  $\Theta - \varphi$ .
- *Revision*. A new sentence that is (typically) inconsistent with a belief system  $\Theta$  is added, but in order that the resulting belief system be consistent, some of the old sentences in  $\Theta$  are deleted. The result of revising  $\Theta$  by a sentence  $\varphi$  is denoted by  $\Theta * \varphi$ .

Of these operations, revision is the most complex one. Indeed the three belief change operations can be reduced into two of them, since revision and contraction may be defined in terms of each other. In particular, revision here is defined as a composition of contraction and expansion: First contract those beliefs of  $\Theta$  that are

in conflict with  $\varphi$ , and then expand the modified theory with sentence  $\varphi$  (known as *Levi's identity*). While expansion can be uniquely and easily defined ( $\Theta + \varphi = \{\alpha \mid \Theta \vee \{\varphi\} \vdash \alpha\}$ ), this is not so with contraction or revision, as several formulas can be retracted to achieve the desired effect. Therefore, additional criteria must be incorporated in order to fix which formula to retract. Here, the general intuition is that changes on the theory should be kept *minimal*, in some sense of informational economy (One way of dealing with this issue is based on the notion of *entrenchment*, a preferential ordering which lines up the formulas in a belief state according to their importance [10.49]. Thus, those formulas that are the *least entrenched*, should be retracted first).

Moreover, *epistemic theories* in this tradition observe certain *integrity constraints* (such as those previously shown for ALP), which concern the theory's preservation of consistency, its deductive closure and two criteria for the retraction of beliefs: The loss of information should be kept minimal and the less entrenched beliefs should be removed first. These are the very basics of the AGM approach (This acronym stands for the three initial letters of its proponents: *Alchourrón, Gärdenfors, and Makinson*, authors of the seminal paper which started this tradition [10.50]).

Abduction may be seen as an epistemic process for belief revision. In this context, an incoming sentence  $\varphi$  is not necessarily an observation, but rather a belief for which an explanation is sought. The previously defined *abductive novelty* and *abductive anomaly* correspond respectively, to the epistemic attitudes of undetermination and rejection (provided that  $\Rightarrow$  is  $\vdash$  and  $\Theta$  closed under logical consequence). Both a novel phenomenon and an anomalous one induce a change in the original theory. The latter calls for a revision and the former for expansion. So, the basic operations for abduction are expansion and revision. Therefore, two epistemic attitudes and changes in them are reflected in an abductive model.

## 10.4 Conclusions

This chapter covered, on the one hand, a brief historical overview of the logic of abduction since its origins in Charles Peirce's view to its privileged place in the cognitive sciences. In the context of philosophy of science, logical abduction is relevant in regard to issues of scientific explanation. In a broader context, one including computer science, abduction is immersed in the heuristics of inferential mechanisms. On the other hand, this chapter offered an in-depth overview of logical abduction. A distinction between approaches in which abduction takes the

Here, then, are two abductive operations for epistemic change (as proposed in [10.8]):

- *Abductive expansion.* Given an abductive novelty  $\varphi$ , a consistent explanation  $\alpha$  for  $\varphi$  is computed in such a way that  $\Theta, \alpha \Rightarrow \varphi$ , and then added to  $\Theta$ .
- *Abductive revision.* Given an abductive anomaly  $\varphi$ , a consistent explanation  $\alpha$  is computed as follows: The theory  $\Theta$  is revised into  $\Theta'$  so that it does not explain  $\neg\varphi$ . That is,  $\Theta' \not\Rightarrow \neg\varphi$ , where  $\Theta' = \Theta - (\beta_1, \dots, \beta_n)$  (In many cases, several formulas and not just one must be removed from the theory. The reason is that sets of formulas which entail (explain)  $\varphi$  should be removed. Example: Given  $\Theta = \{\alpha \rightarrow \beta, \alpha, \beta\}$  and  $\varphi = \neg\beta$ , in order to make  $\Theta, \neg\beta$  consistent, one needs to remove either  $\{\beta, \alpha\}$  or  $\{\beta, \alpha \rightarrow \beta\}$ ). Once  $\Theta'$  is obtained, a consistent explanation  $\alpha$  is calculated in such a way that  $\Theta', \alpha \Rightarrow \varphi$  and then added to  $\Theta$ . Thus, the process of revision involves both contraction and expansion.

Some of the previous examples of abduction given in Sect. 10.1.4 may be described as expansions (1–3), where the background theory gets expanded to account for a new fact. Another one of them (4) is clearly a case calling for theory revision, that in which the theory needs to be *revised* in order to account for an anomaly, such as those found in practical settings like diagnostic reasoning [10.15, 39]. Belief revision theories provide an explicit calculus of modification for both cases and applied to abduction, operations for abductive expansion and abductive revision are defined as well.

Note, however, that in this approach changes occur only in the theory, as the situation or world to be modeled is supposed to be static, only new information is coming in. Another important type of epistemic change studied in AI is that of *update*, the process of keeping beliefs up-to-date as the world changes. A recent proposal in this direction in connection to abduction is to be found later in this part of the handbook, in Chap. 13.

form of an argument and those in which it manifests itself as an inference to the best explanation, is a useful one in philosophy, and was described in Sect. 10.2.

Section 10.3 described three *classical* characterizations of abduction, namely as a logical inference, as a computational process and as a process for epistemic change. These characterizations have been the dominant ones in the logical literature and are still a point of reference to new proposals which go beyond the boundaries of the classical way.

The history of the logic of abduction and of its formal modeling is still on the making. The chapters to follow offer an overview of formal tools to model logical and computational abduction.

# 11. Qualitative Inductive Generalization and Confirmation

Mathieu Beirlaen

Part C | 11.1

Inductive generalization is a defeasible type of inference which we use to reason from the particular to the universal. First, a number of systems are presented that provide different ways of implementing this inference pattern within first-order logic. These systems are defined within the adaptive logics framework for modeling defeasible reasoning. Next, the logics are re-interpreted as criteria of confirmation. It is argued that they withstand the comparison with two qualitative theories of confirmation, Hempel's satisfaction criterion and hypothetico-deductive confirmation.

Logics of induction are tools for evaluating the strength of arguments which are not deductively valid. There are many kinds of argument the conclusion of which is not guaranteed to follow from its premises, and there are many ways to evaluate the strength of such arguments. This chapter focusses on one particular kind of non-deductive argument, and on one particular method of implementation. The type of argument under consideration here is that of inductive generalization, as when we reason from the particular to the universal. A num-

ber of logics are discussed which permit us, given a set of objects sharing or not sharing a number of properties, to infer generalizations of the form *All x are P*, or *All x with property P share property Q*. Inductive generalization is a common practice which has proven its use in scientific endeavor. For instance, given the fact that the relatively few electrons measured so far carry a charge of  $-1.6 \times 10^{-19}$  Coulombs, we believe that all electrons have this charge [11.1].

## 11.1 Adaptive Logics for Inductive Generalization

The methods used here for formalizing practices of inductive generalization stem from the adaptive logics framework. Adaptive logics are tools developed for modeling defeasible reasoning, equipped with a proof theory that nicely captures the dynamics of non-monotonic – in this case, inductive – inference. In proofs for adaptive logics for inductive generalization, the conditional introduction of generalizations is allowed. The proof theory is also equipped with a mechanism taking care that conditionally introduced generalizations get retracted in case their condition is violated, for in-

stance when the generalization in question is falsified by the premises.

In Sect. 11.2 and 11.3 the general framework of adaptive logics is introduced, and a number of existing adaptive logics for inductive generalization are defined. The differences between these logics arise from different choices made along one of two dimensions. A first dimension concerns the specific condition required for introducing generalizations in an adaptive proof. A very permissive approach allows for their free introduction, without taking into account the specifics

of the premises. This is the idea behind the logic **LI**. A more economical approach is to permit the introduction of a generalization on the condition that at least one instance of it is present. This is the rationale behind a second logic, **IL**. In an **IL**-proof a generalization *All P are Q* can be introduced only if the premise set contains at least one object which is either *not-P* or *Q*. More economical still is the rationale behind a third logic, **G**, which aims to capture the requirement of knowing at least one *positive* instance of a generalization before introducing it in a proof. That is, in a **G**-proof a generalization *All P are Q* can be introduced if the premise set contains at least one object which is *both P* and *Q*.

The second dimension along which different consequence relations are generated concerns the specific mechanism used for retracting generalizations introduced in adaptive proofs. It is often not sufficient to demand retraction just in case a generalization is falsified by the premises. For instance, if the consequence sets of our logics are to be closed under classical logic, jointly incompatible generalizations should not be derivable, even though none of them is falsified by our premise set. Within the adaptive logics framework, various strategies are available for retracting conditional moves in an adaptive proof. Two such strategies are presented in this chapter: the reliability strategy and the minimal abnormality strategy.

Combining both dimensions, a family of six adaptive logics for inductive generalization is obtained (it contains the systems **LI**, **IL**, and **G**, each of which can be defined using either the reliability or the minimal abnormality strategy). These logics have all been presented elsewhere (for **LI**, see [11.2–4]. For **IL** and **G**, see [11.5]). The original contribution of this chapter consists in a study comparing these systems to some

existing qualitative criteria of confirmation. There is an overlap between the fields of inductive logic and confirmation theory. In 1943 already, Hempel noted that the development of a logical theory of confirmation might be regarded as a contribution to the field of inductive logic [11.6, p. 123]. In Sect. 11.4 the logics from Sect. 11.2 and 11.3 are re-interpreted as qualitative criteria of confirmation, and are related to other qualitative models of confirmation: Hempel's satisfaction criterion (Sect. 11.4.1) and the hypothetico-deductive model (Sect. 11.4.2). Section 11.4 ends with some remarks on the heuristic guidance that adaptive logics for inductive generalization can provide in the derivation and subsequent confirmation of additional generalizations (Sect. 11.4.3).

The following notational conventions are used throughout the chapter. The formal language used is that of first-order logic without identity. A primitive functional formula of rank 1 is an open formula that does not contain any logical symbols ( $\exists, \forall, \neg, \vee, \wedge, \supset, \equiv$ ), sentential letters, or individual constants, and that contains only predicate letters of rank 1. The set of functional atoms of rank 1, denoted  $\mathcal{A}^f$ , comprises the primitive functional formulas of rank 1 and their negations. A *generalization* is the universal closure of a disjunction of members of  $\mathcal{A}^f$ . That is, the set of generalizations in this technical sense is the set  $\{\forall(A_1 \vee \dots \vee A_n) \mid A_1, \dots, A_n \in \mathcal{A}^f; n \geq 1\}$ , where  $\forall$  denotes the universal closure of the subsequent formula. Occasionally the term generalization is also used for formulas equivalent to a member of this set, e.g.,  $\forall x(Px \supset Qx)$ . It is easily checked that generalizations  $\forall(A_1 \vee \dots \vee A_n)$  can be rewritten as formulas of the general form  $\forall((B_1 \wedge \dots \wedge B_j) \supset (C_1 \vee \dots \vee C_k))$ , and vice versa, where all  $B_i$  and  $C_j$  belong to  $\mathcal{A}^f$ .

## 11.2 A First Logic for Inductive Generalization

In this section the standard format (SF) for adaptive logics is introduced and explained. Its features are illustrated by means of the logic **LI** from [11.3, 4], chronologically the first adaptive logic for inductive generalization. A general characterization of the SF is provided, and its proof theory is explained. For a more comprehensive introduction, including the semantics and generic meta-theory of the SF, see, e.g., [11.7, 8].

### 11.2.1 General Characterization of the Standard Format

An adaptive logic (AL) within the SF is defined as a triple, consisting of:

- (i) A *lower limit logic* (LLL), a logic that has static proofs and contains classical disjunction
- (ii) A *set of abnormalities*, a set of formulas that share a (possibly) restricted logical form, or a union of such sets
- (iii) An *adaptive strategy*.

The LLL is the stable part of the AL: anything derivable by means of the LLL is derivable by means of the AL. Explaining the notion of static proofs is beyond the scope of this chapter. For a full account, see [11.9]. (Alternatively, the static proofs requirement can be replaced by the requirement that the lower limit logic has a reflexive, monotonic, transitive, and compact consequence relation [11.8].) In any case, it suffices to know

that the first-order fragment of Classical Logic (**CL**) meets this requirement, as we work almost exclusively with **CL** as a LLL. The lower limit logic of **LI** is **CL**.

Typically, an AL enables one to derive, for most premise sets, some extra consequences on top of those that are LLL-derivable. These supplementary consequences are obtained by interpreting a premise set as *normally as possible*, or, equivalently, by supposing abnormalities to be false *unless and until proven otherwise*. What it means to interpret a premise set as *normally as possible* is disambiguated by the strategy, element (iii).

The normality assumption made by the logics to be defined in this chapter amounts to supposing that the world is in some sense uniform. *Normal* situations are those in which it is safe to derive generalizations. *Abnormal* situations are those in which generalizations are falsified. In fact, the set of **LI**-abnormalities, denoted  $\Omega_{\mathbf{LI}}$ , is just the set of falsified generalizations (the definitions are those from [11.5]; in [11.10, Sect. 4.2.2] it is shown that the same logic is obtained if  $\Omega_{\mathbf{LI}}$  is defined as the set of formulas of the form  $\neg\forall xA(x)$ , where  $A$  contains no quantifiers, free variables, or constants)

$$\Omega_{\mathbf{LI}} =_{\text{df}} \{ \neg\forall (A_1 \vee \dots \vee A_n) \mid A_1, \dots, A_n \in \mathcal{A}^{f1}; n \geq 1 \} . \quad (11.1)$$

In adaptive proofs, it is possible to make conditional inferences assuming that one or more abnormalities are false. Whether or not such assumptions can be upheld in the continuation of the proof is determined by the adaptive strategy. The SF incorporates two adaptive strategies, the *reliability* strategy and the *minimal abnormality* strategy. In the generic proof theory of the SF, adaptive strategies come with a *marking definition*, which takes care of the withdrawal of certain conditional inferences in dynamic proofs. It will be easier to explain the intuitions behind these strategies after defining the generic proof theory for ALs. For now, just note that in the remainder **LI** is ambiguous between **LI<sup>r</sup>** and **LI<sup>m</sup>**, where the subscripts  $r$  and  $m$  denote the reliability strategy, respectively the minimal abnormality strategy. Analogously for the other logics defined below.

### 11.2.2 Proof Theory

Adaptive proofs are *dynamic* in the sense that lines derived at a certain stage of a proof may be withdrawn at a later stage. Moreover, lines withdrawn at a certain stage can become derivable again at an even later stage, and so on. (A stage of a proof is a sequence of lines and a proof is a sequence of stages. Every proof starts off with stage 1. Adding a line to a proof by applying

one of the rules of inference brings the proof to its next stage, which is the sequence of all lines written so far.)

A line in an adaptive proof consists of four elements: a line number, a formula, a justification and a *condition*. For instance, a line

$$j \quad A \quad i_1, \dots, i_n; R \quad \Delta,$$

reads: at line  $j$ , the formula  $A$  is derived from lines  $i_1 - i_n$  by rule  $R$  on the condition  $\Delta$ . The fourth element, the condition, is what permits the dynamics. Intuitively, the condition of a line in a proof corresponds to an assumption made at that line. In the example above,  $A$  was derived on the assumption that the formulas in  $\Delta$  are false. If, later on in the proof, it turns out that this assumption was too bold, the line in question is withdrawn from the proof by a marking mechanism corresponding to an adaptive strategy. Importantly, only members of the set of abnormalities are allowed as elements of the condition of a line in an adaptive proof. Thus, assumptions always correspond to the falsity of one or more abnormalities, or, equivalently, to the truth of one or more generalizations.

Before explaining how the marking mechanism works, the generic inference rules of the SF must be introduced. There are three of them: a premise introduction rule (Prem), an unconditional rule (RU), and a conditional rule (RC). For adaptive logics with **CL** as their LLL, they are defined as follows

$$\begin{array}{ll} \text{Prem} & \text{If } A \in \Gamma : \\ & \frac{\dots \quad \dots}{A \quad \emptyset} \\ \text{RU} & \text{If } A_1, \dots, A_n \vdash_{\mathbf{CL}} B : \\ & \frac{A_1 \quad \Delta_1}{\vdots \quad \vdots} \\ & \frac{A_n \quad \Delta_n}{\hline B \quad \Delta_1 \cup \dots \cup \Delta_n} \\ \text{RC} & \text{If } A_1, \dots, A_n \vdash_{\mathbf{CL}} B \vee \text{Dab}(\Theta) : \\ & \frac{A_1 \quad \Delta_1}{\vdots \quad \vdots} \\ & \frac{A_n \quad \Delta_n}{\hline B \quad \Delta_1 \cup \dots \cup \Delta_n \cup \Theta} \end{array}$$

Where  $\Gamma$  is the premise set, Prem permits the introduction of premises on the empty condition at any time in the proof. Remember that conditions, at the intuitive level, correspond to assumptions, so Prem stipulates that premises can be introduced at any time without making any further assumptions.

Since ALs strengthen their LLL, one or more rules are needed to incorporate LLL-inferences in AL-proofs. In the proof theory of the SF, this is taken care of by the generic rule RU. This rule stipulates that whenever  $B$  is a **CL**-consequence of  $A_1, \dots, A_n$ , and all of  $A_1, \dots, A_n$  have been derived in a proof, then  $B$  is derivable, provided that the conditions attached to the lines at which  $A_1, \dots, A_n$  were derived are carried over. Intuitively, if  $A_1, \dots, A_n$  are derivable assuming that the members of  $\Delta_1, \dots, \Delta_n$  are false, and if  $B$  is a **CL**-consequence of  $A_1, \dots, A_n$ , then  $B$  is derivable, still assuming that all members of  $\Delta_1, \dots, \Delta_n$  are false.

Before turning to RC, here is an example illustrating the use of the rules Prem and RU. Let  $\Gamma_1 = \{Pa \wedge Qa, Pb, \neg Qc\}$ . Suppose we start an **LI**-proof for  $\Gamma_1$  as follows

1	$Pa \wedge Qa$	Prem	$\emptyset$
2	$Pb$	Prem	$\emptyset$
3	$\neg Qc$	Prem	$\emptyset$
4	$Pa$	1; RU	$\emptyset$
5	$Qa$	1; RU	$\emptyset$

Let  $\Theta$  be a finite set of **LI**-abnormalities, that is,  $\Theta \subset \Omega_{\text{LI}}$ . Then  $\text{Dab}(\Theta)$  refers to the classical disjunction of the members of  $\Theta$  ( $\text{Dab}$  abbreviates *disjunction of abnormalities*; in the remainder, such disjunctions are sometimes referred to as  $\text{Dab}$ -formulas). RC stipulates that, whenever  $B$  is **CL**-derivable from  $A_1, \dots, A_n$  in disjunction with one or more abnormalities, then  $B$  can be inferred assuming that these abnormalities are false, i. e., we can derive  $B$  and add the abnormalities in question to the condition set, together with assumptions made at the lines at which  $A_1, \dots, A_n$  were derived.

For instance, (11.2) is **CL**-valid

$$\forall x(Px \vee Qx) \vee \neg \forall x(Px \vee Qx) \quad (11.2)$$

Note that the second disjunct of (11.2) is a member of  $\Omega_{\text{LI}}$ . In the context of inductive generalization the assumption that the world is as *normal* as possible corresponds to an assumption about the uniformity of the world. In adaptive proofs, such assumptions are made explicit by applications of the conditional rule. Concretely, if a formula like (11.2) is derived in an **LI**-proof, RC can be used to derive the first disjunct on the condition that the second disjunct is false. In fact, since (11.2) is a **CL**-theorem, the generalization  $\forall x(Px \vee Qx)$  can be introduced right away, taking its negation to be false (lines 1–5 are not repeated)

$$6 \quad \forall x(Px \vee Qx) \quad \text{RC} \quad \{\neg \forall x(Px \vee Qx)\}$$

In a similar fashion, RC can be used to derive other generalizations

7	$\forall x Px$	RC	$\{\neg \forall x Px\}$
8	$\forall x Qx$	RC	$\{\neg \forall x Qx\}$
9	$\forall x(\neg Px \vee Qx)$	RC	$\{\neg \forall x(\neg Px \vee Qx)\}$
10	$\forall x(Px \vee \neg Qx)$	RC	$\{\neg \forall x(Px \vee \neg Qx)\}$
11	$\forall x(\neg Px \vee \neg Qx)$	RC	$\{\neg \forall x(\neg Px \vee \neg Qx)\}$

Each generalization is derivable assuming that its corresponding condition is false. However, some of these assumptions clearly cannot be upheld. We know, for instance, that the generalizations derived at lines 8 and 11 are falsified by the premises at lines 3 and 1 respectively. So we need a way of distinguishing between *good* and *bad* inferred generalizations. This is where the adaptive strategy comes in. Since distinguishing *good* from *bad* generalizations can be done in different ways, there are different strategies available to us for making the distinction hard. First, the reliability strategy and its corresponding marking definition are introduced. The latter definition takes care of the retraction of *bad* generalizations.

Marking definitions proceed in terms of the minimal inferred  $\text{Dab}$ -formulas derived at a stage of a proof. A  $\text{Dab}$ -formula that is derived at a proof stage by RU at a line with condition  $\emptyset$  is called an *inferred Dab-formula* of the proof stage.

#### Definition 11.1 Minimal inferred Dab-formula

$\text{Dab}(\Delta)$  is a *minimal inferred Dab-formula* at stage  $s$  of a proof iff  $\text{Dab}(\Delta)$  is an inferred  $\text{Dab}$ -formula at stage  $s$  and there is no  $\Delta' \subset \Delta$  such that  $\text{Dab}(\Delta')$  is an inferred  $\text{Dab}$ -formula at stage  $s$ .

Where  $\text{Dab}(\Delta_1), \dots, \text{Dab}(\Delta_n)$  are the minimal inferred  $\text{Dab}$ -formulas derived at stage  $s$ ,  $U_s(\Gamma) = \Delta_1 \cup \dots \cup \Delta_n$  is the set of formulas that are *unreliable* at stage  $s$ .

#### Definition 11.2 Marking for reliability

Where  $\Delta$  is the condition of line  $i$ , line  $i$  is marked at stage  $s$  iff  $\Delta \cap U_s(\Gamma) \neq \emptyset$ .

To illustrate the marking mechanism, consider the following extension of the **LI**-proof for  $\Gamma_1$  (marked lines are indicated by a  $\checkmark$ -sign; lines 1–5 are not repeated in the proof)

6	$\forall x(Px \vee Qx)$	RC	$\{\neg \forall x(Px \vee Qx)\} \checkmark$
7	$\forall x Px$	RC	$\{\neg \forall x Px\} \checkmark$
8	$\forall x Qx$	RC	$\{\neg \forall x Qx\} \checkmark$

9	$\forall x(\neg Px \vee Qx)$ $\{\neg \forall x(\neg Px \vee Qx)\} \checkmark$	RC
10	$\forall x(Px \vee \neg Qx)$ $\{\neg \forall x(Px \vee \neg Qx)\}$	RC
11	$\forall x(\neg Px \vee \neg Qx)$ $\{\neg \forall x(\neg Px \vee \neg Qx)\} \checkmark$	RC
12	$\neg \forall x Qx$ $\emptyset$	3; RU
13	$\neg \forall x(\neg Px \vee \neg Qx)$ $\emptyset$	1; RU
14	$\neg \forall x Px \vee \neg \forall x(\neg Px \vee Qx)$ $\emptyset$	3; RU
15	$\neg \forall x(Px \vee Qx) \vee \neg \forall x(\neg Px \vee Qx)$ $\emptyset$	3; RU

As remarked above, the generalizations derived at lines 8 and 11 are falsified by the premises, so it makes good sense to mark them and thereby consider them not derived anymore. As soon as we derive the negations of these generalizations (lines 12 and 13) Definition 11.2 takes care that lines 8 and 11 are marked. The generalizations derived at lines 6, 7, and 9 are not falsified by the data, yet they are marked according to Definition 11.2, due to the derivability of the minimal inferred Dab-disjunctions at lines 14 and 15. We know, for instance, that the generalizations derived at lines 7 and 9 cannot be upheld together: at line 14 we inferred that they are jointly incompatible in view of the premises. Definition 11.2 takes care that *both* lines 7 and 9 are marked at stage 15, since

$$U_{15}(\Gamma_1) = \{\neg \forall x Px, \neg \forall x Qx, \neg \forall x(Px \vee Qx), \\ \neg \forall x(\neg Px \vee Qx), \neg \forall x(\neg Px \vee \neg Qx)\}. \quad (11.3)$$

The only inferred generalization left unmarked at stage 15 is  $\forall x(Px \vee \neg Qx)$ , derived at line 10.

Due to the dynamics of adaptive proofs, we cannot just take a formula to be an AL-consequence of some premise set  $\Gamma$  once we derived it at some stage on an unmarked line in a proof for  $\Gamma$ , for it may be that there are extensions of the proof in which the line in question gets marked. Likewise, we need to take into account the fact that lines marked at a stage of a proof may become unmarked at a later stage. This is taken care of by using the concept of *final derivability*:

**Definition 11.3 Final derivability**

$A$  is *finally derived* from  $\Gamma$  at line  $i$  of a finite proof stage  $s$  iff (i)  $A$  is the second element of line  $i$ , (ii) line  $i$

is not marked at stage  $s$ , and (iii) every extension of the proof in which line  $i$  is marked may be further extended in such a way that line  $i$  is unmarked.

**Definition 11.4 Logical consequence for  $\mathbf{LI}^f$**

$\Gamma \vdash_{\mathbf{LI}^f} A$  ( $A$  is finally  $\mathbf{LI}^f$ -derivable from  $\Gamma$ ) iff  $A$  is finally derived at a line of an  $\mathbf{LI}^f$ -proof from  $\Gamma$ .

Given the premise set  $\Gamma_1$ , there are no extensions of the proof above in which any of the marked lines become unmarked, nor are there extensions in which line 10 is marked and cannot be unmarked again in a further extension of the proof. Hence, by Definitions 11.3 and 11.4

$$\Gamma_1 \not\vdash_{\mathbf{LI}^f} \forall x Px, \quad (11.4)$$

$$\Gamma_1 \not\vdash_{\mathbf{LI}^f} \forall x Qx, \quad (11.5)$$

$$\Gamma_1 \not\vdash_{\mathbf{LI}^f} \forall x(Px \vee Qx), \quad (11.6)$$

$$\Gamma_1 \vdash_{\mathbf{LI}^f} \forall x(Px \vee \neg Qx), \quad (11.7)$$

$$\Gamma_1 \not\vdash_{\mathbf{LI}^f} \forall x(\neg Px \vee Qx), \quad (11.8)$$

$$\Gamma_1 \not\vdash_{\mathbf{LI}^f} \forall x(\neg Px \vee \neg Qx). \quad (11.9)$$

The logic  $\mathbf{LI}^f$  is non-monotonic: adding new premises may block the derivation of generalizations that were finally derivable from the original premise set. For instance, suppose that we add the premise  $\neg Pd \wedge Qd$  to  $\Gamma_1$ . Since the extra premise provides a counter-instance to the generalization  $\forall x(Px \vee \neg Qx)$ , the latter should no longer be  $\mathbf{LI}^f$ -derivable from the new premise set. The following proof illustrates that this is indeed the case

1	$Pa \wedge Qa$ $\emptyset$	Prem
2	$Pb$ $\emptyset$	Prem
3	$\neg Qc$ $\emptyset$	Prem
4	$\neg Pd \wedge Qd$ $\emptyset$	Prem
5	$\forall x(Px \vee Qx)$ $\{\neg \forall x(Px \vee Qx)\} \checkmark$	RC
6	$\forall x Px$ $\{\neg \forall x Px\} \checkmark$	RC
7	$\forall x Qx$ $\{\neg \forall x Qx\} \checkmark$	RC
8	$\forall x(\neg Px \vee Qx)$ $\{\neg \forall x(\neg Px \vee Qx)\} \checkmark$	RC

9	$\forall x(Px \vee \neg Qx)$ $\{\neg \forall x(Px \vee \neg Qx)\} \checkmark$	RC
10	$\forall x(\neg Px \vee \neg Qx)$ $\{\neg \forall x(\neg Px \vee \neg Qx)\} \checkmark$	RC
11	$\neg \forall x Px$ $\emptyset$	4; RU
12	$\neg \forall x Qx$ $\emptyset$	3; RU
13	$\neg \forall x(\neg Px \vee \neg Qx)$ $\emptyset$	1; RU
14	$\neg \forall x(Px \vee Qx) \vee \neg \forall x(\neg Px \vee Qx)$ $\emptyset$	3; RU
15	$\neg \forall x(Px \vee \neg Qx)$ $\emptyset$	4; RU

Line 9 is marked in view of the Dab-formula derived at line 15. There is no way to extend this proof in such a way that the line in question gets unmarked. Hence,  $\Gamma_1 \cup \{\neg Pd \wedge Qd\} \not\vdash_{\mathbf{L}^{\mathbf{F}}} \forall x(Px \vee \neg Qx)$ . In fact, no nontautological generalizations whatsoever are  $\mathbf{L}^{\mathbf{F}}$ -derivable from the extended premise set  $\Gamma_1 \cup \{\neg Pd \wedge Qd\}$ .

### 11.2.3 Minimal Abnormality

Different interpretations of the same set of data may lead to different views concerning which generalizations should or should not be derivable. Each such view may be driven by its own rationale, and choosing one such rationale over the other is not a matter of pure logic. For that reason, different strategies are available to adaptive logicians, each interpreting a set of data in their own sensible way, depending on the context. The reliability strategy was defined already. The minimal abnormality strategy is slightly less skeptical. Consequently, for some premise sets, generalizations may be  $\mathbf{L}^{\mathbf{m}}$ -derivable, but not  $\mathbf{L}^{\mathbf{F}}$ -derivable.

Like reliability, the minimal abnormality strategy comes with its marking definition. Let a *choice set* of  $\Sigma = \{\Delta_1, \Delta_2, \dots\}$  be a set that contains one element out of each member of  $\Sigma$ . A *minimal choice set* of  $\Sigma$  is a choice set of  $\Sigma$  of which no proper subset is a choice set of  $\Sigma$ . Where  $\text{Dab}(\Delta_1), \text{Dab}(\Delta_2), \dots$  are the minimal inferred Dab-formulas derived from a premise set  $\Gamma$  at stage  $s$  of a proof,  $\Phi_s(\Gamma)$  is the set of minimal choice sets of  $\{\Delta_1, \Delta_2, \dots\}$ .

#### Definition 11.5 Marking for minimal abnormality

Where  $A$  is the formula and  $\Delta$  the condition of line  $i$ , line  $i$  is marked at stage  $s$  iff (i) there is no  $\varphi \in \Phi_s(\Gamma)$  such that  $\varphi \cap \Delta = \emptyset$ , or (ii) for some  $\varphi \in \Phi_s(\Gamma)$ , there

is no line at which  $A$  is derived on a condition  $\Theta$  for which  $\varphi \cap \Theta = \emptyset$ .

An example will clarify matters. Let  $\Gamma_2 = \{Pa \wedge Qa \wedge Ra, \neg Rb \wedge (\neg Pb \vee \neg Qb), \neg Pc \wedge \neg Qc \wedge Rc\}$ .

1	$Pa \wedge Qa \wedge Ra$ $\emptyset$	Prem
2	$\neg Rb \wedge (\neg Pb \vee \neg Qb)$ $\emptyset$	Prem
3	$\neg Pc \wedge \neg Qc \wedge Rc$ $\emptyset$	Prem
4	$\forall x(Px \vee Qx)$ $\{\neg \forall x(Px \vee Qx)\} \checkmark$	RC
5	$\forall x(Px \vee Rx)$ $\{\neg \forall x(Px \vee Rx)\} \checkmark$	RC
6	$\forall x(\neg Px \vee Rx)$ $\{\neg \forall x(\neg Px \vee Rx)\} \checkmark$	RC
7	$\neg \forall x(Px \vee Qx)$ $\emptyset$	3; RU
8	$\neg \forall x(Px \vee Rx) \vee \neg \forall x(\neg Px \vee Rx)$ $\emptyset$	2; RU
9	$\forall x(Px \vee Rx) \vee \forall x(\neg Px \vee Rx)$ $\{\neg \forall x(Px \vee Rx)\}$	5; RU
10	$\forall x(Px \vee Rx) \vee \forall x(\neg Px \vee Rx)$ $\{\neg \forall x(\neg Px \vee Rx)\}$	6; RU

To see what is happening in this proof, we need to understand the markings. Note that there are two minimal choice sets at stage 10

$$\Phi_{10}(\Gamma_2) = \{\{\neg \forall x(Px \vee Qx), \neg \forall x(Px \vee Rx)\}, \{\neg \forall x(Px \vee Qx), \neg \forall x(\neg Px \vee Rx)\}\} . \quad (11.10)$$

Line 4 is marked in view of clause (i) in Definition 11.5, since its condition intersects with each minimal choice set in  $\Phi_{10}(\Gamma_2)$ . Lines 5 and 6 are marked in view of clause (ii) in Definition 11.5. For the minimal choice set  $\{\neg \forall x(Px \vee Qx), \neg \forall x(Px \vee Rx)\}$ , there is no line at which  $\forall x(Px \vee Rx)$  was derived on a condition that does not intersect with this set. Hence line 5 is marked. Analogously, line 6 is marked because, for the minimal choice set  $\{\neg \forall x(Px \vee Qx), \neg \forall x(\neg Px \vee Rx)\}$ , there is no line at which  $\forall x(\neg Px \vee Rx)$  was derived on a condition that does not intersect with this set.

Things change, however, when we turn to lines 9 and 10. In these cases, none of clauses (i) or (ii) of Def-

inition 11.5 apply: for each of these lines, there is a minimal choice set in  $\Phi_{10}(\Gamma_2)$  which does not intersect with the line's condition; and for each of the sets in  $\Phi_{10}(\Gamma_2)$ , we have derived the formula  $\forall x(Px \vee Rx) \vee \forall x(\neg Px \vee Rx)$  on a condition that does not intersect with it. Hence, these lines remain unmarked at stage 10 of the proof.

Things would have been different if we made use of the reliability strategy, since

$$U_{10}(\Gamma_2) = \{ \neg \forall x(Px \vee Qx), \neg \forall x(Px \vee Rx), \\ \neg \forall x(\neg Px \vee Rx) \}. \quad (11.11)$$

In view of  $U_{10}(\Gamma_2)$  and Definition 11.2, all of lines 4–6 and 9–10 would be marked if the above proof were a  $\mathbf{LI}^{\mathbf{F}}$ -proof.

As with the reliability strategy, logical consequence for the minimal abnormality strategy is defined in terms of final derivability (Definition 11.3). A consequence relation for  $\mathbf{LI}^{\mathbf{m}}$  is defined simply by replacing all occurrences of  $\mathbf{LI}^{\mathbf{F}}$  in Definition 11.4 with  $\mathbf{LI}^{\mathbf{m}}$ . Although the proof above can be extended in many interesting ways, showing the (non-)derivability of many more

generalizations than those currently occurring in the proof, nothing will change in terms of final derivability with respect to the formulas derived at stage 10

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{m}}} \forall x(Px \vee Qx), \quad (11.12)$$

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{m}}} \forall x(Px \vee Rx), \quad (11.13)$$

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{m}}} \forall x(Px \vee \neg Rx), \quad (11.14)$$

$$\Gamma_2 \vdash_{\mathbf{LI}^{\mathbf{m}}} \forall x(Px \vee Rx) \vee \forall x(\neg Px \vee Rx), \quad (11.15)$$

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{F}}} \forall x(Px \vee Qx), \quad (11.16)$$

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{F}}} \forall x(Px \vee Rx), \quad (11.17)$$

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{F}}} \forall x(Px \vee \neg Rx), \quad (11.18)$$

$$\Gamma_2 \not\vdash_{\mathbf{LI}^{\mathbf{F}}} \forall x(Px \vee Rx) \vee \forall x(\neg Px \vee Rx). \quad (11.19)$$

At the beginning of Sect. 11.2.3 it was mentioned that the rationale underlying the reliability strategy is slightly more skeptical than that underlying the minimal abnormality strategy. The point is illustrated by the proof for  $\Gamma_2$ . As we saw, the formula  $\forall x(Px \vee Rx) \vee \forall x(\neg Px \vee Rx)$  is  $\mathbf{LI}^{\mathbf{m}}$ -derivable from  $\Gamma_2$ , but not  $\mathbf{LI}^{\mathbf{F}}$ -derivable from  $\Gamma_2$ .

### 11.3 More Adaptive Logics for Inductive Generalization

$\mathbf{LI}$  interprets the world as *uniform* by taking as normal those situations in which a generalization is true, and as abnormal those situations in which a generalization is false. But of course, if uniformity is identified with the truth of *every* generalization in this way, the world can never be completely uniform (for the simple fact that many generalizations are incompatible and cannot be jointly true). Perhaps a more natural way to interpret the uniformity of the world is to take all objects to have the same properties: as soon as one object has property  $P$ , we try to infer that all objects have property  $P$ . This is the rationale behind the logic  $\mathbf{IL}$  from [11.5].

Roughly, the idea behind  $\mathbf{IL}$  is to generalize from instances. Given an instance, the derivation of a generalization is permitted on the condition that no counterinstances are derivable. So abnormal situations are those in which both an instance and a counter-instance of a generalization are present. This is the formal definition of the set of  $\mathbf{IL}$ -abnormalities

$$\Omega_{\mathbf{IL}} =_{\text{df}} \{ \exists(A_1 \vee \dots \vee A_n) \wedge \exists \neg(A_1 \vee \dots \vee A_n) \mid \\ A_1, \dots, A_n \in \mathcal{A}^{f1}; n \geq 1 \}. \quad (11.20)$$

The logic  $\mathbf{IL}$  is defined by the lower limit logic  $\mathbf{CL}$ , the set of abnormalities  $\Omega_{\mathbf{IL}}$ , and the adaptive strategy reliability ( $\mathbf{IL}^{\mathbf{r}}$ ) or minimal abnormality ( $\mathbf{IL}^{\mathbf{m}}$ ).

In an  $\mathbf{IL}$ -proof generalizations cannot be conditionally introduced from scratch, since an instance is required. In this respect,  $\mathbf{IL}$  is more demanding than  $\mathbf{LI}$ . However, it does not follow that for this reason  $\mathbf{IL}$  is a weaker logic, since it is also more difficult to derive (disjunctions of) abnormalities in  $\mathbf{IL}$ . A simple example will illustrate that, for many premise sets,  $\mathbf{IL}$  is in fact stronger than  $\mathbf{LI}$ . Consider the following  $\mathbf{IL}$ -proof from  $\Gamma_3 = \{Pa, \neg Pb \vee Qb\}$

1	$Pa$	Prem
	$\emptyset$	
2	$\neg Pb \vee Qb$	Prem
	$\emptyset$	
3	$\forall xPx$	1; RC
	$\{ \exists xPx \wedge \exists x\neg Px \}$	
4	$Qb$	2, 3; RU
	$\{ \exists xPx \wedge \exists x\neg Px \}$	
5	$\forall xQx$	4; RC
	$\{ \exists xPx \wedge \exists x\neg Px, \exists xQx \wedge \exists x\neg Qx \}$	

In view of  $Pa \vdash_{\mathbf{CL}} \forall xPx \vee (\exists xPx \wedge \exists x\neg Px)$ , we applied RC to line 1 and conditionally inferred  $\forall xPx$  at line 3. Next, we used RU to infer  $Qb$  from this newly obtained generalization together with the premise at line 2. We

now have an instance of  $\forall xQx$ , so we can conditionally infer the latter generalization, taking over the condition of line 4. Importantly, not a single disjunction of members of  $\Omega_{\mathbf{IL}}$  is **CL**-derivable from  $\Gamma_3$ . This means that there is no way to mark any of lines 3–5 in any extension of this proof, independently of which strategy we use.

Consequence relations for  $\mathbf{IL}^r$  and  $\mathbf{IL}^m$  are again definable in terms of final derivability (Definition 11.3). All we need to do is replace all occurrences of  $\mathbf{LI}^r$  in Definition 11.4 with  $\mathbf{IL}^r$ , respectively  $\mathbf{IL}^m$ . Hence

$$\Gamma_3 \vdash_{\mathbf{IL}} \forall xPx, \quad (11.21)$$

$$\Gamma_3 \vdash_{\mathbf{IL}} \forall xQx. \quad (11.22)$$

Compare the **IL**-proof above with the following **LI**-proof from  $\Gamma_3$

1	$Pa$	Prem
	$\emptyset$	
2	$\neg Pb \vee Qb$	Prem
	$\emptyset$	
3	$\forall xPx$	RC
	$\{\neg \forall xPx\} \checkmark$	
4	$Qb$	2, 3; RU
	$\{\neg \forall xPx\} \checkmark$	
5	$\forall xQx$	RC
	$\{\neg \forall xQx\} \checkmark$	
6	$\neg \forall xPx \vee \neg \forall x \neg Qx$	1, 2; RU
	$\emptyset$	
7	$\neg \forall xQx \vee \neg \forall x(\neg Px \vee \neg Qx)$	1, 2; RU
	$\emptyset$	

Independently of the adaptive strategy used (reliability or minimal abnormality), there are no extensions of this **LI**-proof in which any of lines 3–5 become unmarked. Therefore

$$\Gamma_3 \not\vdash_{\mathbf{LI}} \forall xPx, \quad (11.23)$$

$$\Gamma_3 \not\vdash_{\mathbf{LI}} \forall xQx. \quad (11.24)$$

The premise set  $\Gamma_3$  not only serves to show that **IL** is not strictly weaker than **LI** in terms of derivable generalizations. It also illustrates that, although in an **IL**-proof we generalize on the basis of instances, such an instance need not always be **CL**-derivable from the premise set. In the proof from  $\Gamma_3$ , we derived the generalization  $\forall xQx$  even though no instance of this generalization is **CL**-derivable from  $\Gamma_3$ . Instead, we first derived  $\forall xPx$  (of which  $\Gamma_3$  *does* provide us with an instance), and

then used this generalization to *infer* an instance of  $\forall xQx$ . This is perfectly in line with the intuition behind **IL**: If deriving a generalization on the basis of an instance leads us to more instances of other generalizations, then, assuming the world to be as uniform as possible, we take the world to be uniform with respect to these other generalizations as well.

When discussing inductive generalization, confirmation theorists often use the more fine-grained distinction between mere instances of a generalization, positive instances, and negative instances. For example, given a generalization  $\forall x(Px \supset Qx)$ , any  $a$  such that  $Pa \supset Qa$  is an *instance* of  $\forall x(Px \supset Qx)$ ; any  $a$  such that  $Pa \wedge Qa$  is a *positive instance* of  $\forall x(Px \supset Qx)$ ; and any  $a$  such that  $Pa \wedge \neg Qa$  is a *negative instance* of  $\forall x(Px \supset Qx)$ . Instead of requiring a mere instance before introducing a generalization, some confirmation theorists have suggested the stronger requirement for a positive instance, that is, a negative instance of the contrary generalization (Sect. 11.4.3). According to this idea, interpreting the world as uniform as possible amounts to generalizing whenever a positive instance is available to us. Abnormal situations, then, are those in which both a positive and a negative instance of a generalization are available to us. There is a corresponding variant of **IL** that hard-codes this idea in its set of abnormalities: the logic **G** from [11.5]. The latter is defined by the lower limit logic **CL**, the set of abnormalities  $\Omega_{\mathbf{G}}$  and either the reliability strategy ( $\mathbf{G}^r$ ) or the minimal abnormality strategy ( $\mathbf{G}^m$ ).

$$\begin{aligned} \Omega_{\mathbf{G}} =_{\text{df}} & \\ & \{ \exists(A_1 \wedge \dots \wedge A_n \wedge A_0) \wedge \exists(A_1 \wedge \dots \wedge A_n \wedge \neg A_0) \mid \\ & A_0, A_1, \dots, A_n \in \mathcal{A}^{f1}; n \geq 0 \}. \end{aligned} \quad (11.25)$$

In proofs to follow  $\exists(A_1 \wedge \dots \wedge A_n \wedge A_0) \wedge \exists(A_1 \wedge \dots \wedge A_n \wedge \neg A_0)$  is abbreviated as  $A_1 \wedge \dots \wedge A_n \wedge \pm A_0$  (where again  $A_0, A_1, \dots, A_n \in \mathcal{A}^{f1}$ ). As an illustration of the workings of **G**, consider the following **G**-proof from  $\Gamma_4 = \{Pa \wedge Qa, \neg Qb, \neg Pc\}$

1	$Pa \wedge Qa$	Prem
	$\emptyset$	
2	$\neg Qb$	Prem
	$\emptyset$	
3	$\neg Pc$	Prem
	$\emptyset$	
4	$\forall x(Px \supset Qx)$	1; RC
	$\{Px \wedge \pm Qx\}$	

5	$\forall x(Qx \supset Px)$ $\{Qx \wedge \pm Px\}$	1; RC
6	$\forall x(Px \equiv Qx)$ $\{Px \wedge \pm Qx, Qx \wedge \pm Px\}$	4, 5; RU
7	$\exists xPx \wedge \exists x\neg Px$ $\emptyset$	1, 3; RU
8	$\exists xQx \wedge \exists x\neg Qx$ $\emptyset$	1, 2; RU

The formulas derived at lines 4–6 are finally **G**-derivable in the proof. Since **G**-consequence too is defined in terms of final derivability, it follows, independently of the strategy used, that

$$\Gamma_4 \vdash_{\mathbf{G}} \forall x(Px \supset Qx), \quad (11.26)$$

$$\Gamma_4 \vdash_{\mathbf{G}} \forall x(Qx \supset Px), \quad (11.27)$$

$$\Gamma_4 \vdash_{\mathbf{G}} \forall x(Px \equiv Qx). \quad (11.28)$$

Now consider the following **IL**-proof from  $\Gamma_4$  (where  $A_1, \dots, A_n \in \mathcal{A}^{f1}$ ,  $!(A_1 \vee \dots \vee A_n)$  abbreviates  $\exists(A_1 \vee \dots \vee A_n) \wedge \exists \neg(A_1 \vee \dots \vee A_n)$ )

1	$Pa \wedge Qa$ $\emptyset$	Prem
2	$\neg Qb$ $\emptyset$	Prem
3	$\neg Pc$ $\emptyset$	Prem
4	$\forall x(Px \supset Qx)$ $\{!(\neg Px \vee Qx)\} \checkmark$	1; RC
5	$\forall x(Qx \supset Px)$ $\{!(\neg Qx \vee Px)\} \checkmark$	1; RC
6	$\forall x(Px \equiv Qx)$ $\{!(\neg Px \vee Qx), !( \neg Qx \vee Px)\} \checkmark$	4, 4; RU
7	$!Px$ $\emptyset$	1, 3; RU
8	$!Qx$ $\emptyset$	1, 2; RU
9	$!(Px \vee Qx) \vee !( \neg Px \vee Qx)$ $\emptyset$	1, 2; RU
10	$!(\neg Qx \vee Px) \vee !(Px \vee Qx)$ $\emptyset$	1, 3; RU
11	$!(\neg Px \vee \neg Qx)$ $\emptyset$	1, 2; RU

The minimal inferred Dab-formulas inferred at lines 7–11 will remain minimal in any extension of this proof

(none of the disjuncts of any of the formulas derived at lines 9 or 10 is separately derivable). Accordingly, the marks in this proof will not change. Hence, independently of the strategy used

$$\Gamma_4 \not\vdash_{\mathbf{IL}} \forall x(Px \supset Qx), \quad (11.29)$$

$$\Gamma_4 \not\vdash_{\mathbf{IL}} \forall x(Qx \supset Px), \quad (11.30)$$

$$\Gamma_4 \not\vdash_{\mathbf{IL}} \forall x(Px \equiv Qx). \quad (11.31)$$

Two more remarks are in order. First, the example above suggests that **G** is in general stronger than **IL**. This is correct for the minimal abnormality strategy, but false for the reliability strategy. An illustration is provided by the premise set  $\Gamma_5 = \{Pa, Qb, Rb, Qc, \neg Rc\}$ . The generalization  $\forall x(\neg Px \supset Qx)$  cannot be inferred on the condition  $\neg Px \wedge \pm Qx$ , since we lack a positive instance. It *can* be inferred on the conditions  $\pm Qx$  or  $\pm Px$  in view of  $\forall xQx \vdash_{\mathbf{CL}} \forall x(\neg Px \supset Qx)$  and  $\forall xPx \vdash_{\mathbf{CL}} \forall x(\neg Px \supset Qx)$ , but none of these conditions are reliable in view of the derivability of minimal Dab-formulas like  $\pm Px \vee (Px \wedge \pm Rx)$  and  $\pm Qx \vee (Qx \wedge \pm Px) \vee (Px \wedge \pm Rx)$ .

The situation is different in an **IL**<sup>r</sup>-proof, where deriving  $\forall x(\neg Px \supset Qx)$  on the condition  $!(Px \vee Qx)$  in a proof from  $\Gamma_5$  is both possible and final. That is, for every derivable Dab-formula in which  $!(Px \vee Qx)$  occurs, we can derive a shorter (minimal) disjunction of abnormalities in which it no longer occurs. Summing up

$$\Gamma_5 \not\vdash_{\mathbf{G}^r} \forall x(\neg Px \supset Qx), \quad (11.32)$$

$$\Gamma_5 \vdash_{\mathbf{IL}^r} \forall x(\neg Px \supset Qx). \quad (11.33)$$

The second remark is that the requirement for a *positive* instance before generalizing in a **G**-proof is still insufficient to guarantee that for every **G**-derivable generalization a positive instance is **CL**-derivable from the premises. The following proof from  $Pa$  illustrates the point

1	$Pa$	Prem	$\emptyset$
2	$\forall xPx$	1; RC	$\{\pm Px\}$
3	$\forall x(Qx \supset Px)$	2; RU	$\{\pm Px\}$

Independently of the strategy used, no means are available to mark line 3, hence  $Pa \vdash_{\mathbf{G}} \forall x(Qx \supset Px)$ , even though no positive instance of  $\forall x(Qx \supset Px)$  is available. More on this point below (see the discussion on Hempel's raven paradox in Sect. 11.4.1 and in the Appendix).

A total of six logics have been presented so far: the logics **LI**<sup>r</sup>, **LI**<sup>m</sup>, **IL**<sup>r</sup>, **IL**<sup>m</sup>, **G**<sup>r</sup>, and **G**<sup>m</sup>. Each of these systems interprets the claim that the world is uniform in a slightly different way, leading to slightly different log-

ics. Importantly, there is no Carnapian embarrassment of riches here: each of the systems has a clear intuition behind it.

The systems presented here can be combined so as to implement *Popper's* suggestion that more general hypotheses should be given precedence over less general ones [11.11]. For instance, if two generalizations  $\forall x(Px \supset Qx)$  and  $\forall x((Rx \wedge Sx) \supset Tx)$  are jointly incom-

patible with the premises, a combined system gives precedence to the more general hypothesis and delivers only  $\forall x(Px \supset Qx)$  as a consequence. There are various ways to hard-code this idea, resulting in various new combined adaptive logics for inductive generalization, each slightly different from the others. These combinations are not fully spelled out here. For a brief synopsis, see [11.5, Sect. 5].

## 11.4 Qualitative Inductive Generalization and Confirmation

Inductive logic and confirmation theory overlap to some extent. As early as 1943, *Hempel* noted that the development of a logical theory of confirmation might be regarded as a contribution to the field of inductive logic [11.6, p. 123]. Following Carnap and Popper's influential work on inductive logic and corroboration respectively, many of the existing criteria of confirmation are quantitative in nature, measuring the *degree* of confirmation of a hypothesis by the evidence, possibly taking into account auxiliary hypotheses and background knowledge. Here, the logics defined in the previous two sections are presented as *qualitative* criteria of confirmation, and are related to other qualitative models of confirmation. Quantitative criteria of confirmation are not considered. For *Carnap's* views on inductive logic, see [11.12]. For *Popper's*, see [11.11]. For introductions to inductive logic and probabilistic measures of confirmation, see, e.g., [11.13–16].

Let **I** be any adaptive logic for inductive generalization defined in one of the previous sections. (All remarks on **I**-confirmation readily generalize to the combined systems from [11.5, Sect. 5].) Where  $H$  is the hypothesis and  $\Gamma$  contains the evidence, **I**-confirmation is defined in terms of **I**-consequence:

### Definition 11.6 **I**-confirmation

$\Gamma$  **I**-confirms  $H$  iff  $\Gamma \vdash_{\mathbf{I}} H$ .

$\Gamma$  **I**-disconfirms  $H$  iff  $\Gamma \vdash_{\mathbf{I}} \neg H$ .

$\Gamma$  is **I**-neutral with respect to  $H$  iff  $\Gamma \not\vdash_{\mathbf{I}} H$  and  $\Gamma \not\vdash_{\mathbf{I}} \neg H$ .

This definition of **I**-confirmation has the virtue of simplicity and formal precision. The two main qualitative alternatives to **I**-confirmation are *Hempel's* satisfaction criterion and the hypothetico-deductive model of confirmation. In Sect. 11.4.1, **I**-confirmation is compared to *Hempel's* adequacy conditions, which serve as a basis for his satisfaction criterion. In Sect. 11.4.2, **I**-confirmation is compared to hypothetico-deductive confirmation. Section 11.4.3 concerns the use of the

criteria from Definition 11.6 as heuristic tools for hypothesis generation and confirmation.

### 11.4.1 **I**-Confirmation and *Hempel's* Adequacy Conditions

Let an *observation report* consist of a set of molecular sentences (sentences containing no free variables or quantifiers). According to *Hempel*, the following conditions should be satisfied by any adequate criterion for confirmation [11.17]:

- (1) *Entailment condition*: Any sentence which is entailed by an observation report is confirmed by it.
- (2) *Consequence condition*: If an observation report confirms every one of a class  $K$  of sentences, then it also confirms any sentence which is a logical consequence of  $K$ :
  - (a) *Special consequence condition*: If an observation report confirms a hypothesis  $H$ , then it also confirms every consequence of  $H$ .
  - (b) *Equivalence condition*: If an observation report confirms a hypothesis  $H$ , then it also confirms every hypothesis which is logically equivalent to  $H$ .
- (3) *Consistency condition*: Every logically consistent observation report is logically compatible with the class of all the hypotheses which it confirms.

If *logical consequence* is taken to be **CL**-consequence, as *Hempel* did, then **I**-confirmation satisfies conditions (1)-(3) no matter which adaptive logic for inductive generalization is used, due to **I**'s closure under **CL**. So all of the resulting criteria of confirmation meet *Hempel's* adequacy conditions. (For (3) the further property of *smoothness* or *reassurance* is required, from which it follows that the **I**-consequence set of consistent premise sets is consistent as well [11.7, Sect. 6].)

The definition of *Hempel's* own criterion requires some preparation (the formal presentation of *Hempel's* criterion is taken from [11.18]). An atomic formula  $A$

is *relevant* to a formula  $B$  iff there is some model  $M$  of  $A$  such that: if  $M'$  differs from  $M$  only in the value assigned to  $B$ ,  $M'$  is not a model of  $A$ . The *domain* of a formula  $A$  is the set of individual constants that occur in the atomic formulas that are relevant for  $A$ . The *development* of a universally quantified formula  $A$  for another formula  $B$  is the restriction of  $A$  to the domain of  $B$ , that is, the truth value of  $A$  is evaluated with respect to the domain of  $B$ . For instance, the domain of  $Pa \wedge (Pb \vee Qc)$  is  $\{a, b, c\}$  whereas the domain of  $Pa \wedge Qa$  is  $\{a\}$ ; and the development of  $\forall x(Px \supset Qx)$  for  $Pa \wedge \neg Qb$  is  $(Pa \supset Qa) \wedge (Pb \supset Qb)$ .

### Definition 11.7 Hempel's satisfaction criterion

An observation report  $E$  *directly confirms* a hypothesis  $H$  if  $E$  entails the development of  $H$  for  $E$ .

An observation report  $E$  *confirms* a hypothesis  $H$  if  $H$  is entailed by a class of sentences each of which is directly confirmed by  $E$ .

An observation report  $E$  *disconfirms* a hypothesis  $H$  if it confirms the denial of  $H$ .

An observation report  $E$  is *neutral* with respect to a hypothesis  $H$  if  $E$  neither confirms nor disconfirms  $H$ .

There are two reasons for arguing that Hempel's satisfaction criterion is too restrictive, and two reasons for arguing that it is too liberal. Each of these is discussed in turn. First, in order for the evidence to confirm a hypothesis  $H$  according to Hempel's criterion, *all* objects in the development of  $H$  must be known to be instances of  $H$ . This is a very strong requirement. **I**-confirmation is different in this respect. For instance,

$$Pa, Qa, \neg Pb, \neg Qb, Pc \vdash_{\mathbf{I}} \forall x(Px \supset Qx) . \quad (11.34)$$

In (11.34) it is unknown whether  $c$  instantiates the hypothesis  $\forall x(Px \supset Qx)$ , since the premises do not tell us whether  $Pc \supset Qc$ . The development of  $\forall x(Px \supset Qx)$  entails  $Pc \supset Qc$ , whereas the premise set of (11.34) does not. So the hypothesis  $\forall x(Px \supset Qx)$  is not directly confirmed by these premises according to the satisfaction criterion, nor is it entailed by one or more sentences which are directly confirmed by them. Therefore the satisfaction criterion judges the premises to be neutral with respect to the hypothesis  $\forall x(Px \supset Qx)$ , whereas (11.34) illustrates that  $\forall x(Px \supset Qx)$  is **I**-confirmed by these premises.

Second, given the law  $\forall x(Px \supset Rx)$ , the report  $\{Pa, Qa, Pb, Qb\}$ , does not confirm the hypothesis  $\forall x(Rx \supset Qx)$  according to Hempel's original formulation of the satisfaction criterion. The reason is that *auxiliary hypotheses* like  $\forall x(Px \supset Rx)$  contain quantifiers and therefore cannot be elements of observation reports. (The original formulation of Hempel's criterion

can, however, be adjusted so as to take into account background knowledge [11.19, 20].) For problems related to auxiliary hypotheses, see also Sect. 11.4.2. For now, it suffices to note that the criteria from Definition 11.6 do not face this problem, as quantified formulas are perfectly allowed to occur in premise sets. For instance, the set  $\{Pa, Qa, Pb, Qb, \forall x(Px \supset Rx)\}$  **I**-confirms the hypothesis  $\forall x(Rx \supset Qx)$

$$Pa, Qa, Pb, Qb, \forall x(Px \supset Rx) \vdash_{\mathbf{I}} \forall x(Rx \supset Qx) . \quad (11.35)$$

It seems, then, that **I**-confirmation is not too restrictive a criterion for confirmation. However, there are two senses in which **I**-confirmation, like Hempelian confirmation, can be said to be too liberal. The first has to do with Goodman's well-known *new riddle of induction* [11.21]. The family of adaptive logics for inductive generalization makes no distinction between regularities that are *projectible* and regularities that are not. Using Goodman's famous example, let an emerald be *grue* if it is green before January 1st 2020, and blue thereafter. Then the fact that all hitherto observed emeralds are *grue* confirms the hypothesis that all emeralds are *grue*. The latter regularity is not projectible into the future, as we do not seriously believe that in 2020 we will start observing blue emeralds. Nonetheless, it is perfectly fine to define a predicate denoting the property of being *grue*, just as it is perfectly fine to define a predicate denoting the property of being green. Yet the hypothesis *all emeralds are green* is projectible, whereas *all emeralds are grue* is not.

The problem of formulating precise rules for determining which regularities are projectible and which are not is difficult and important, but it is an epistemological problem that cannot be solved by purely logical means. Consequently, it falls outside the scope of this article. See [11.21] for Goodman's formulation and proposed solution of the problem, and [11.22] for a collection of essays on the projectibility of regularities.

Finally, one may argue that **I**-confirmation is too liberal on the basis of Hempel's own *raven paradox*. Where  $Ra$  abbreviates that  $a$  is a raven, and  $Ba$  abbreviates that  $a$  is black, a non-black non-raven **I**-confirms the hypothesis that all ravens are black

$$\neg Ba, \neg Ra \vdash_{\mathbf{I}} \forall x(Rx \supset Bx) . \quad (11.36)$$

Even the logic **G** does not block this inference. The reason is that we are given a positive instance of the generalization  $\forall x(\neg Bx \supset \neg Rx)$ , so we can derive this generalization on the condition  $\exists x(\neg Bx \wedge \neg Rx) \wedge \exists x(\neg Bx \wedge Rx)$ . As the generalization  $\forall x(\neg Bx \supset \neg Rx)$

is **G**-derivable from the premises, so is the logically equivalent hypothesis that all ravens are black,  $\forall x(Rx \supset Bx)$  (remember that **G**, like all logics defined in the previous section, is closed under **CL**).

Hempel's own reaction to the raven paradox was to bite the bullet and accept its conclusion [11.23]. According to Hempel, a non-black non-raven indeed confirms the raven hypothesis in case we did not know beforehand that the bird in question is not a raven. For example, if we observe a grey bird resembling a raven, then finding out that it was a crow confirms the raven hypothesis [11.18]. But as pointed out in [11.19] this defense is insufficient. Even in cases in which it is *known* that a non-black bird is not a raven, the bird in question, although irrelevant to the raven hypothesis, still confirms it.

If – like Hempel – one accepts its conclusion, the raven paradox poses no further problems for **I**-confirmation. Those who disagree are referred to the Appendix, where a relatively simple adaptive alternative to **G**-confirmation is defined which blocks the paradox by means of a non-material conditional invalidating the inference from *all non-black objects are non-ravens* to *all ravens are black*.

### 11.4.2 I-Confirmation and the Hypothetico-Deductive Model

If a hypothesis predicts an event which is observed at a later time, or if it subsumes a given observation report as a consequence of one of its postulates, then this counts as evidence in favor of the hypothesis. The hypothetico-deductive model of confirmation (HD confirmation) is an attempt to formalize this basic intuition according to which a piece of evidence confirms a hypothesis if the latter entails the evidence.

In its standard formulation, HD confirmation also takes into account auxiliary hypotheses. Where  $\Delta$  is a set of background information distinct from the evidence  $E$ ,

#### Definition 11.8 HD-confirmation

$E$  HD-confirms  $H$  relative to  $\Delta$  iff:

- (i)  $\{H\} \cup \Delta$  is consistent,
- (ii)  $\{H\} \cup \Delta$  entails  $E$  ( $\{H\} \cup \Delta \vdash E$ ),
- (iii)  $\Delta$  alone does not entail  $E$  ( $\Delta \not\vdash E$ ).

The intuitive difference conveyed by HD confirmation and Hempelian confirmation becomes concrete if HD confirmation is compared with Hempel's adequacy criteria from Sect. 11.4.1. Let  $H$  abbreviate *Black swans exist*, let  $E$  consist of a black swan, and let  $\Delta$  be

the empty set. Then, according to Hempel's entailment condition,  $H$  is confirmed by  $E$ , since  $E \vdash H$ . Not so according to HD confirmation, for condition (ii) of Definition 11.8 is violated ( $H \not\vdash E$ ) [11.24]. The same example illustrates how HD confirmation violates the following condition, which holds for the satisfaction criterion in view of Definition 11.7 [11.25]:

- (4) Complementarity condition:  $E$  confirms  $H$  iff  $E$  disconfirms  $\neg H$ .

The consequence condition too is clearly invalid for HD confirmation. For instance,  $Ra \supset Ba$  HD confirms  $\forall x(Rx \supset Bx)$ , but it does not HD confirm the weaker hypothesis  $\forall x(Rx \supset (Bx \vee Cx))$ , since  $\forall x(Rx \supset (Bx \vee Cx)) \not\vdash Ra \supset Ba$ .

An advantage of HD confirmation is that it fares better with the raven paradox. The observation of a black raven ( $Ra, Ba$ ) is not deducible from the raven hypothesis  $\forall x(Rx \supset Bx)$ , so black ravens do not in general confirm the raven hypothesis. But birds that are known to be ravens *do* confirm the raven hypothesis once it is established that they are black. For once it is known that an object is a raven, the observation that it is black is entailed by this knowledge together with the hypothesis ( $\forall x(Rx \supset Bx), Ra \vdash Ba$ ). Likewise, a non-black non-raven does not generally confirm the raven hypothesis. Only objects that are known to be non-black can confirm the hypothesis by establishing that they are not ravens. In formulas:  $\forall x(Rx \supset Bx), \neg Ba \vdash \neg Ra$ .

HD confirmation faces a number of standard objections, of which three are discussed here. The first is the problem of irrelevant conjunctions and disjunctions. In view of Definition 11.8 it is easily checked that whenever a hypothesis  $H$  confirms  $E$  relative to  $\Delta$ , so does  $H' = H \wedge K$  for any arbitrary  $K$  consistent with  $\Delta$ . Thus adding arbitrary conjuncts to confirmed hypotheses preserves confirmation. Dually, adding arbitrary disjuncts to the data likewise preserves confirmation. That is, whenever  $H$  confirms  $E$  relative to  $\Delta$ ,  $H$  also confirms  $E'$  relative to  $\Delta$ , where  $E' = E \vee F$  for any arbitrary  $F$ .

Various solutions have been proposed for dealing with such problems of irrelevancy, but as so often the devil is in the details (see [11.20] for a nice overview and further references). For present purposes, it suffices to say that **I**-confirmation is not threatened by problems of irrelevance. Clearly, if the evidence  $E$  **I**-confirms a hypothesis  $H$ , it does not follow that it **I**-confirms  $H \wedge K$  for some arbitrary  $K$  consistent with  $\Delta$ , since from  $\{E\} \cup \Delta \vdash_{\mathbf{I}} H$  it need not follow that  $\{E\} \cup \Delta \vdash_{\mathbf{I}} H \wedge K$ . Nor does it follow that  $E \vee F$  confirms  $H$  relative to  $\Delta$ , since from  $\{E\} \cup \Delta \vdash_{\mathbf{I}} H$  it need not follow that  $\{E \vee F\} \cup \Delta \vdash_{\mathbf{I}} H$ .

A second objection against HD confirmation concerns the inclusion of background information in Def-

inition 11.8. In general, this inclusion is an advantage, since evidence often does not (dis)confirm a hypothesis simpliciter. Rather, evidence (dis)confirms hypotheses with respect to a set of auxiliary (background) assumptions or theories. The vocabulary of a theory often extends beyond what is directly observable. Notwithstanding Hempel's conviction to the contrary, nowadays philosophers largely agree that the use of purely theoretical terms is both intelligible and necessary in science [11.26]. Making the confirmation relation relative to a set of auxiliaries allows for the inclusion of bridging principles connecting observation terms with theoretical terms, permitting purely theoretical hypotheses to be confirmed by pure observation statements [11.27]. However, making confirmation relative to background assumptions makes HD vulnerable to a type of objection often traced back to *Duhem* [11.28] and *Quine* [11.29]. Suppose that a hypothesis  $H$  entails an observation  $E$  relative to  $\Delta$ , and that  $E$  is found to be false. Then either (a)  $H$  is false or (b) a member of  $\Delta$  is false. But the evidence does not tell us which of (a) or (b) is the case, so we always have the option to retain  $H$  and blame some auxiliary hypothesis in the background information. More generally, one may object that what gets (dis)confirmed by observations is not a hypothesis taken by itself, but the conjunction of a hypothesis and a set of background assumptions or theories.

With *Elliott Sober*, we can counter such holistic objections by pointing to the different epistemic status of hypotheses *under* test and auxiliary hypotheses (or hypotheses *used* in a test). Auxiliaries are independently testable, and when used in an experiment we already have good reasons to think of these hypotheses as true. Moreover, they are epistemically independent of the test outcome. So if a hypothesis is disconfirmed by the HD criterion, we can, in the vast majority of cases, maintain that it is the hypothesis we need to retract, and not one of the background assumptions [11.30].

A parallel point can be made concerning **I**-confirmation. Here too, we can add to the premises a set  $\Delta$  of auxiliary or background assumptions. And here too, we can use Sober's defence against objections from evidential holism. A nice feature of **I**-confirmation is that in adaptive proofs the weaker epistemic status of hypotheses inferred from an observation report in conjunction with a set of auxiliaries is reflected by their non-empty condition. Whereas auxiliaries are introduced as premises on the empty condition, inductively generated hypotheses are derived conditionally and may be retracted at a later stage of the proof. For a more fine-grained treatment of background information in adaptive logics for inductive generalization, see [11.5, Sect. 6].

The third objection against HD confirmation dates back to *Hempel's* [11.17], in which he argued that a variant of HD confirmation (which he calls the *prediction criterion* of confirmation) is circular. The problem is that in HD confirmation the hypothesis to be confirmed functions as a premise from which we derive the evidence, and that it is unclear where this premise comes from. The hypothesis is not generated, but given in advance, so HD confirmation presupposes the prior attainment – by inductive reasoning – of a hypothesis. This inductive move, *Hempel* argues, already presupposes the idea of confirmation, making the HD account circular.

The weak step in *Hempel's* argument consists in his assumption that the inductive jump to the original attainment of a hypothesis already presupposes the confirmation of this hypothesis. In testing or generating a hypothesis we need not yet *believe* or *accept* it. Typically, belief and acceptance come only after confirming the hypothesis. Indeed, in probabilistic notions of confirmation the idea is often exactly this: confirming a hypothesis amounts to increasing our degree of belief in it. *Hempel's* circularity objection, it seems, confuses hypothesis generation and hypothesis confirmation.

*Hempel's* circularity objection does not undermine HD confirmation, but it points to the wider scope of the adaptive account as compared to HD confirmation. In an **I**-proof, the conditional rule allows us to *generate* hypotheses. Hypotheses are not given in advance but are computable by the logic itself. Moreover, a clear distinction can be made between hypothesis generation and hypothesis confirmation. Hypotheses generated in an **I**-proof may be derivable at some stage of the proof, but the central question is whether they can be retained – whether they are *finally* derivable. **I**-confirmation, then, amounts to final derivability in an **I**-proof whereas the inductive step of hypothesis generation is represented by retractable applications of RC.

### 11.4.3 Interdependent Abnormalities and Heuristic Guidance

For any of the adaptive logics for inductive generalization defined in this chapter, at most one positive instance is needed to try and derive and, subsequently, confirm a generalization for a given set of premises. This is a feature that **I**-confirmation shares with the other qualitative criteria of confirmation. As a simple illustration, note that an observation report consisting of a single observation  $Pa$  confirms the hypothesis  $\forall xPx$  according to all qualitative criteria discussed in this chapter. Proponents of quantitative approaches to confirmation may object that this is insufficient; that a stronger criterion is needed which requires *more* than one instance for a hypothesis to be confirmed. Against

this view, one can uphold that confirmation is mainly falsification-driven. Rather than confirming hypotheses by heaping up positive instances, we try and test them by searching for negative instances. In the remainder of this section, it is argued by means of a number of examples that **I**-confirmation is sufficiently selective as a criterion for confirming generated hypotheses. The examples moreover allow for the illustration of an additional feature of **I**-confirmation: its use as a heuristic guide for provoking further tests in generating and confirming additional hypotheses.

Simple examples like the one given in the previous paragraph may suggest that, in the absence of falsifying instances, a single instance usually suffices to **I**-confirm a hypothesis. This is far from the truth. Consider the simple premise set  $\Gamma_6 = \{\neg Pa \vee Qa, \neg Qb, Pc\}$ . This premise set contains instances of all of the generalizations  $\forall xPx$ ,  $\forall x\neg Qx$ , and  $\forall x(Px \supset Qx)$ . Not a single one of these is **IL**-confirmed, however, due to the derivability of the following disjunctions of abnormalities

$$!Px \vee !Qx, \quad (11.37)$$

$$!Px \vee !(\neg Px \vee Qx), \quad (11.38)$$

$$!(Px \vee Qx) \vee !(\neg Px \vee Qx), \quad (11.39)$$

$$!Qx \vee !(\neg Px \vee Qx), \quad (11.40)$$

$$!(\neg Px \vee Qx) \vee !(\neg Px \vee \neg Qx). \quad (11.41)$$

Note that  $\Gamma_6$  contains positive instances of both  $\forall xPx$  and  $\forall x\neg Qx$ , so not even a positive instance suffices for a generalization to be finally **IL**-derivable in the absence of falsifying instances. The same is true if we switch from **IL** to **G**. None of  $\forall xPx$ ,  $\forall x\neg Qx$ , or  $\forall x(Px \supset Qx)$  is **G**-confirmed, due to the derivability of the following disjunctions of abnormalities

$$\pm Px \vee \pm Qx, \quad (11.42)$$

$$\pm Px \vee (Px \wedge \pm Qx), \quad (11.43)$$

$$\pm Qx \vee (Qx \wedge \pm Px). \quad (11.44)$$

The reason for the non-confirmation of generalizations like  $\forall xPx$ ,  $\forall x\neg Qx$ , or  $\forall x(Px \supset Qx)$  in this example has to do with the dependencies that exist between abnormalities. Even if a generalization is not falsified by the data, it is often the case that this generalization is not compatible with a different generalization left unfalsified by the data. As a further illustration, consider the premise set  $\Gamma_7 = \{\neg Ra, \neg Ba, Rb\}$ . Again, although no falsifying instance is present, the generalization  $\forall x(Rx \supset Bx)$  is not **IL**-derivable. The reason is the derivability of the following minimal disjunction of abnormalities

$$!(\neg Rx \vee Bx) \vee !(\neg Rx \vee \neg Bx). \quad (11.45)$$

Examples like these illustrate that **I**-confirmation is not too liberal a criterion of confirmation. They also serve to illustrate a different point. Minimal Dab-formulas like (11.45) evoke questions. Which of the two abnormalities is the case? For this particular premise set, establishing which of  $Bb$  or  $\neg Bb$  is the case would settle the matter. For if  $Bb$  were the case, then the second disjunct of (11.45) would be derivable, and (11.45) would no longer be minimal. Consequently, the abnormality  $\exists x(\neg Rx \vee Bx) \wedge \exists x\neg(\neg Rx \vee Bx)$  would no longer be part of a minimal disjunction of abnormalities, and the generalization  $\forall x(Rx \supset Bx)$  would become finally derivable. Analogously, if  $\neg Bb$  were the case, then the first disjunct of (11.45) would become derivable, and, by the same reasoning, the generalization  $\forall x(Rx \supset \neg Bx)$  would become finally derivable. Thus

$$\Gamma_7 \cup \{Bb\} \vdash_{\mathbf{IL}} \forall x(Rx \supset Bx), \quad (11.46)$$

$$\Gamma_7 \cup \{\neg Bb\} \vdash_{\mathbf{IL}} \forall x(Rx \supset \neg Bx). \quad (11.47)$$

Two more comments are in order here. First, this example illustrates that confirming a hypothesis often involves the disconfirmation of the contrary hypothesis. We saw that if we use Hempel's criterion a non-black non-raven confirms the raven hypothesis. But as Goodman pointed out "the prospects for indoor ornithology vanish when we notice that under these same conditions, the contrary hypothesis that no ravens are black is equally well confirmed" [11.21, p. 71]. Thus, according to Goodman, confirming the raven hypothesis  $\forall x(Rx \supset Bx)$  requires disconfirming its contrary  $\forall x(Rx \supset \neg Bx)$ . This is exactly what happens in the example: in order to **IL**-derive  $\forall x(Rx \supset Bx)$ , a falsifying instance for its contrary is needed, as (11.46) illustrates. Goodman's suggestion that the confirmation of a hypothesis requires the falsification/disconfirmation of its contrary was picked up by Israel Scheffler, who developed it further in his [11.31]. Note that falsifying the contrary of the raven hypothesis amounts to finding a positive instance of the raven hypothesis. Thus, in demanding a positive instance before permitting generalization in a **G**-proof, the latter system goes further than **IL** in implementing Goodman's idea. As we saw, however, not even **G** goes all the way: a generalization may be **G**-derivable even in the absence of a positive instance.

Second, if empirical (observational or experimental) means are available to answer questions like  $\{Bb, \neg Bb\}$  in the foregoing example, these questions may be called *tests* [11.2]. Adaptive logics for inductive generalization provide heuristic guidance in the sense that interdependencies between abnormalities evoke such tests. Importantly, further tests may lead to

the derivability of new generalizations. In the example, deciding the question  $\{Bb, \neg Bb\}$  in favor of  $Bb$  leads to the confirmation of  $\forall x(Rx \supset Bx)$  and to the disconfirmation of  $\forall x(Rx \supset \neg Bx)$ , while deciding it in favor of  $\neg Bb$  leads to the confirmation of  $\forall x(Rx \supset \neg Bx)$  and to the disconfirmation of  $\forall x(Rx \supset Bx)$ . This is an important practical advantage of **I**-confirmation over other qualitative criteria: adaptive logics for inductive generalization evoke tests for increasing the number of confirmed generalizations.

The illustrations so far may suggest that this heuristic guidance provided by **I**-confirmation only applies to hypotheses that are logically related or closely connected, like the raven hypothesis and its contrary. But the point is more general, as the following example illustrates.

Consider the premise set

$$\Gamma_8 = \{Pa, Qa, \neg Ra, \neg Pb, \\ \neg Qb, Rb, Pc, Rc, Qd, \neg Pe\}.$$

Despite the fact that  $\Gamma_8$  contains positive instances of the generalizations  $\forall x(Px \supset Qx)$  and  $\forall x(Rx \supset \neg Qx)$ , and despite the fact that these generalizations are not falsified by  $\Gamma_8$ , none of them is **IL**-derivable due to the derivability of the disjunction

$$!(\neg Px \vee Qx) \vee !(\neg Rx \vee \neg Qx). \quad (11.48)$$

## 11.5 Conclusions

A number of adaptive logics for inductive generalization were presented each of which, it was argued, can be re-interpreted as a criterion of confirmation. The logics in question can be classified along two dimensions. The first dimension concerns when it is permitted to introduce a generalization in an adaptive proof. The logic **LI** permits the free introduction of generalizations. **IL** and **G** require instances of a generalization before introducing it in a proof. Interestingly, these stronger requirements do not result in stronger logics.

The second dimension along which the logics defined in this chapter can be classified concerns their

By the same reasoning as in the previous illustration,  $\Gamma_8$  evokes the question  $\{Qc, \neg Qc\}$ . If this question is a test (if it can be answered by empirical means), the answer will confirm one of the generalizations  $\forall x(Px \supset Qx)$  and  $\forall x(Rx \supset \neg Qx)$ , and will disconfirm the other generalization [11.2].

The example generalizes. In **LI** and **G** too, the derivability of  $\forall x(Px \supset Qx)$  and  $\forall x(Rx \supset \neg Qx)$  is blocked due to the **CL**-derivability of the **LI**-minimal Dab-formula (11.49), respectively the **G**-minimal Dab-formula (11.50)

$$\neg \forall x(Px \supset Qx) \vee \neg \forall x(Rx \supset \neg Qx), \quad (11.49)$$

$$(Px \wedge \pm Qx) \vee (Rx \wedge \pm \neg Qx). \quad (11.50)$$

Here too, deciding the question  $\{Qc, \neg Qc\}$  resolves the matter. Thus, where  $\mathbf{I} \in \{\mathbf{LI}, \mathbf{IL}, \mathbf{G}\}$

$$\Gamma_8 \not\vdash_{\mathbf{I}} \forall x(Px \supset Qx), \quad (11.51)$$

$$\Gamma_8 \not\vdash_{\mathbf{I}} \forall x(Rx \supset \neg Qx), \quad (11.52)$$

$$\Gamma_8 \cup \{Qc\} \vdash_{\mathbf{I}} \forall x(Px \supset Qx), \quad (11.53)$$

$$\Gamma_8 \cup \{Qc\} \not\vdash_{\mathbf{I}} \forall x(Rx \supset \neg Qx), \quad (11.54)$$

$$\Gamma_8 \cup \{\neg Qc\} \not\vdash_{\mathbf{I}} \forall x(Px \supset Qx), \quad (11.55)$$

$$\Gamma_8 \cup \{\neg Qc\} \vdash_{\mathbf{I}} \forall x(Rx \supset \neg Qx). \quad (11.56)$$

For some concrete heuristic rules applicable to the logic **LI**, see [11.3].

adaptive strategy. Here, no surprises arise. A logic defined using the reliability strategy is in general weaker than its counterpart logic defined using the minimal abnormality strategy (this was shown to be the case for all adaptive logics defined within the standard format [11.7, Theorem 11]).

When re-interpreted as criteria of confirmation, the logics defined here withstand the comparison with their main rivals, i. e., Hempel's satisfaction criterion and the hypothetico-deductive model of confirmation. In conclusion, the adaptive confirmation criteria defined in Sect. 11.4 offer an interesting alternative perspective on (qualitative) confirmation theory.

## 11.A Appendix: Blocking the Raven Paradox?

If a formalism defined in terms of **CL** behaves overly permissive, a good strategy to remedy this problem is to add further criteria of validity or relevance. For instance, in order to avoid problems of irrelevant conjunctions and disjunctions, hypothetico-deductivists may impose further demands on HD confirmation [11.32–35].

A similar strategy could be adopted with respect to **I**-confirmation and the raven paradox. In this appendix, an alternative adaptive logic of induction, **IC**, is defined, as is a corresponding criterion of confirmation which is slightly less permissive than the criteria from Sect. 11.4. **IC** makes use of a non-classical conditional resembling a number of conditionals originally defined in order to avoid the so-called paradoxes of material implication. First, an extension of **CL** is introduced, including this new conditional connective. Next, the adaptive logic **IC** is defined.

The new conditional,  $\rightarrow$ , is fully characterized by the following rules and axiom schema's

$$\frac{A, (A \rightarrow B)}{B}, \quad (\text{MP})$$

$$\frac{A \equiv B}{(A \rightarrow C) \equiv (B \rightarrow C)}, \quad (\text{RCEA})$$

$$\frac{A \equiv B}{(C \rightarrow A) \equiv (C \rightarrow B)}, \quad (\text{RCEC})$$

$$(A \rightarrow (B \wedge C)) \equiv ((A \rightarrow B) \wedge (A \rightarrow C)), \quad (\text{D}\wedge)$$

$$((A \vee B) \rightarrow C) \equiv ((A \rightarrow C) \wedge (B \rightarrow C)), \quad (\text{D}\vee)$$

((RCEA), (RCEC), and (D $\wedge$ ) fully characterize the conditional of Chellas's logic **CR** from [11.36]. The latter was also used for capturing explanatory conditionals in [11.37]. See also [11.38, Chap. 5] for some closely related conditional logics, including an extension of Chellas's systems that validates (MP).)

Let  $\text{CL}^{\rightarrow}$  be the logic resulting from adding  $\rightarrow$  to the language of **CL**, and from adding (MP)-(D $\vee$ ) to the list of rules and axioms of **CL**. Note that the conditional  $\rightarrow$  is strictly stronger than  $\supset$

$$(A \rightarrow B) \supset (A \supset B). \quad (11.57)$$

(By (MP),  $A, (A \rightarrow B) \vdash_{\text{CL}^{\rightarrow}} B$ . By the deduction theorem for  $\supset$ ,  $A \rightarrow B \vdash_{\text{CL}^{\rightarrow}} A \supset B$ . By the deduction theorem again,  $\vdash_{\text{CL}^{\rightarrow}} (A \rightarrow B) \supset (A \supset B)$ .)

In view of this bridging principle between both conditionals it is easily seen that counter-instances to a formula of the form  $\forall x(A(x) \supset B(x))$  form counter-instances to  $\forall x(A(x) \rightarrow B(x))$ , and falsify the latter formula as well. For instance, if  $Pa \wedge \neg Qa$ , then, by **CL**,  $\neg \forall x(Px \supset Qx)$ , and, by (11.57),  $\neg \forall x(Px \rightarrow Qx)$ .

The adaptive logic **IC** is fully characterized by the lower limit logic  $\text{CL}^{\rightarrow}$ , the set of abnormalities

$$\begin{aligned} \Omega_{\text{IC}} =_{\text{df}} & \{ \exists (A_1 \wedge \dots \wedge A_n \wedge A_0) \\ & \wedge \neg \forall ((A_1 \wedge \dots \wedge A_n) \rightarrow A_0) \mid \\ & A_0, A_1, \dots, A_n \in \mathcal{A}^{\uparrow}; n \geq 0 \}, \end{aligned} \quad (11.58)$$

and the adaptive strategy reliability (**IC**<sup>r</sup>) or minimal abnormality (**IC**<sup>m</sup>). **IC** is defined within the SF. All rules and definitions for its proof theory are as for the other logics defined in this chapter, except that in the definition of RU and RC, **CL** is replaced with  $\text{CL}^{\rightarrow}$ .

The following proof illustrates how formulas are derived conditionally in **IC**

1	$\neg Ra$	Prem
	$\emptyset$	
2	$\neg Ba$	Prem
	$\emptyset$	
3	$\forall x(\neg Bx \rightarrow \neg Rx)$	1, 2; RC
	$\{ \exists x(\neg Bx \wedge \neg Rx) \wedge \neg \forall x(\neg Bx \rightarrow \neg Rx) \}$	

Given only the premises  $\neg Ra$  and  $\neg Ba$ , there is no possible extension of this proof in which line 3 gets marked. Hence

$$\neg Ra, \neg Ba \vdash_{\text{IC}} \forall x(\neg Bx \rightarrow \neg Rx). \quad (11.59)$$

However, contraposition is invalid for the new conditional  $\rightarrow$ , hence we cannot derive the raven hypothesis from the formula derived at line 3. Note also that, in view of (11.60), we cannot use the conditional rule RC to derive  $\forall x(Rx \rightarrow Bx)$  on the condition  $\{ \exists x(Rx \wedge Bx) \wedge \neg \forall x(Rx \rightarrow Bx) \}$  in an **IC**-proof, since

$$\begin{aligned} \neg Ra, \neg Ba \not\vdash_{\text{CL}^{\rightarrow}} \forall x(Rx \rightarrow Bx) \\ \vee \{ \exists x(Rx \wedge Bx) \wedge \neg \forall x(Rx \rightarrow Bx) \}. \end{aligned} \quad (11.60)$$

Therefore

$$\neg Ra, \neg Ba \not\vdash_{\text{IC}} \forall x(Rx \rightarrow Bx). \quad (11.61)$$

Thus, if conditional statements of the form *for all x, if A(x) then B(x)* are taken to be **IC**-confirmed only if the conditional in question is an arrow ( $\rightarrow$ ) instead of a material implication, then the raven paradox, in its original formulation, is blocked.

An additional property of **IC** is that *strengthening the antecedent* fails for  $\rightarrow$ . In Sect. 11.3, for instance, we saw that

$$Pa \vdash_{\text{G}} \forall x(Qx \supset Px). \quad (11.62)$$

In **IC**, (11.62) still holds for the material implication, but not for the new conditional. In an **IC**-proof from  $Pa$  we can still derive  $\forall xPx$  on the condition  $\{\exists xPx \wedge \exists x\neg Px\}$ , and since **IC** extends **CL** it still follows that  $\forall x(Px \supset Qx)$

$$Pa \vdash_{\mathbf{IC}} \forall xPx, \tag{11.63}$$

$$Pa \vdash_{\mathbf{IC}} \forall x(Qx \supset Px). \tag{11.64}$$

However, since  $\forall xPx \not\vdash_{\mathbf{CL}} \forall x(Qx \rightarrow Px)$ , and since we do not have any further means to conditionally derive the formula  $\forall x(Qx \rightarrow Px)$  in an **IC**-proof

$$Pa \not\vdash_{\mathbf{IC}} \forall x(Qx \rightarrow Px). \tag{11.65}$$

Originally, the logics in the **G**-family were constructed as logics requiring a *positive instance* before we are allowed to apply RC. This is reflected in the definition of the set of **G**-abnormalities. In order to derive a formula like  $\forall x(Px \supset Qx)$  on its corresponding condition, a positive instance, e.g.,  $Pa \wedge Qa$ , is needed. Examples like (11.36) and (11.62) show, however, that such a positive instance is not always required in order to **G**-derive a generalization. The logic **IC**, it seems, does much better in this respect. However, it still does not fully live up to the requirement for a positive instance before generalizing, as the following **IC**-proof from  $\Gamma_9 = \{\neg Ra \wedge \neg Ba, Rb, Bc\}$  illustrates (where  $A_0, A_1, \dots, A_n \in \mathcal{A}^I$ ,  $\dagger((A_1 \wedge \dots \wedge A_n) \rightarrow A_0)$  abbreviates  $\exists(A_1 \wedge \dots \wedge A_n \wedge A_0) \wedge \neg \forall((A_1 \wedge \dots \wedge A_n) \rightarrow A_0)$ ).

1	$\neg Ra \wedge \neg Ba$	Prem
	$\emptyset$	
2	$Rb$	Prem
	$\emptyset$	
3	$Bc$	Prem
	$\emptyset$

11.4 D. Batens, L. Haesaert: On classical adaptive logics of induction, *Logique et Analyse* **173–175**, appeared

4	$\forall x(\neg Bx \rightarrow \neg Rx)$ $\{\dagger(\neg Bx \rightarrow \neg Rx)\}$	1; RC
5	$Bb$ $\{\dagger(\neg Bx \rightarrow \neg Rx)\}$	2, 4; RU
6	$\forall x(Rx \rightarrow Bx)$ $\{\dagger(Rx \rightarrow Bx), \dagger(\neg Bx \rightarrow \neg Rx)\}$	2, 5; RC

The key step in this proof is the derivation of  $Bb$  at line 5, which together with  $Rb$  provides us with a positive instance of the raven hypothesis.  $Bb$  is derivable from lines 2 and 4 in view of **CL** and (11.57). Except for the formulas  $\exists xRx \wedge \exists x\neg Rx$  and  $\exists xBx \wedge \exists x\neg Bx$ , no minimal Dab-formulas are **CL** $\rightarrow$ -derivable from  $\Gamma_9$ . Therefore

$$\Gamma_9 \vdash_{\mathbf{IC}} \forall x(Rx \rightarrow Bx). \tag{11.66}$$

As (11.61) illustrates the logic **IC** avoids the raven paradox in its original formulation. A possible drawback of **IC** is that it does not fully meet the demand for a positive instance when confirming a hypothesis (Sect. 11.4.3). It is left open whether it is possible and desirable to further extend **IC** so as to fully meet this demand.

# Modeling Hypothetical Reasoning by Formal Logics

Tjerk Gauderis

In this chapter, it is discussed to which extent hypothetical reasoning can be modeled by formal logics. It starts by exploring this idea in general (Sects. 12.1 and 12.2), which leads to the conclusion that in order to model this kind of reasoning formally, a more fine-grained classification of reasoning patterns should be in order. After such a classification is provided in Sect. 12.3, a formal framework that has proven successful to capture some of these patterns is described (Sects. 12.4 and 12.6) and some of the specific problems for this procedure are discussed (Sect. 12.5). The chapter concludes by presenting two logics for hypothetical reasoning in an informal way (Sects. 12.7 and 12.8) such that the nontechnically skilled reader can get a flavor of how formal methods can be used to describe hypothetical reasoning.

## 12.1 The Feasibility of the Project

To an outsider, the claim that hypothetical or abductive reasoning, that is, the act of *forming* and *suggesting* hypotheses for certain observations or puzzling facts, can be modeled by means of formal logics might sound as outlandish as claiming that computers have the same cognitive and creative abilities as humans. After all, abductive or hypothetical reasoning – by which we always mean the reasoning *toward* (explanatory) hypotheses, not *starting from* certain (possibly counterfactual) hy-

potheses [12.1] – is often considered to be the hallmark of creative ingenuity, leading to our rich and wide diversity of ideas, innovations, and scientific theories. It just seems impossible that this richness can be reconstructed or created by just using formal tools, which are by nature abstracted from the specific semantic content. This argument, in short the *creativity excludes logic* argument, is the main reason why even the field itself is sharply divided between believers and nonbelievers.

This argument, however, is a straw man. Nobody would argue for the claim that hypothetical reasoning can be modeled by means of formal logics along these lines. What is argued in this chapter and the various sources it cites is the more modest claim that certain aspects and forms of hypothetical reasoning can be modeled with the aid of formal systems that are specifically suited for this task.

There are three important ways in which this modest claim differs from the straw man that is attacked by the *creativity excludes logic* argument:

1. Abductive reasoning is not a monolithic concept: it does not consist of a single method or procedure, but consists of many different patterns; formal logics are only used to capture one specific and precisely defined pattern at a time.
2. The logics that are used for this goal are not necessarily classical or deductive.
3. The relation between formal logics and abductive reasoning is not that of an agent and an activity (i. e., formal logics do not display themselves abductive reasoning like humans do) but that of a model and a target: Formal logics are used by (human) agents to model and – to a certain extent – to simulate certain aspects of human abductive reasoning.

The semantic content that is lacking in abductive reasoning is provided by these agents.

In the remainder of this introduction, the types of logics that are suitable for modeling abductive or hypothetical reasoning are discussed in further detail and the framework that is used for the logics in this chapter is introduced in general terms.

For those who are still a bit suspicious how abductive or hypothetical reasoning patterns can be modeled using formal logics, it needs to be stressed that it is not meant that any of these patterns is a valid inference in classical logic (CL) or any other (nontrivial) deductive logic. To model defeasible reasoning steps such as hypothesis formation, one has to use nonmonotonic logics: logics for which an extension of a premise set does not always yield a consequence set that is a superset of the original consequence set. Or, put more simply, logics according to which new information may lead to revoke old conclusions.

It is important to note that the purpose in using logics for this task is not the classical purpose of the discipline of logic. Classically, the discipline of logic studies the correct way to infer further knowledge from already known facts. The correct way should guarantee the truth of the new facts, under the supposition that the old facts are true. Accordingly, this has motivated the search for the right (deductive) logic (whether it be classical logic or another one such as intuitionistic logic).

The purpose here, however, is to model or explicate human reasoning patterns. As these patterns are fallible, leading to conclusions that are not necessarily true even if the premises are assumed to be true, it should be possible to revoke previously derived results; hence, the use of nonmonotonic logics. Also, because there are many patterns of human reasoning, it is natural to conceive of a plenitude of logics in order to describe them.

Let this be explained a bit more formally. A logic can be considered as a function from the power set of the sentences of a language to itself. So, given a language  $L$  and the set  $\mathcal{W}$  of its well-formed formulas

$$\mathbf{L} : \wp(\mathcal{W}) \rightarrow \wp(\mathcal{W}) . \quad (12.1)$$

Hence, a logic determines for every set of sentences (or premise set)  $\Gamma$  the sentences of which can be inferred from it ( $Cn_{\mathbf{L}}(\Gamma) =_{\text{df}} \mathbf{L}(\Gamma)$ ). Therefore, as a reasoning pattern is nothing more than the inference of some statements given some initial statements, in principle, a logic can be devised to model any reasoning pattern in science. If this pattern can be formally described, description by a formal logic is, in principle, possible. It has to be added, though, that in reality, scientific and human reasonings include not only sentences or propositions, but also direct observations, sketches, and various other symbolic representations. Yet, for the purpose of modeling particular reasoning patterns, those sources can be generally represented by suitable propositions.

Deductive logics, such as CL, have the property of monotonicity, that is, for all premise sets  $\Gamma$  and  $\Gamma'$

$$Cn_{\mathbf{L}}(\Gamma) \subseteq Cn_{\mathbf{L}}(\Gamma \cup \Gamma') . \quad (12.2)$$

Most patterns of human reasoning, however, do not meet this criterion. For instance, if an agent infers a hypothesis, s/he is well aware of the fact that it might need to be revoked on closer consideration of the available background knowledge or in light of new information.

Although nonmonotonic reasoning has typically received less attention in the field of logic than monotonic reasoning, various frameworks for defeasible reasoning and nonmonotonic logics are available such as default logic, adaptive logics, and belief revision (see [12.2] for a general overview of the variation in approaches). In this chapter, the progress that has been made on modeling abduction within the adaptive logics framework is overviewed. This is a framework created by *Batens* over the past three decades (see [12.3] or [12.4] for an extensive overview and thorough formal introduction). This framework for devising nonmonotonic logics has some advantages that suit very well the project of modeling abductive reasoning patterns.

First, the focus in the adaptive logic program is, in contrast with other approaches to nonmonotonic reasoning, on proof theory. For these logics, a dynamic proof style has been defined in order to mimic to a certain extent actual human reasoning patterns. More in particular, these dynamic proofs display the two forms of revoking previously derived results that can also be found in human reasoning: revoking old conclusions on closer consideration of the available evidence (internal dynamics) and revoking them in light of new information (external dynamics). One should not be misled, however, by this idea of dynamic proofs in thinking that the consequence set of adaptive logics for a certain premise set depends on the proof. Adaptive logics are proper proof-invariant logics that assign for each premise set  $\Gamma$  exactly one consequence set  $Cn_L(\Gamma)$ .

Second, over the years, a solid meta-theory has been built for this framework, which guarantees that if

an adaptive logic is created according to certain standards (the so-called *standard format*), many important metatheoretical properties are generically proven. This creates an opportunity for projects such as this to focus almost exclusively on the application of these formal methods without having to worry too much about proving their metatheoretical characteristics.

Finally, as the framework is presented as a unified framework for nonmonotonic logics, it has been applied in many different contexts. Over the years, adaptive logics have been devised for, apart from abduction, paraconsistent reasoning, induction, argumentation, deontic reasoning, etc. Most of these applications have been studied at the Centre for Logic and Philosophy of Science (Ghent University). At this center's website, many references can be found to papers in various contexts. The reference works mentioned earlier, [12.3] and [12.5], also give a good overview of the various applications.

## 12.2 Advantages and Drawbacks

Explicating patterns of hypothesis formation by means of formal logics has a clear advantage: By reducing patterns to their formal and structural essence, an insight into the pattern's precise conditions and applications is gained that is hard to achieve purely by studying different cases.

Another great advantage of the formal explication of human reasoning patterns is that it allows for the possibility of providing artificially intelligent agents (which, in general, lack the human capacity for context awareness unless it is explicitly provided) with formal patterns to simulate human reasoning. In the case of hypothesis formation, this possibility has presently already found applications in the artificial intelligence subfields of abduction (diagnosis), planning, and machine learning (see [12.6] for an overview).

The method of explicating patterns of hypothesis formation by means of formal adaptive logics also has certain drawbacks, however.

First, formal logics are expressed in terms of a formal language, in which not all elements of human reasoning processes can be represented. This leads inevitably to certain losses. A very obvious example is that in general only propositions can be represented in logics. It means that all observations, figures, or other symbolic representations must be reduced to descriptions of them. A more important example in the case of abduction is the implication relation. The adaptive logics framework that is used in this chapter is, certainly for ampliative logics such as those for abduction

or induction, largely built around the use of a classical material implication (mostly to keep things sufficiently simple). As a result of this, all relations between a hypothesis and the observations that led to their formation (their triggers) are modeled by material implications. It is clear that this is a strong reduction of the actual richness of such relations. Hypotheses do not have to imply their triggers: they can also just be correlated with them or be probabilistically likely; or the relation can be much more specific, as in the case of an explanatory or causal relation. This issue is relevant beyond the field of adaptive logics. *Paul* [12.6, p. 36] has claimed that most approaches to abduction use a material implication that is implicitly interpreted as some kind of explanatory or causal relation. See also [12.7] for an attempt to better capture the explanatory conditional.

Second, if one sets out to model actual historical human reasoning processes by means of dynamic logical proofs (as the adaptive framework allows us to do), one quickly finds that it is not an easy task to boil down those actual processes to the microstructure of their individual reasoning steps. As human agents often combine individual steps and seldom take note of each individual step, these types of models always contain an aspect of simulation.

Human reasoning also does not proceed linearly step by step as proofs do: It contains circular motions, off-topic deviations, and irrational connections that cannot be captured by formal logics. Therefore, models of

such reasoning processes are always, to a great extent, idealized.

Natural languages are also immensely more complex than any formal language can aspire to be. Therefore, models of human reasoning are unavoidably simplifications. Furthermore, as formal logics state everything explicitly, any modeler of human reasoning has to simplify deliberately the actual cases, only to achieve a certain degree of comprehensibility.

Altogether, it is clear that formal models of human reasoning processes are, in fact, only models: They contain abstractions, simulations, simplifications, and idealizations. And although these techniques are the key characteristics of models, such as those used in science, it is not always easy to evade the criticism that formal logics can only handle toy examples.

Third, certain patterns of creative hypothesis formation, that is, those that introduce the hypothetical existence of new concepts, cannot be modeled by first-order logics. They seem to require at least the use of second-order logics, and this is a possibility of which, at present, the adaptive logics framework is not capable.

Fourth, as one is here purely concerned with hypothesis formation and not with hypothesis selection, formal methods will generate sets of possible hypotheses that may grow exponentially in relation to the

growth of the agent's background knowledge. It is clear that this also poses a limit to the application of these methods to real-world problems.

Finally, one might question the normativity of this project (and more generally of the adaptive logics program). By aiming to describe actual human reasoning processes, this branch of logics appears to put a descriptive ideal first, which contrasts sharply with the strongly normative ideals in the field of logic in general. The standard answer to this question is that adaptive logics attempt to provide both: On the one hand, they aim to describe actual reasoning patterns; on the other, once these patterns are identified, they aim to prescribe how these patterns should be rationally applied. Yet, this does not answer how the trade-off between these two goals of description and normativity should be conceived. Is it better to have a large set of logics that is able to describe virtually any pattern actually found in human reasoning, or should one keep this set trimmed and qualify most actual human reasoning as failing to accord with the highest normative standards? Therefore, it remains a legitimate criticism that the goals of description and prescription cannot be so easily joined: how their trade-off should be dealt with needs further theoretical underpinning.

## 12.3 Four Patterns of Hypothetical Reasoning

The quest to characterize abduction under a single schema was abandoned around 1980. The main reasons were that such attempts (*Hanson's* [12.8, 9] proposal to call abduction *the logic of discovery*) often did not provide much detailed guidance for actual discovery processes, and that even these general attempts always captured only a part of the discovery process (e.g., *inference to the best explanation*, which was first emphasized by *Harman* [12.10], describes only the selection of hypotheses, not their formation).

Around the same time, research from different fields such as the philosophy of science based on historical cases, artificial intelligence, and cognitive science resulted in a new consensus that there is a plenitude of patterns, heuristics, and methods of discovery, which are open to normative guidance; yet, this guidance might be content-, subject-, or context dependent [12.11, 12].

Various authors in the literature on abduction have tried to provide classifications of various patterns of abductions [12.13–15]. For an overview of several logic-based characterizations of abductions, see also the introductory chapter of this section. Although these

attempts differ slightly, some general patterns clearly stand out. In the following, the author's personal interpretation of these major general patterns is given. The main reason this deviates from the previous classifications is that an attempt is made to simplify the rather prolific classifications, yet to provide a sufficient basis for formal modeling. This is possible because it is not attempted to give a fully exhaustive list or a list the elements of which are mutually exclusive. The only purpose was to give a simple list as a basis that covers most instances of abductive reasoning and can serve as the basis of formal modeling.

Before the classification of these major patterns found in abductive reasoning is given, it is important to note that abductive inferences form explanatory hypotheses for observed facts using the agent's background beliefs (or knowledge). Therefore, these patterns have the structure of the inference of a hypothesis (HYP) from some observed facts (OBS) and a part of the agent's background beliefs (or knowledge) (BBK). These latter are, apart from toy examples, typically more than a few factual statements and often encompass a whole explanatory framework of (shared) assump-

tions and knowledge that provides the explanatory link between hypothesis and observations (see [12.16] for an elaborate discussion of the role of an explanatory framework in logical approaches to explanation).

In line with the Fregean tradition, *factual statements* are considered as statements of a *concept* with regard to one or more *objects* (or a logical combination of such statements). For instance, the statement *there was a civil war in France in 1789* can be analyzed as the concept *a country in civil war* applied to or *with regard to* the object *France in 1789*. A *fact* is a true factual statement. As such, concepts can also be considered as the *class* of all objects (or tuples of objects) for which the concept with regard to that object (or tuple of objects) is a fact. An *observed fact* is a factual statement describing an agent's observation that she considers to be true. This can be broadly conceived to include also, for instance, a graph or a table of measurements in a paper. Together, the observed facts form the *trigger* for the agent.

In this semiformal description of these patterns, that  $p$  should be considered as a hypothesis is expressed by using a formulation of the form *it might be that p*; beliefs and observed facts can be expressed simply by stating their content. Concepts such as *a country in civil war* or *a bipedal hominid* are denoted by uppercase letters (typically  $F$  for observed, factual concepts and  $E$  for explanatory concepts) and objects such as *France in 1789* or *Lucy* by lowercase letters such as  $x$  or  $y$ . A finite set or list of (related) objects or concepts can then be expressed, for example, by  $x_1, \dots, x_n$  or  $F_1, \dots, F_n$  where generally  $n \geq 1$  (hence, including the possibility of a single object or concept; the other case is indicated by  $n \geq 2$ ). Finally, that a concept applies to certain objects will be indicated by the phrase *with regard to*:

1. *Abduction of a singular fact*

(OBS)	$F$ with regard to $x_1, \dots, x_n$ ( $n \geq 1$ )
(BBK)	$E$ with regard to $x_1, \dots, x_n$ explains $F$ with regard to those objects in a certain explanatory framework EF.
(HYP) It might be that $E$ with regard to $x_1, \dots, x_n$	

Some examples of this pattern, which has also been called *simple abduction* by *Thagard* [12.13], *factual abduction* by *Schurz* [12.14], and *selective fact abduction* by *Hoffmann* [12.15], are as follows:

- The inference that (HYP) the hominid who has been dubbed Lucy ( $x_1$ ) might have been bipedal ( $E$ ) from (OBS) observing the particular structure of her pelvis and knee bones ( $F$ ) and (BBK)

knowledge about how the structure of pelvis and knee bones relates to the locomotion of animals (EF).

- The inference that (HYP) two particles ( $x_1$  and  $x_2$ ) might have opposite electric charges ( $E$ ), from (OBS) observing their attraction ( $F$ ) and (BBK) knowledge of the Coulomb force (EF).

2. *Abduction of a Generalization*

(OBS)	$F$ with regard to <i>all observed</i> objects of class $D$
(BBK)	$E$ with regard to <i>some</i> objects explains $F$ with regard to those objects in a certain explanatory framework EF.
(HYP) It might be that $E$ with regard to <i>all existing</i> objects of class $D$	

Some examples of this pattern, which has also been called *rule abduction* [12.13], *law abduction* [12.14], and *selective law abduction* [12.15], are as follows:

- The inference that (HYP) *all* hominids of the last three million years ( $D$ ) might have been bipedal ( $E$ ), from (OBS) observing the similar structure of the pelvis and knee bones ( $F$ ) of *all observed* hominid skeletons dated to be younger than three million years ( $D$ ) and (BBK) knowledge about how the structure of pelvis and knee bones relates to the locomotion of animals (EF).
- The inference that (HYP) *all* emitted radiation from a particular chemical element ( $D$ ) might be electrically neutral ( $E$ ), from (OBS) observing in *all* experiments *conducted so far* that radiation emitted by this element ( $D$ ) continues in a straight path in an external magnetic field perpendicular to the stream of radiation ( $F$ ) and (BBK) knowledge of the Lorentz force and Newton's second law (EF).

3. *Existential abduction*, or the abduction of *the existence* of unknown objects from a particular class

(OBS)	$F$ with regard to $x_1, \dots, x_n$ ( $n \geq 1$ )
(BBK)	The existence of objects $y_1, \dots, y_m$ ( $m \geq 1$ ) of class $E$ would explain $F$ with regard to $x_1, \dots, x_n$ in a certain explanatory framework EF.
(HYP) It might be that there exist objects $y_1, \dots, y_m$ of class $E$	

Some examples of this pattern, which was already called *existential abduction* by *Thagard* [12.13],

and has also been called *first-order existential abduction* [12.14] and *selective type abduction* [12.15], are as follows:

- The inference that (HYP) a hominid ( $y_1$ ) of the genus *Australopithecus* ( $E$ ) might have lived in this area, from (OBS) observing a set of vulcanized foot imprints ( $x_1, \dots, x_n$  of class  $F$ ) and (BBK) the belief that these foot imprints are of an *Australopithecus* (EF).
  - The inference that (HYP) there might be other charged particles ( $y_1, \dots, y_m$  of class  $E$ ) in the chamber, from (OBS) observing deflections in the path ( $F$ ) of a charged particle ( $x_1$ ) in a chamber without external electric or magnetic fields and (BBK) the knowledge of the Coulomb and Lorentz forces and Newton's second law (EF).
4. *Conceptual abduction* or the abduction of a *new concept*

(OBS)  $F_1, \dots, F_m$  ( $m \geq 2$ ) with regard to each of  $x_1, \dots, x_n$  ( $n \geq 2$ )

(BBK) No known concept explains why  $F_1, \dots, F_m$  with regard to each of  $x_1, \dots, x_n$

---

(HYP) It might be that there is a *similarity* between the  $x_1, \dots, x_n$ , which can be labeled with a *new concept*  $E$  that explains why  $F_1, \dots, F_m$  with regard to each of  $x_1, \dots, x_n$  in a certain explanatory framework EF.

It was *Schurz* [12.14] who pointed out that this pattern is rational and useful for science only if the observation concerns several objects each individually having the same or similar properties, so that some form of conceptual unification is obtained. Otherwise, for each fact, it could be suggested that there exists an ad hoc power that explains (only) this single fact.

Some examples of this pattern, which largely coincides with the various types of *second-order abduction*, as *Schurz* [12.14] suggests and several types of *creative abduction* conceived by *Hoffmann* [12.15], are as follows:

- The inference that (HYP) there might be a new species of hominids ( $E$ ), from (OBS) observing various hominid fossils ( $x_1, \dots, x_n$ ) that are similar in many ways ( $F_1, \dots, F_m$ ) and (BBK) believing that these fossils cannot be classified in the current taxonomy of hominids (EF).
- The inference that (HYP) there might exist a new type of interaction ( $E$ ), from (OBS) observing similar interactive behavior

( $F_1, \dots, F_m$ ) between certain types of particles ( $x_1, \dots, x_n$ ) in similar experiments and (BBK) believing that this behavior cannot be explained by the already known interactions, properties of the involved particles and properties of the experimental setup (EF).

Using the terminology of *Magnani* [12.18] and following the distinction of *Schurz* [12.14], the first two patterns, the abduction of a singular fact and that of a generalization, can be considered as instances of *selective abduction*, as the agent selects an appropriate hypothesis in her background knowledge, while the latter two, existential abduction and conceptual abduction, can be called *creative abduction*, as the agent creates a new hypothetical concept or object. It has to be added that *Hoffmann* [12.15] would dispute this distinction, as he sees the third pattern (existential abduction) in the first place as the selection of an already known type (e.g., the genus *Australopithecus*), and not so much as the creation of a new token (someone of this genus of which his/her existence is now hypothesized).

As stated before, this list is not exhaustive. Further patterns have been identified, such as the abduction of a new perspective [12.15], for example, suggesting that a problem might have a geometrical solution instead of an algebraic one; *analogical abduction* [12.13], for example, explaining similar properties of water and light, by hypothesizing that light could also be wave-like; or *theoretical model abduction* [12.14], for example, explaining some observation by suggesting suitable initial conditions given some governing principles or laws. Some have even considered *visual abduction*, the inference from the observation itself to a statement describing this observation, as a separate pattern [12.19]. For some of these patterns (or instances of them), it is possible to argue that they are a special case of one of the patterns mentioned earlier. For instance, the suggestion of the wave nature of light can also be seen as an instance of conceptual abduction, in which the (mathematical) concept *wave behavior* is constructed to explain the similar properties of water and light; yet, it is true that the analogical nature of this inference makes it a special subpattern with interesting properties in itself. This is also how *Schurz* [12.14] presents it: In his classification, analogical abduction is one of the types of second-order existential abduction he conceives of.

Perhaps more important to note is that these patterns are not mutually exclusive given a particular instance of abductive reasoning. For instance, the inference that leads to the explanation of why a particular piece of iron is rusted can be described both as singular fact abduction (this piece of iron underwent a reaction

with oxygen) and as existential abduction (there were oxygen atoms present with which this piece of iron reacted). But in essence it describes the same explanation for the same explanandum.

Also, combinations occur. For instance, if a new particle is hypothesized as an explanation for an experimental anomaly (such as, for instance, *Wolfgang Pauli's* suggestion of the neutrino in the case of the anomalous  $\beta$  spectrum [12.20]), then this is both an instance of existential abduction – there is a not yet observed particle that causes the observed phenomenon – and an instance of conceptual abduction – these hypothesized particles are of a new kind of combination, which coincides with *Hoffmann's* [12.15] pattern of *creative fact abduction*. Yet in the mind of the scientist, this process of hypothesis formation might have occurred in a single reasoning step.

One should not, however, be too worried about these issues, if it is remembered that these patterns are categories for linguistic descriptions of actual reasoning processes. Any actual instance of hypothesis formation can be described in several ways by means of natural language, and some of these expressions can be formally analyzed in more than one way. Therefore, one should not focus too much on the exact classification of particular instances of hypothesis formation. Yet, this does not render meaningless the project of explicating various patterns of hypothesis formation. The goal of this project is to provide normative guidance for future hypothesis formation. If particular problems or observations can be looked at from different perspectives and, therefore, expressed in various ways, it is only beneficial for an agent to have multiple patterns of hypothesis formation at her disposal.

## 12.4 Abductive Reasoning and Adaptive Logics

Now, the various attempts to model abductive reasoning by means of adaptive logics are presented, though it first needs to be explained why the framework of adaptive logics is fit for this job.

First, adaptive logics allow for a direct implementation of defeasible reasoning steps (in casual applications of *affirming the consequent*). This makes it possible to construct logical proofs that nicely integrate defeasible (in this case ampliative) and deductive inferences. This corresponds to natural reasoning processes.

Second, the formal apparatus of an adaptive logic instructs exactly which formulas would falsify a (defeasible) reasoning step. As these formulas are assumed to be false (so long as one cannot derive them), they are called *abnormalities* in the adaptive logic literature. So, if one or a combination of these abnormalities is derived in a proof, it instructs in a formal way which defeasible steps cannot be maintained. This possibility of defeating previous reasoning steps mirrors nicely the dynamics found in actual human reasoning.

Third, for all adaptive logics in standard format, such as the presented logics  $\mathbf{LA}_s^r$  and  $\mathbf{MLA}_s^s$ , there are generic proofs for most of the important metatheoretical properties such as soundness and completeness [12.4].

So far, most research effort has been focused on modeling singular fact abduction, which already proves to be, even it appears to be the easiest case, a rich and

fruitful point of departure. This is not exclusive to the adaptive logics framework: In general, very little logics have been proposed for other forms besides singular abduction. Some of the few exceptions are [12.13] and [12.16]. (This last logic, which is an adaptive logic, suffers, however, from some complications [12.7, appendix B] and [12.21, p. 140].) For these reasons, this overview is limited to the various attempts to model singular fact abduction within the framework of adaptive logics.

The history of research into singular fact abduction within the adaptive logics community dates back to the early 2000s and can be traced through the articles [12.22–28]. Besides presenting early logics for singular fact abduction, this research has also shown that there actually exist two types of singular fact abduction (see also Sect. 12.5). In recent years, for each of these two types of abductions, an adaptive logic in a standard format (see Sect. 12.6) has been developed:  $\mathbf{LA}_s^r$  for practical abduction [12.29] and  $\mathbf{MLA}_s^s$  for theoretical abduction [12.30]. These will be the two logics that will be presented and explained in this chapter (see Sects. 12.7 and 12.8). It further needs to be noted that recent research has even pushed further by considering abduction from inconsistent theories [12.31], adaptations for use in AI ([12.32], improved version in [12.21, Ch. 5]), and a first logic for propositional singular fact abduction [12.7].

## 12.5 The Problem of Multiple Explanatory Hypotheses

The early research into logics for abduction has shown that two types of abduction logics can actually be constructed, depending on how the logic deals with multiple explanatory hypotheses for a single observation.

To explain this problem, consider the following example. Suppose one has to form hypotheses for the puzzling fact  $Pa$ , while one's background knowledge contains both  $(\forall x)(Qx \supset Px)$  and  $(\forall x)(Rx \supset Px)$ . There are two ways in which one can proceed. First, one could construct a logic in which one could derive only the disjunction  $(Qa \vee Ra)$  and not the individual hypotheses  $Qa$  and  $Ra$ . This first way, called *practical abduction* (according to the definition suggested in [12.24, pp. 224–225] and first used in [12.27]) and modeled by the logic  $\text{LA}_s^r$  ([12.29], Sect. 12.7), is suitable for modeling situations in which one has to *act* on the basis of the conclusions before having the chance to find out which hypothesis actually is the case. A good example is how people react to unexpected behavior. If someone suddenly starts to shout, people will typically react in a hesitant way, taking into account that either they themselves are somehow at fault or that the shouting person is just frustrated or crazy and acting inappropriately.

Second, someone with a theoretical perspective (for instance, a scientist or a detective) is interested in finding out which of the various hypotheses is the actual explanation. Therefore, it is important that s/he can *abduce* the individual hypotheses  $Qa$  and  $Ra$  in order to examine them further one by one. Early work on these kinds of logics has been done in [12.27, 28]. Yet, these logics have a quite complex proof theory. This is because, on the one hand, one has to be able to derive  $Qa$  and  $Ra$  separately, but on the other, one has to prevent

the derivation of their conjunction  $(Qa \wedge Ra)$ , because it seems counterintuitive to take the conjunction of two possible hypotheses as an explanation: For instance, if the street is wet, it would be weird to suggest that it has rained and that the fire department also just held an exercise. Moreover, if the two possible hypotheses are actually incompatible, it would lead to logical explosion in a classical logical context.

Logical explosion is the situation that just any statement can be derived from a certain premise set. In CL this occurs when a premise set contains a contradiction, that is, both a particular statement and its negation can be derived from the premise set, which makes an *ex falso quodlibet* argument possible. Briefly, such an argument goes as follows: suppose one's premise set contains both the statements  $p$  and  $\neg p$ . Then, by means of addition, one can first derive  $p \vee q$  for any random  $q$ . (Informally, as one already knows that  $p$  is true, any statement of the form *p or . . .* will also be true.) But, as  $\neg p$  also holds, one can derive  $q$  from this disjunction by means of a disjunctive syllogism (the logical rule that if you know that one side of disjunction is false, the other side has to be true to make the disjunction true).

The logic  $\text{MLA}_s^s$  [12.30] presented in this overview (Sect. 12.8) solves this problem by adding modalities to the language and deriving the hypotheses  $\diamond Qa$  and  $\diamond Ra$  instead of  $Qa$  and  $Ra$ . By conceiving of hypotheses as logical possibilities, the conjunction problem is automatically solved because  $\diamond Qa \wedge \diamond Ra$  does not imply  $\diamond(Qa \wedge Ra)$  in any standard modal logic. This approach also nicely coincides with the common idea that hypotheses are possibilities. These features make the logic  $\text{MLA}_s^s$  very suitable for the modeling of actual theoretical abductive reasoning processes.

## 12.6 The Standard Format of Adaptive Logics

Before the logics for abduction  $\text{LA}_s^r$  and  $\text{MLA}_s^s$  are presented, the reader should first be provided with the necessary background about the adaptive logics framework, and, more in particular, with the nuts and bolts of its standard format. This will, of course, be a limited introduction, and the reader is referred to, for example, [12.3] or [12.4] for a thorough introduction.

### Definition 12.1

An *adaptive logic in the standard format* is defined by a triple:

- (i) A *lower limit logic* (henceforth **LLL**): a reflexive, transitive, monotonic, and compact logic that has a characteristic semantics
- (ii) A *set of abnormalities*  $\Omega$ : a set of **LLL**-contingent formulas (that are not theorems of **LLL**) characterized by a logical form, or a union of such sets
- (iii) An adaptive *strategy*.

The lower limit logic **LLL** specifies the stable part of the adaptive logic. Its rules are unconditionally valid

in the adaptive logic, and anything that follows from the premises by **LLL** will never be revoked. Apart from that, it is also possible in an adaptive logic to derive defeasible consequences. These are obtained by assuming that the elements of the set of abnormalities are *as much as possible* false. The adaptive strategy is needed to specify *as much as possible*. This will become clearer further on.

Strictly speaking, the standard format for adaptive logics requires that a lower limit logic contains, in addition to the **LLL** operators, also the operators of **CL**. However, these operators have merely a technical role (in the generic meta-theory for adaptive logics) and are not used in the applications presented here. Therefore, given the introductory nature of this section, this will not be explained into further detail. In the logics presented in this chapter, the condition is implicitly assumed to be satisfied.

### 12.6.1 Dynamic Proof Theory

As stated before, a key advantage of adaptive logics is their *dynamic proof theory* which models human reasoning. This dynamics is possible because a *line* in an adaptive proof has – along with a line number, a formula and a justification – a fourth element, that is, the *condition*. A condition is a finite subset of the set of abnormalities and specifies which abnormalities need to be assumed to be false for the formula on that line to be derivable.

The inference rules in an adaptive logic reduce to three generic rules. Where  $\Gamma$  is the set of premises,  $\Theta$  is a finite subset of the set of abnormalities  $\Omega$  and  $Dab(\Theta)$  the (classical) disjunction of the abnormalities in  $\Theta$ , and where

$$A \quad \Delta. \quad (12.3)$$

indicates that  $A$  occurs in the proof on the condition  $\Delta$ , the inference rules are given by the generic rules

$$\begin{array}{l} \text{PREM} \quad \text{If } A \in \Gamma : \\ \quad \vdots \\ \quad \vdots \\ \hline A \quad \emptyset \end{array}$$

$$\begin{array}{l} \text{RU} \quad \text{If } A_1, \dots, A_n \vdash_{\text{LLL}} B : \\ A_1 \quad \Delta_1 \\ \quad \vdots \\ \quad \vdots \\ A_n \quad \Delta_n \\ \hline B \quad \Delta_1 \cup \dots \cup \Delta_n \end{array}$$

$$\begin{array}{l} \text{RC} \quad \text{If } A_1, \dots, A_n \vdash_{\text{LLL}} B \vee Dab(\Theta) \\ A_1 \quad \Delta_1 \\ \quad \vdots \\ \quad \vdots \\ A_n \quad \Delta_n \\ \hline B \quad \Delta_1 \cup \dots \cup \Delta_n \cup \Theta \end{array}$$

The premise rule **PREM** states that a premise may be introduced at any line of a proof on the empty condition. The unconditional inference rule **RU** states that, if  $A_1, \dots, A_n \vdash_{\text{LLL}} B$  and  $A_1, \dots, A_n$  occur in the proof on the conditions  $\Delta_1, \dots, \Delta_n$ , one may add  $B$  on the condition  $\Delta_1 \cup \dots \cup \Delta_n$ . The strength of an adaptive logic comes from the third rule, the conditional inference rule **RC**, which works analogously to **RU**, but introduces new conditions. So, it allows one to take defeasible steps based on the assumption that the abnormalities are false (this rule also makes clear that any adaptive proof can be transformed into a Fitch-style proof in the **LLL** by writing down for each line the disjunction of the formula and all of the abnormalities in the condition). Several examples of how these rules are employed will follow.

The only thing that is still needed is a criterion that defines when a line of the proof is considered to be defeated. At first sight, it seems straightforward to mark lines of which one of the elements of the condition is *unconditionally* derived from the premises, this means that it is derived on the empty condition (defeated lines in a proof are marked instead of deleted, because, in general, it is possible that they may later become unmarked in an extension of the proof). But this strategy, called the *simple strategy*, usually has a serious flaw. If it is possible to derive unconditionally a disjunction of abnormalities  $Dab(\Delta)$  that is *minimal*, that is, if there is no  $\Delta' \subset \Delta$  such that  $Dab(\Delta')$  can be unconditionally derived, the simple strategy would ignore this information. This is problematic, however, because at least one of the disjuncts of the ignored disjunction has to be true. Therefore, one can use the simple strategy only in cases where

$$\begin{array}{l} \Gamma \vdash_{\text{LLL}} Dab(\Delta) \\ \text{only if} \\ \text{there is an } A \in \Delta \text{ such that } \Gamma \vdash_{\text{LLL}} A \end{array} \quad (12.4)$$

with  $Dab(\Delta)$  being any disjunction of abnormalities out of  $\Omega$ . This condition will be met for the logic  $\mathbf{MLA}_s^s$  (Sect. 12.8); this logic will, hence, employ the simple strategy.

The majority of logics, however, do not meet this criterion and for those logics, more advanced strategies

have been developed. The best known of these are *reliability* and *minimal abnormality*. The logic  $\mathbf{LA}_s^r$  uses the reliability strategy. This strategy, which will be explained and illustrated in the following, orders to mark any line of which one of the elements is unconditionally derived as a disjunct from a minimal disjunction of abnormalities.

At this point, all elements are introduced to explain the naming of the two logics that will be presented in this chapter: As might be expected  $\mathbf{LA}$  and  $\mathbf{MLA}$  stand for *logic for abduction* and *modal logic for abduc-*

*tion* and the superscripts  $r$  and  $s$  stand for the adaptive strategies *reliability* and *simple strategy*, respectively. The subscript  $s$  originally denoted that the logic was formulated in the standard format for adaptive logics, but in [12.21], it is argued that it is more useful to interpret this  $s$  as that they are logics for *singular fact abduction*. After all, most adaptive logics are nowadays formulated in the standard format anyhow, and this allows us to contrast these logics with the logic  $\mathbf{LA}_\forall^r$  which is a logic for *abduction of generalizations* [12.16, 21].

## 12.7 $\mathbf{LA}_s^r$ : A Logic for Practical Singular Fact Abduction

In this section, the reader is introduced to the logic  $\mathbf{LA}_s^r$  [12.29] in an informal manner. This will allow the reader to gain a better understanding of the framework of adaptive logics and the functioning of its dynamic proof theory. In the next section, the same approach will be used for the logic  $\mathbf{MLA}_s^r$ . The formal definitions of both logics will be presented in the appendix for those who are interested.

In order to model abductive reasoning processes of singular facts, the logic  $\mathbf{LA}_s^r$  (as will the logic  $\mathbf{MLA}_s^r$ ) contains, in addition to deductive inference steps, defeasible reasoning steps based on an argumentation schema known as *affirming the consequent* (combined with Universal Instantiation)

$$(\forall\alpha)(A(\alpha) \supset B(\alpha)), B(\beta)/A(\beta). \quad (12.5)$$

The choice for a predicate logic is motivated by the fact that a material implication is used to model the relation between *explanans* and *explanandum*. As is well known that  $B \vdash_{\mathbf{CL}} A \supset B$ , a propositional logic would allow one to derive anything as a hypothesis. In the predicative case, the use of the universal quantifier can avoid this. This can be seen if we compare  $\vdash_{\mathbf{CL}} B(\beta) \supset (A(\beta) \supset B(\beta))$  with  $\not\vdash_{\mathbf{CL}} B(\beta) \supset (\forall\alpha)(A(\alpha) \supset B(\alpha))$  (see [12.7] for a propositional logic for abduction that solves this problem in another way).

Let the list of desiderata for this logic first be overviewed. This is important because in specifying the set of abnormalities and the strategy, one has to check whether they allow one to model practical abductive reasoning according to one's expectations. Apart from the fact that by means of this logic one should be able to derive hypotheses according to the schema of *affirming the consequent*, one has to make sure that one cannot derive – as a side effect – random hypotheses which

are not related to the explanandum. Finally, as has been pointed out in the introduction, it is a nice feature of adaptive logics that they enable one to integrate defeasible and deductive steps.

### 12.7.1 Lower Limit Logic

The lower limit logic of  $\mathbf{LA}_s^r$  is a classical first-order logic  $\mathbf{CL}$ . This means that the deductive inferences of this logic are the reasoning steps modeled by classical logic. Also, as this logic is an extension of classical logic, any classical consequence of a premise set will also be a consequence of the premise set according to this logic.

### 12.7.2 Set of Abnormalities $\Omega$

If one takes (here and in further definitions) the metavariables  $A$  and  $B$  to represent (well-formed) formulas,  $\alpha$  a variable and  $\beta$  a constant of the language in which the logic is defined  $\mathcal{L}$ , we can define the set of abnormalities of the logics  $\mathbf{LA}_s^r$  as

$$\begin{aligned} \Omega = \{ & (\forall\alpha)(A(\alpha) \supset B(\alpha)) \\ & \wedge (B(\beta) \wedge \neg A(\beta)) \} \mid \\ & \text{No predicate occurring in } B \\ & \text{occurs in } A \} \end{aligned} \quad (12.6)$$

The first line is the logical form of the abnormality; the second line in the definition is to prevent self-explanatory hypotheses. To understand the functioning of this logical form, consider the following example proof starting from the premise set,  $\{Qa, \forall x(Px \supset Qx)\}$ ,  $\forall x(Px \supset Rx)$ . The official layout of this chapter in two columns forces to split each line of the proof over

two lines and write the condition of the line on a second line, starting with an  $\rightarrow$  arrow

1	$\forall x(Px \supset Qx)$	-;PREM	
	$\rightarrow \emptyset$		
2	$Qa$	-;PREM	
	$\rightarrow \emptyset$		
3	$Pa \vee \neg Pa$	-; RU	
	$\rightarrow \emptyset$		
4	$Pa \vee (\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa))$	1,2,3;RU	
	$\rightarrow \emptyset$		
5	$Pa$	4;RC	
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$		

From this premise set, one would like to be able to form the hypothesis  $Pa$ . One obtains this hypothesis as follows. One starts by writing two premises on the first two lines and a tautology on the third line (all these lines are not dependent on earlier lines, indicated by the dash). These three lines allow one then to derive the disjunction on line 4 by means of the unconditional inference rule RU. This disjunction has the exact form that allows one now to derive conditionally the hypothesis  $Pa$  from it by applying the rule RC.

From this hypothesis, one can reason further in a deductive way by applying, for example, modus ponens (note that the result of this inference has also a nonempty condition)

5	$Pa$	4;RC	
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$		
6	$\forall x(Px \supset Rx)$	-; PREM	
	$\rightarrow \emptyset$		
7	$Ra$	5,6;RU	
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$		

Suppose now that one comes to know that  $\neg Pa$  is the case and add this premise to the premise set and continue the proof. Strictly speaking, this is not what is actually done. What is actually done is to start a new proof with another premise set (the extended set). But it is easily seen that one can start this new proof with exactly the same lines as the old proof. This way, it looks as if one has extended the old proof. Therefore, it made sense to use the phrase *adding premises and continuing a proof* as it also nicely mirrors how human beings deal with incoming information: They do not start over their reasoning but incorporate the new information at

the point where they have arrived.

5	$Pa$	4;RC	
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$		
6	$\forall x(Px \supset Rx)$	-; PREM	
	$\rightarrow \emptyset$		
7	$Ra$	5, 6; RU	
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$		
8	$\neg Pa$	-;PREM	
	$\rightarrow \emptyset$		
9	$\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)$	1,2,6;RU	
	$\rightarrow \emptyset$		

This new premise makes it possible to derive unconditionally on line 9 the condition of the hypothesis  $Pa$ . At this point, it is clear that one should not trust anymore the hypothesis formed on line 5, which one indicates by marking this line with a checkmark, indicating that one lost one's confidence in this formula once one wrote down line 9. As the formula  $Ra$  is arrived at by reasoning further upon the hypothesis  $Pa$ , it has (at least) the same condition, and is, hence, at this point also marked.

In summary, each time one defeasibly derives a hypothesis, one has to state explicitly the condition the (suspected) truth of which would defeat the hypothesis. Therefore, one can assume the hypothesis to be true as long as one can assume the condition to be false; but as soon as one has evidence that the condition might be true, one should withdraw the hypothesis.

### 12.7.3 Reliability Strategy

In the previous example, one withdrew the hypothesis because its condition was explicitly derived. However, have a look at the following example proof from the premise set  $\{Qa, Ra, \forall x(Px \supset Qx), \forall x(\neg Px \supset Rx)\}$

1	$\forall x(Px \supset Qx)$	-;PREM	
	$\rightarrow \emptyset$		
2	$\forall x(\neg Px \supset Rx)$	-;PREM	
	$\rightarrow \emptyset$		
3	$Qa$	-;PREM	
	$\rightarrow \emptyset$		
4	$Ra$	-;PREM	
	$\rightarrow \emptyset$		
5	$Pa$	1,3;RC	
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$		
6	$\neg Pa$	2,4;RC	
	$\rightarrow \{\forall x(\neg Px \supset Rx) \wedge (Ra \wedge Pa)\}$		

There is clearly something fishy about this situation. As the conditions on lines 5 and 6 are not derivable from this premise set, logical explosion would allow one to derive anything from this premise set, if one were to use the simple strategy. Still, it is quite obvious that at least one of those two conditions has to be false, as the disjunction of these two conditions is a theorem of the lower limit logic. Yet, as one does not know from these premises which disjunct is true and which one is false, the most reliable thing to do is to mark both lines

⋮	⋮	⋮					
5	$Pa$	1,3;RC	✓ <sup>7</sup>				
	$\rightarrow \{\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)\}$						
6	$\neg Pa$	2,4;RC	✓ <sup>7</sup>				
	$\rightarrow \{\forall x(\neg Px \supset Rx) \wedge (Ra \wedge Pa)\}$						
7	$(\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa))$ $\vee (\forall x(\neg Px \supset Rx) \wedge (Ra \wedge Pa))$	1-4;RU					
	$\rightarrow \emptyset$						

This marking strategy is called the *reliability strategy* and it orders one to mark lines for which an element of the condition has been unconditionally derived as a disjunct of a minimal disjunction of abnormalities (or in short, a minimal *Dab* formula). It is important to note that (1) the disjunction should only hold disjuncts that have the form of an abnormality (otherwise, a defeating disjunction could be constructed for every hypothesis) and (2) that this disjunction should be minimal (as disjunctions can always be extended by applications of the addition rule). To clarify this last point: Suppose one was able to derive the condition of line 5 by itself, then the disjunction on line 7 would not be minimal anymore and there would be no reason anymore to mark line 6.

### 12.7.4 Practical Abduction

The logic  $\mathbf{LA}_s^r$  is a logic for practical abduction (Sect. 12.5). This means that it solves the problem of multiple explanatory hypotheses by only allowing the disjunction of the various hypotheses to be derived. Consider the following example from the premise set  $\{Ra, \forall x(Px \supset Rx), \forall x(Qx \supset Rx)\}$

1	$\forall x(Px \supset Rx)$	-;PREM					
	$\rightarrow \emptyset$						
2	$\forall x(Qx \supset Rx)$	-;PREM					
	$\rightarrow \emptyset$						
3	$Ra$	-;PREM					
	$\rightarrow \emptyset$						

4	$Pa$	1,3;RC	✓ <sup>6</sup>				
	$\rightarrow \{\forall x(Px \supset Rx) \wedge (Ra \wedge \neg Pa)\}$						
5	$Qa$	2,3;RC	✓ <sup>7</sup>				
	$\rightarrow \{\forall x(Qx \supset Rx) \wedge (Ra \wedge \neg Qa)\}$						
6	$(\forall x(Px \supset Rx) \wedge (Ra \wedge \neg Pa))$ $\vee (\forall x((Qx \wedge \neg Px) \supset Rx)$ $\wedge (Ra \wedge \neg(Qa \wedge \neg Pa)))$	1-3;RC					
	$\rightarrow \emptyset$						
7	$(\forall x(Qx \supset Rx) \wedge (Ra \wedge \neg Qa))$ $\vee (\forall x((Px \wedge \neg Qx) \supset Rx)$ $\wedge (Ra \wedge \neg(Pa \wedge \neg Qa)))$	1-3;RC					
	$\rightarrow \emptyset$						
8	$\forall x((Px \vee Qx) \supset Rx)$	1,2;RU					
	$\rightarrow \emptyset$						
9	$Pa \vee Qa$	3,8;RC					
	$\rightarrow \{\forall x((Px \vee Qx) \supset Rx)$ $\wedge (Ra \wedge \neg(Pa \vee Qa))\}$						

Because of the fact that the minimal *Dab* formulas on lines 6 and 7 could be derived from the premises, the individual hypotheses *Pa* and *Qa* have to be withdrawn; yet, the condition of their disjunction on line 9 is not part of a minimal *Dab* formula from these premises. This shows that this logic only allows one to derive a disjunction in the case of multiple explanatory hypotheses, and none of the individual disjuncts.

### 12.7.5 Avoiding Random Hypotheses

Another important feature of a logic for abduction is that it prevents from allowing one to derive random hypotheses. The three most common ways to introduce random hypotheses is:

1. By deriving an explanation for a tautology, for example, deriving *Xa* from the theorems  $Pa \vee \neg Pa$  and  $\forall x(Xx \supset (Px \vee \neg Px))$
2. By deriving contradictions as explanations, which leads to logical explosion, for example, deriving  $Xa \wedge \neg Xa$  from *Pa* and the theorem  $\forall x((Xx \wedge \neg Xx) \supset Px)$
3. By deriving hypotheses that are not the most parsimonious ones, for example, deriving  $Pa \wedge Xa$  from *Qa* and  $\forall x(Px \supset Qx)$  (and its consequence  $\forall x((Px \wedge Xx) \supset Qx)$ ).

The logic  $\mathbf{LA}_s^r$  prevent these three ways by similar mechanisms as the mechanism to block individual hypotheses illustrated above. Elaborate examples for each of these three ways can be found in [12.29].

## 12.8 $\mathbf{MLA}_s^s$ : A Logic for Theoretical Singular Fact Abduction

In this section, the reader will be introduced to the logic  $\mathbf{MLA}_s^s$  [12.30] in a similar informal manner. Formal definitions can again be found in the appendix. Analogously, this logic also models deductive steps combined with applications of *affirming the consequent* (combined with universal instantiation); yet, it treats the problem of multiple explanatory hypotheses now in a different way: It allows one to derive these hypotheses individually; yet to avoid logical explosion caused by mutually exclusive hypotheses, it treats them as modal possibilities (Sect. 12.5).

The list of desiderata for this logic is very analogous as the one for the logic  $\mathbf{LA}_s^s$ , except for treating the problem of multiple explanatory hypotheses in a different manner. Specific for this logic (as this logic is aimed at modeling the reasoning of, e.g., scientists or detectives [12.33]) is the desideratum that it handles contradictory hypotheses, predictions, and counterevidence in a natural way.

### 12.8.1 Formal Language Schema

As this logic is a modal logic, the language of this logic is an extension of the language of the classical logic  $\mathbf{CL}$ . Let the standard predicative language of the classical logic be denoted with  $\mathcal{L}$ .  $C$ ,  $\mathcal{V}$ ,  $\mathcal{F}$ , and  $\mathcal{W}$  will further be used to refer, respectively, to the sets of individual constants, individual variables, all (well-formed) formulas of  $\mathcal{L}$ , and the closed (well-formed) formulas of  $\mathcal{L}$ .

$\mathcal{L}_M$ , the language of the logic  $\mathbf{MLA}_s^s$ , is  $\mathcal{L}$  extended with the modal operator  $\Box$ .  $\mathcal{W}_M$ , the set of closed formulas of  $\mathcal{L}_M$  is the smallest set that satisfies the following conditions:

1. If  $A \in \mathcal{W}$ , then  $A, \Box A \in \mathcal{W}_M$
2. If  $A \in \mathcal{W}_M$ , then  $\neg A \in \mathcal{W}_M$
3. If  $A, B \in \mathcal{W}_M$ ,  
then  $A \wedge B, A \vee B, A \supset B, A \equiv B \in \mathcal{W}_M$ .

It is important to notice that there are no occurrences of modal operators within the scope of another modal operator or a quantifier. The set  $\mathcal{W}_\Gamma$ , the subset of  $\mathcal{W}_M$ , the elements of which can act as premises in the logic, is further defined as

$$\mathcal{W}_\Gamma = \{\Box A \mid A \in \mathcal{W}\}. \quad (12.7)$$

It is easily seen that

$$\mathcal{W}_\Gamma \subset \mathcal{W}_M. \quad (12.8)$$

### 12.8.2 Lower Limit Logic

The **LLL** of  $\mathbf{MLA}_s^s$  is the predicative version of  $D$ , restricted to the language schema  $\mathcal{W}_M$ .  $D$  is characterized by a full axiomatization of predicate CL together with two axioms, an inference rule, and a definition

$$\mathbf{K} \quad \Box(A \supset B) \supset (\Box A \supset \Box B), \quad (12.9)$$

$$\mathbf{D} \quad \Box A \supset \neg \Box \neg A, \quad (12.10)$$

$$\mathbf{NEC} \quad \text{if } \vdash A, \text{ then } \vdash \Box A, \quad (12.11)$$

$$\diamond A =_{\text{df}} \neg \Box \neg A \quad (12.12)$$

This logic is one of the weakest normal modal logics that exist and is obtained by adding the  $D$ -axiom to the axiomatization of the better known minimal normal modal logic  $\mathbf{K}$ .

The semantics for this logic can be expressed by a standard possible world Kripke semantics where the accessibility relation  $R$  between possible worlds is *serial*, that is, for every world  $w$  in the model, there is at least one world  $w'$  in the model such that  $Rww'$ .

### 12.8.3 Intended Interpretation of the Modal Operators

As indicated above, explanatory hypotheses – the results of abductive inferences – will be represented by formulas of the form  $\diamond A$  ( $A \in \mathcal{W}$ ). Formulas of the form  $\Box B$  are used to represent explananda, other observational data, and relevant background knowledge. Otherwise, this information would not be able to revoke derived hypotheses (for instance,  $\neg A$  and  $\diamond A$  are not contradictory, whereas  $\Box \neg A$  and  $\diamond A$  are). The reason **D** is chosen instead of **K** is that it is assumed that the explananda and background information are together consistent. This assumption is modeled by the **D**-axiom (for instance, the premise set  $\{\Box \neg Pa, \Box (\forall x)Px\}$  is a set modeling an inconsistent set of background knowledge and observations, but in the logic **K**, this set would not be considered inconsistent, because anything cannot be derived from this set by *Ex Falso Quodlibet*. To be able to do this, the **D**-axiom is needed.)

### 12.8.4 Set of Abnormalities

Since the final form of the abnormalities is quite complex – although the idea behind is straightforward – two more basic proposals that are constitutive for the final form will first be considered and it will be shown why they are insufficient. Obviously, only closed well-formed formulas can be an element of any set of

abnormalities. This will not be explicitly stated each time.

### 12.8.5 First Proposal $\Omega_1$

This first proposal is a modal version of the set of abnormalities of the logic  $\mathbf{LA}_s^+$

$$\Omega_1 = \{\Box(\forall\alpha(A(\alpha) \supset B(\alpha)) \wedge (B(\beta) \wedge \neg A(\beta))) \mid \text{No predicate occurring in } B \text{ occurs in } A\} \quad (12.13)$$

Analogous to the logic  $\mathbf{LA}_s^+$ , this means that a derived hypothesis will be defeated if one shows explicitly that the hypothesis cannot be the case.

### 12.8.6 Simple Strategy

For this logic, the *simple strategy* can be used, which means, as stated before, that one has to mark lines for which one of the elements of the condition is unconditionally derived. It can easily be seen that the condition for the use of the simple strategy, that is,

$$\begin{aligned} &\Gamma \vdash_{\text{LLL}} \text{Dab}(\Delta) \\ &\text{only if} \\ &\text{there is an } A \in \Delta \text{ such that } \Gamma \vdash_{\text{LLL}} A, \end{aligned} \quad (12.14)$$

is fulfilled here. Since all premises have the form  $\Box A$ , the only option to derive a disjunction of abnormalities would be to apply addition, that is, to derive  $(\Box A \vee \Box B)$  from  $\Box A$  (or  $\Box B$ ), because it is well known that  $\Box(A \vee B) \not\vdash \Box A \vee \Box B$  in any standard modal logic (it is also possible to derive a disjunction from the premises by means of the *K*-axiom. For instance,  $\Box(A \supset B) \vdash \neg\Box A \vee \Box B$ , but the first disjunct will always be equivalent to a possibility ( $\Diamond\neg A$ ) and can, hence, not be an abnormality).

### 12.8.7 Contradictory Hypotheses

As a first example of the functioning of this logic, consider the following example starting from the premise set  $\{\Box Qa, \Box Ra, \Box\forall x(Px \supset Qx), \Box\forall x(\neg Px \supset Rx)\}$ . As the reader is by now probably accustomed to the functioning of the abnormalities, it is also shown how this logic is able to handle contradictory hypotheses without causing explosion.

$$\begin{aligned} 1 &\quad \Box\forall x(Px \supset Qx) && \text{-;PREM} \\ &\quad \longrightarrow \emptyset \\ 2 &\quad \Box\forall x(\neg Px \supset Rx) && \text{-;PREM} \\ &\quad \longrightarrow \emptyset \end{aligned}$$

$$\begin{aligned} 3 &\quad \Box Qa && \text{-;PREM} \\ &\quad \longrightarrow \emptyset \\ 4 &\quad \Box Ra && \text{-;PREM} \\ &\quad \longrightarrow \emptyset \\ 5 &\quad \Diamond Pa && 1,3;\text{RC} \\ &\quad \longrightarrow \{\Box(\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa))\} \\ 6 &\quad \Diamond \neg Pa && 2,4;\text{RC} \\ &\quad \longrightarrow \{\Box(\forall x(\neg Px \supset Rx) \\ &\quad \quad \wedge (Ra \wedge \neg\neg Pa))\} \\ 7 &\quad \Diamond Pa \wedge \Diamond \neg Pa && 5,6;\text{RU} \\ &\quad \longrightarrow \{\Box(\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa)), \\ &\quad \quad \Box(\forall x(\neg Px \supset Rx) \wedge (Ra \wedge \neg\neg Pa))\} \end{aligned}$$

$\Diamond Pa$  and  $\Diamond \neg Pa$  are derivable hypotheses because both the conditions on lines 5–7 are not unconditionally derivable from the premise set. It is also interesting to note that, because of the properties of the lower limit *D*, it is not possible to derive from these premises that  $\Diamond(Pa \wedge \neg Pa)$ . The conjunction of two hypotheses is never considered as a hypothesis itself, unless there is further background information that links these two hypotheses in some way.

### 12.8.8 Predictions and Evidence

To show that this logic handles predictions and (counter) evidence for these predictions in a natural way, let the premise set be extended with the additional implication  $\Box\forall x(Px \supset Sx)$

$$\begin{aligned} 8 &\quad \Box\forall x(Px \supset Sx) && \text{-;PREM} \\ &\quad \longrightarrow \emptyset \\ 9 &\quad \Diamond Sa && 5,8;\text{RU} \\ &\quad \longrightarrow \{\Box(\forall x(Px \supset Qx) \wedge (Qa \wedge \neg Pa))\} \end{aligned}$$

With this extra implication, the prediction  $\Diamond Sa$  can be derived. As long as one has no further information about this prediction (for instance, by observation), it remains a hypothesis derived on the same condition as  $\Diamond Pa$ . If one would test this prediction, one would have two possibilities. On the one hand, if the prediction turns out to be false, the premise  $\Box\neg Sa$  could be added to the premise set

$$\begin{aligned} &\vdots && \vdots \\ &\vdots && \vdots \\ 5 &\quad \Diamond Pa && 1,3;\text{RC} \quad \checkmark^{12} \\ &\quad \longrightarrow \{\Box(\forall x(Px \supset Qx) \\ &\quad \quad \wedge (Qa \wedge \neg Pa))\} \\ &\vdots && \vdots \\ &\vdots && \vdots \\ 9 &\quad \Diamond Sa && 5,8;\text{RU} \quad \checkmark^{12} \\ &\quad \longrightarrow \{\Box(\forall x(Px \supset Qx) \\ &\quad \quad \wedge (Qa \wedge \neg Pa))\} \end{aligned}$$

10	$\Box \neg Sa$	PREM
	$\longrightarrow \emptyset$	
11	$\Box \neg Pa$	8,10;RU
	$\longrightarrow \emptyset$	
12	$\Box (\forall x(Px \supset Qx)$	
	$\wedge (Qa \wedge \neg Pa))$	1,3,11;RU
	$\longrightarrow \emptyset$	

In this case, one could subsequently derive  $\Box \neg Pa$ , which would falsify the hypothesis  $\diamond Pa$ . On the other hand, if the prediction  $Sa$  turned out to be true, the premise  $\Box Sa$  could have been added, but this extension of the premise set would not allow us to derive  $\Box Pa$ . Since true predictions only *corroborate* the hypothesis but do not *prove* it, while false predictions directly *falsify* the hypothesis, one can say that this logic handles predictions in a *Popperian* way, although in using this vocabulary, the reader has to be reminded that  $MLA_s^s$  is a logic for modeling abduction and handling explanatory hypotheses, not a formal methodology of science. This logic has nothing to say about the confirmation of theories for which Popper actually employed the concepts of corroboration and falsification [12.34].

### 12.8.9 Contradictions

One of the three ways a logic of abduction could generate random hypotheses as a side effect is by allowing for the abduction of contradictions. How this is possible and how the logic prevents this are illustrated in the following proof from the premise set  $\{\Box Qa\}$

1	$\Box Qa$	-;PREM
	$\longrightarrow \emptyset$	
2	$\Box \forall x((Xx \wedge \neg Xx) \supset Qx)$	-;RU
	$\longrightarrow \emptyset$	
3	$\diamond (Xa \wedge \neg Xa)$	1,2;RC $\checkmark^4$
	$\longrightarrow \{\Box (\forall x((Xx \wedge \neg Xx) \supset Qx)$	
	$\wedge (Qa \wedge \neg (Xa \wedge \neg Xa)))\}$	
4	$\Box (\forall x((Xx \wedge \neg Xx) \supset Qx)$	1;RU
	$\wedge (Qa \wedge (\neg Xa \vee Xa)))$	
	$\longrightarrow \emptyset$	

### 12.8.10 Tautologies

Still, there are other ways to derive random hypotheses that are not prevented by the first proposal for the set of abnormalities  $\Omega_1$ . For instance,  $\Omega_1$  does not prevent that random hypotheses can be derived from a tautology, as illustrated by the following example. As is impossible in the following proof from the premise set  $\emptyset$  to unconditionally derive the abnormality in the condition of line 3 from the premises, the formula of line

3, the random hypothesis  $\diamond Xa$ , remains derived in every possible extension of the proof.

1	$\Box (Qa \vee \neg Qa)$	-;RU
	$\longrightarrow \emptyset$	
2	$\Box \forall x(Xx \supset (Qx \vee \neg Qx))$	-;RU
	$\longrightarrow \emptyset$	
3	$\diamond Xa$	1,2;RC
	$\longrightarrow \{\Box (\forall x(Xx \supset (Qx \vee \neg Qx))$	
	$\wedge ((Qa \vee \neg Qa) \wedge \neg Xa))\}$	

Therefore, let the set of abnormalities be adjusted to obtain the second proposal  $\Omega_2$ .

### 12.8.11 Second Proposal $\Omega_2$

No hypothesis can be abduced from a tautology if the abnormalities have the following form

$$\Omega_2 = \{ \Box (\forall \alpha (A(\alpha) \supset B(\alpha)) \wedge (B(\beta) \wedge \neg A(\beta))) \vee \Box \forall \alpha B(\alpha) \mid \text{No predicate occurring in } B \text{ occurs in } A \}$$
(12.15)

It is clear that one can keep using the simple strategy with this new set of abnormalities. It is also easily seen that all of the advantages and examples described above still hold. Each time one can derive an abnormality of  $\Omega_1$ , one can derive the corresponding abnormality of  $\Omega_2$  by a simple application of the *addition* rule. Finally, the problem raised by tautologies, as illustrated in the previous example, is solved in an elegant way, because the form of abnormalities makes sure that the abnormality will always be a theorem in case the explanandum is a theorem. So, nothing can be abduced from tautologies.

### 12.8.12 Most Parsimonious Explanantia

Still, there is third way to derive random hypotheses that cannot be prevented by  $\Omega_2$ . Consider, for instance, the following proof from the premise set  $\{\Box Ra, \Box \forall x(Px \supset Rx)\}$

1	$\Box Ra$	-;PREM
	$\longrightarrow \emptyset$	
2	$\Box \forall x(Px \supset Rx)$	-;PREM
	$\longrightarrow \emptyset$	
3	$\Box \forall x((Px \wedge Xx) \supset Rx)$	2;RU
	$\longrightarrow \emptyset$	
4	$\diamond (Pa \wedge Xa)$	1,3;RC
	$\longrightarrow \{\Box (\forall x((Px \wedge Xx) \supset Rx)$	
	$\wedge (Ra \wedge \neg (Pa \wedge Xa))) \vee \Box \forall x Rx\}$	

$$5 \quad \diamond Xa \quad 4;RU \\ \longrightarrow \{\Box(\forall x((Px \wedge Xx) \supset Rx) \\ \wedge (Ra \wedge \neg(Pa \wedge Xa))) \vee \Box\forall xRx\}$$

The reason why the random hypothesis  $\diamond Xa$  can be derived is the absence of a mechanism to ensure that the abduced hypothesis is the most parsimonious one and not the result of *strengthening the antecedent* of an implication. Before defining the final and actual set of abnormalities that also prevent this way of generating random hypotheses, a new notation has to be introduced to keep things as perspicuous as possible.

### 12.8.13 Notation

Suppose  $A_{PCN}(\alpha)$  is the *prenex conjunctive normal* form of  $A(\alpha)$ . This is an equivalent form of the formula  $A(\alpha)$  where all quantifiers are first moved to the front of the expression and where, consequently, the remaining (quantifier-free) expression is written in a conjunctive normal form, that is, as a conjunction of disjunctions of literals. Hence, apart from the quantifiers which are all at the front, it is entirely made up of a big conjunction of subformulae.

$$A_{PCN}(\alpha) = (Q_1\gamma_1) \cdots (Q_m\gamma_m) \\ (A_1(\alpha) \wedge \cdots \wedge A_n(\alpha)) \\ \text{and } \vdash A_{PCN}(\alpha) \equiv A(\alpha) \quad (12.16)$$

with  $m \geq 0$ ,  $n \geq 1$ ,  $Q_i \in \{\forall, \exists\}$  for  $i \leq m$ ,  $\gamma_i \in \mathcal{V}$  for  $i \leq m$ ,  $\alpha \in \mathcal{V}$  and  $A_i(\alpha)$  disjunctions of literals in  $\mathcal{F}$  for  $i \leq n$ .

Then, the new notation  $A_i^{-1}(\alpha)$  ( $1 \leq i \leq n$ ) can be introduced so that there is a way to take out one of the conjuncts of a formula in the PCN form. In cases where the conjunction consists of only one conjunct (and, obviously, no more parsimonious explanation is possible), the substitution with a random tautology will make sure that the condition for parsimony, added in the next set of abnormalities, is satisfied trivially

$$\text{if } n > 1: \\ A_i^{-1}(\alpha) =_{\text{df}} (Q_1\gamma_1) \cdots (Q_m\gamma_m) (A_1(\alpha) \wedge \cdots \\ \wedge A_{i-1}(\alpha) \wedge A_{i+1}(\alpha) \wedge \cdots \wedge A_n(\alpha)) \\ \text{with } A_j (1 \leq j \leq n) \text{ the } j\text{-th conjunct} \\ \text{of } A_{PCN}(\alpha) \quad (12.17)$$

$$\text{if } n = 1: \\ A_1^{-1}(\alpha) =_{\text{df}} \top \\ \text{with } \top \text{ any tautology of } \mathbf{CL}. \quad (12.18)$$

### 12.8.14 Final Proposal $\Omega$

With this notation, the logical form of the set of abnormalities  $\Omega$  of the logic  $\mathbf{MLA}_s^s$  can be written as

$$\Omega = \{\Box(\forall\alpha(A(\alpha) \supset B(\alpha)) \wedge (B(\beta) \wedge \neg A(\beta))) \\ \vee \Box\forall\alpha B(\alpha) \vee \bigvee_{i=1}^n \Box\forall\alpha(A_i^{-1}(\alpha) \supset B(\alpha)) \mid \\ \text{No predicate occurring in } B \text{ occurs in } A\} \quad (12.19)$$

This form might look complex, but its functioning is quite straightforward. What is constructed is the disjunction of the three reasons why one should refrain from considering  $A(\beta)$  as a good explanatory hypothesis for the phenomenon  $B(\beta)$ , even if one has  $(\forall\alpha)(A(\alpha) \supset B(\alpha))$ . The disjunction will make sure that the hypothesis  $A(\beta)$  is rejected as soon as one of the following is the case:

1. When  $\neg A(\beta)$  is derived
2. When  $B(\beta)$  is a tautology (and obviously, does not need an explanatory hypothesis)
3. When  $A(\beta)$  has a redundant part and is, therefore, not an adequate explanatory hypothesis.

For the same reasons, as stated in the description of  $\Omega_2$ , one can keep using the simple strategy and all of the advantages and examples described above will still hold.

Let one has a look at how this final set of abnormalities solve the previous problem. As the condition is fully written out, one can easily see that the third disjunct  $\Box\forall x(Px \supset Rx)$  is actually a premise, and that, hence, the abnormality on line 4 unconditionally derivable is

$$\begin{array}{ll} 1 & \Box Ra \quad \text{---;PREM} \\ & \longrightarrow \emptyset \\ 2 & \Box\forall x(Px \supset Rx) \quad \text{---;PREM} \\ & \longrightarrow \emptyset \\ 3 & \Box\forall x((Px \wedge Qx) \supset Rx) \quad 2;RU \\ & \longrightarrow \emptyset \\ 4 & \diamond(Pa \wedge Qa) \quad 1,3;RC \checkmark^5 \\ & \longrightarrow \{\Box(\forall x((Px \wedge Qx) \supset Rx) \\ & \quad \wedge (Ra \wedge \neg(Pa \wedge Qa))) \vee \Box\forall xRx \\ & \quad \vee \Box\forall x(Px \supset Rx) \vee \Box\forall x(Qx \supset Rx)\} \\ 5 & \Box(\forall x((Px \wedge Qx) \supset Rx) \wedge \quad 2;RU \\ & \quad (Ra \wedge \neg(Pa \wedge Qa))) \vee \Box\forall xRx \\ & \quad \vee \Box\forall x(Px \supset Rx) \vee \Box\forall x(Qx \supset Rx) \\ & \longrightarrow \emptyset \end{array}$$

This concludes the informal presentation of this logic, which, in its final form, meets all desiderata put up front.

## 12.9 Conclusions

There is quite some ground covered in this chapter, the main purpose of which was to show in a direct yet nuanced fashion the feasibility and the limits of modeling hypothetical reasoning by means of formal logics. It started with an argument for this claim in a general way, showing which assumptions one has to assume or reject to take this view. As far as there is argued for the feasibility of this project, the attention was also drawn to certain limits, pitfalls, and disadvantages of it. This discussion was then expanded by identifying four main abduction patterns, which showed that no pattern of hypothetical reasoning can be easily modeled.

In the second part of this chapter, gears were shifted and a glimpse was shown of what is already possible today with current logical techniques, by explaining in detail two logics originating in the adaptive logics framework:  $\mathbf{LA}_s^r$  for practical fact abduction and  $\mathbf{MLA}_s^s$  for theoretical singular fact abduction. The purpose of including the full details of these logics is threefold: First, it shows the reader how certain steps, which are

admittedly modest, can be taken in the project of formally modeling hypothetical reasoning. At the same time, the reader is introduced to the unificational framework of adaptive logics that shows promise to take some further steps along the road. Finally, it also shows that the use of formal models draws the attention to various issues about these reasoning patterns which were previously left unattended, for example, the difference between practical and theoretical abduction or the importance of avoiding random hypotheses by restricting the use of tautologies and contradictions.

However, if one looks at the prospect of modeling abductive reasoning by means of formal (adaptive) logics, one has to conclude that so far only the tip of the iceberg has been scratched. At present, apart from a single exception, only logics have been devised for singular fact abduction, which is, in fact, the most easy of the various patterns of abduction. Yet, the complications that already arise on this level warn dreamers that the road ahead will be steep and arduous.

## 12.A Appendix: Formal Presentations of the Logics $\mathbf{LA}_s^r$ and $\mathbf{MLA}_s^s$

In this appendix, the logics  $\mathbf{LA}_s^r$  and  $\mathbf{MLA}_s^s$  will, for the sake of completeness be defined in a formal and precise way. This section is limited to what is needed to present these specific logics. For a more general formal presentation of adaptive logics in the standard format, see [12.4].

Like any adaptive logic in the standard format, the logics  $\mathbf{LA}_s^r$  and  $\mathbf{MLA}_s^s$  are characterized by the triple of a lower limit logic, a set of abnormalities, and an adaptive strategy.

For  $\mathbf{LA}_s^r$ , the lower limit logic is  $\mathbf{CL}$ , the strategy is the *reliability strategy* and the set of abnormalities  $\Omega_{\mathbf{LA}_s^r}$  is defined by

$$\begin{aligned} \Omega_{\mathbf{LA}_s^r} = \{ & (\forall \alpha (A(\alpha) \supset B(\alpha)) \\ & \wedge (B(\beta) \wedge \neg A(\beta))) \mid \\ & \text{No predicate occurring in } B \\ & \text{occurs in } A \} \end{aligned} \quad (12.20)$$

For  $\mathbf{MLA}_s^s$ , the lower limit logic is  $\mathbf{D}$ , the strategy is the *simple strategy* and the set of abnormalities  $\Omega_{\mathbf{MLA}_s^s}$  is, relying on the previously introduced abbreviation, defined by

$$\begin{aligned} \Omega_{\mathbf{MLA}_s^s} = \{ & \Box (\forall \alpha (A(\alpha) \supset B(\alpha)) \\ & \wedge (B(\beta) \wedge \neg A(\beta))) \\ & \vee \Box \forall \alpha B(\alpha) \\ & \vee \bigvee_{i=1}^n \Box \forall \alpha (A_i^{-1}(\alpha) \supset B(\alpha)) \mid \\ & \text{No predicate occurring in } B \\ & \text{occurs in } A \} \end{aligned} \quad (12.21)$$

### 12.A.1 Proof Theory

The proof theory of these logics is characterized by the three generic inference rules introduced in Sect. 12.2 and the following definitions.

Within adaptive logics, proofs are considered to be chains of subsequent stages. A *stage of a proof* is a sequence of lines obtained by application of the three generic rules. As such, every proof starts off with the first stage which is an empty sequence. Each time a line is added to the proof by applying one of the inference rules, the proof comes to its next stage, which is the sequence of lines written so far extended with the new line.

**Definition 12.2 (Minimal Dab formula at stage  $s$ )**

A Dab formula  $Dab(\Delta)$  ( $Dab(\Theta)$  is the (classical) disjunction of the abnormalities in a finite subset  $\Theta$  of the set of abnormalities  $\Omega$ ) is a *minimal Dab formula at stage  $s$*  if and only if  $Dab(\Delta)$  is derived on the empty condition at stage  $s$ , and there is no  $\Delta' \subset \Delta$  for which  $Dab(\Delta')$  is derived on the empty condition at stage  $s$ .

**Definition 12.3 (Set of unreliable formulas  $U_s(\Gamma)$  at stage  $s$ )**

The *set of unreliable formulas  $U_s(\Gamma)$  at stage  $s$*  is the union of all  $\Delta$  for which  $Dab(\Delta)$  is a minimal Dab formula at stage  $s$ .

**Definition 12.4 (Marking for the reliability strategy)**

Line  $i$  with condition  $\Theta$  is *marked for the reliability strategy at stage  $s$*  of a proof if and only if  $\Theta \cap U_s(\Gamma) \neq \emptyset$ .

**Definition 12.5 (Marking for the simple strategy)**

Line  $i$  with condition  $\Theta$  is *marked for the simple strategy at stage  $s$*  of a proof, if stage  $s$  contains a line of which  $A \in \Theta$  is the formula and  $\emptyset$  the condition.

**Definition 12.6 (Derivation of a formula at stage  $s$ )**

A formula  $A$  is *derived from  $\Gamma$  at stage  $s$*  of a proof if and only if  $A$  is the formula of a line that is unmarked at stage  $s$ .

**Definition 12.7 (Final derivation of a formula at stage  $s$ )**

A formula  $A$  is *finally derived from  $\Gamma$  at stage  $s$*  of a proof if and only if  $A$  is derived at line  $i$ , line  $i$  is not marked at stage  $s$  and every extension of the proof in which  $i$  is marked may be further extended in such a way that line  $i$  is unmarked.

Using the simple strategy, it is not possible that a marked line becomes unmarked at a later stage of a proof. Therefore, the final criterion reduces for this strategy to the requirement that the line remains unmarked in every extension of the proof.

**Definition 12.8 (Final derivability for  $\mathbf{LA}_s^r$ )**

For all  $\Gamma \subset \mathcal{W}_\Gamma$ :  $\Gamma \vdash_{\mathbf{LA}_s^r} A$  ( $A \in \mathcal{Cn}_{\mathbf{LA}_s^r}(\Gamma)$ ) if and only if  $A$  is finally derived in an  $\mathbf{LA}_s^r$ -proof from  $\Gamma$ .

**Definition 12.9 (Final derivability for  $\mathbf{MLA}_s^s$ )**

For all  $\Gamma \subset \mathcal{W}_\Gamma$ :  $\Gamma \vdash_{\mathbf{MLA}_s^s} A$  ( $A \in \mathcal{Cn}_{\mathbf{MLA}_s^s}(\Gamma)$ ) if and only if  $A$  is finally derived in a  $\mathbf{MLA}_s^s$ -proof from  $\Gamma$ .

**12.A.2 Semantics**

The semantics of an adaptive logic is obtained by a selection on the models of the lower limit logic. For a more elaborate discussion of the following definitions, the reader is referred to the original articles and the aforementioned theoretical overviews of adaptive logics.

**Definition 12.10**

A  $\mathbf{CL}$ -model  $M$  of the premise set  $\Gamma$  is *reliable* if and only if  $\{A \in \Omega \mid M \models A\} \subseteq \Delta_1 \cup \Delta_2 \cup \dots$  with  $\{Dab(\Delta_1), Dab(\Delta_2), \dots\}$  the set of minimal Dab-consequences of  $\Gamma$ .

**Definition 12.11**

A  $\mathbf{D}$ -model  $M$  of the premise set  $\Gamma$  is *simply all right* if and only if  $\{A \in \Omega \mid M \models A\} = \{A \in \Omega \mid \Gamma \vdash_{\mathbf{D}} A\}$ .

**Definition 12.12 (Semantic consequence of  $\mathbf{LA}_s^r$ )**

For all  $\Gamma \subset \mathcal{W}_\Gamma$ :  $\Gamma \models_{\mathbf{LA}_s^r} A$  if and only if  $A$  is verified by all *reliable* models of  $\Gamma$ .

**Definition 12.13 (Semantic consequence of  $\mathbf{MLA}_s^s$ )**

For all  $\Gamma \subset \mathcal{W}_\Gamma$ :  $\Gamma \models_{\mathbf{MLA}_s^s} A$  if and only if  $A$  is verified by all *simply all right* models of  $\Gamma$ .

The fact that these two logics are in a standard form warrants that the following theorems hold.

**Theorem 12.1 Soundness and completeness of  $\mathbf{LA}_s^r$ )**

$\Gamma \vdash_{\mathbf{LA}_s^r} A$  if and only if  $\Gamma \models_{\mathbf{LA}_s^r} A$ .

**Theorem 12.2 (Soundness and completeness of  $\mathbf{MLA}_s^s$ )**

$\Gamma \vdash_{\mathbf{MLA}_s^s} A$  if and only if  $\Gamma \models_{\mathbf{MLA}_s^s} A$ .

# 13. Abductive Reasoning in Dynamic Epistemic Logic

Angel Nepomuceno–Fernández, Fernando Soler–Toscano, Fernando R. Velázquez–Quesada

This chapter proposes a study of abductive reasoning addressing it as an epistemic process that involves both an agent's information and the actions that modify this information. More precisely, this proposal presents and discusses definitions of an abductive problem and an abductive solution in terms of an agent's information (her knowledge and beliefs) and the involved epistemic actions (observation and belief revision). The discussion is then formalized with tools from dynamic epistemic logic; under such framework, the properties of the given definitions are studied, an epistemic action representing the application of an abductive step is introduced, and an illustrative example is provided. A number of the most interesting properties of abductive reasoning (those highlighted by Peirce) are shown to be better modeled within this approach.

Within logic, abductive reasoning has been studied mainly from a purely syntactic perspective. Definitions of an abductive problem and its solution(s) are given in terms of a theory and a formula, and therefore most of the formal logical work on the subject has focused on:

1. Discussing what a theory and a formula should satisfy in order to constitute an abductive problem, and what a formula should satisfy in order to be an abductive solution [13.1]; see also Chap. 10
2. Proposing algorithms to find abductive solutions [13.2–6]
3. Analyzing the structural properties of abductive consequence relations [13.7–9].

In all these studies, which follow the so-called Aliseda–Kakas/Kowalski–Magnani/Meheus (AKM)-schema of abduction Chap. 10, explanationism and consequentialism are considered, but the epistemic character of abductive reasoning seems to have been

pushed into the background. Such character is considered crucial in this chapter, as it will be discussed.

This chapter's main proposal is an *epistemic and dynamic* approach to abductive reasoning. The proposal is close to the ideas of [13.10–13] in that it stresses the key role that agents play within the abductive reasoning scenario; after all, at the heart, abduction deals with agents and their (individual or collective) information. In this sense, this collaboration is closer to the Gabbay–Woods (GW)-schema [13.14, 15], see also Chap. 14, which is based on the concept of *ignorance problem* that arises when a cognitive agent has a cognitive target that cannot be attained from what she currently knows, and thus highlights the distinctive epistemic feature of abduction that is key to this chapter's considerations. Even so, this presentation goes one step further, as it fully adopts a dynamic perspective by making explicit the actions involved in the abductive process; after all, abduction studies the way agents react epistemically (as individuals or groupwise) to new observations.

More precisely, this proposal argues (Sect. 13.2) that abductive reasoning can be better understood as a *process* that involves *an agent's information*. To this end, it presents definitions of an abductive problem and an abductive solution in terms of an agent's knowledge and her beliefs as well as a *subjective* criteria for selecting *the agent's* best explanation, and outlines a policy through which the chosen abductive solution can be integrated into the agent's information. Then, the discussed ideas and definitions are formalized using tools from *dynamic epistemic logic* (DEL). This choice is not accidental: classical epistemic logic (EL [13.16, 17]) with its possible worlds semantic model is a powerful framework that allows to represent an agent's knowledge and beliefs not only about propositional facts but also about her own information. Its dynamic extension, DEL [13.18, 19], allows the representation of diverse epistemic actions (as diverse forms of announcements and different policies for belief revision) that make such

information change. Section 13.3 introduces the needed tools, and then the ideas and definitions discussed in Sect. 13.2 are formalized in Sects. 13.4, 13.5, 13.6, and 13.7. The chapter closes with a brief exploration (Sect. 13.8) of the epistemic and dynamic aspects of abductive reasoning that are brought to light when non-ideal agents are considered.

*Abductive reasoning* The concept of abductive reasoning has been discussed in various fields, and this has led to different ideas of what abduction should consist of (see [13.20], among others). For example, while certain authors claim that there is an abductive problem only when neither the observed  $\chi$  nor its negation follows from a theory [13.2], others say that there is also an abductive problem when, though  $\chi$  does not follow, its negation does [13.1], a situation that has been typically called a belief revision problem. There are also several opinions of what an abductive solution is. Most of the work on strategies for finding abductive solutions focuses on formulas that are already part of the system (the aforementioned [13.2–6]), while some others take a broader view, allowing not only changes in the underlying logical consequence relation [13.21] but also the creation and modification of concepts [13.22].

The present proposal focuses on a simple account: Abductive reasoning will be understood as a reasoning process that goes from a single unjustified fact to its abductive explanations, where an explanation is a formula of the system that satisfies certain properties. Still, similar epistemic and dynamic approaches can be made to other interpretations of abduction, as those that involve the creation of new concepts or changes in awareness [13.23, 24].

*Abductive reasoning in dynamic epistemic logic* This contribution is a revised version of a proposal whose different parts have been presented in diverse venues. While Sects. 13.2, 13.4, and 13.6 are based on [13.25], Sects. 13.5 and 13.7 are based on [13.26] and Sect. 13.8 is based on [13.27].

## 13.1 Classical Abduction

After Peirce's formulation of abductive reasoning (see [13.28] and Chap. 10), he immediately adds [13.29, p. 231] that:

“[The abductive solution] cannot be abductively inferred, or if you prefer the expression, cannot be abductively conjectured, until its entire content is already present in the premises, *If [the abductive solution] were true, [the abductive problem] would be a matter of course.*”

According to these ideas, abduction is a process that is triggered when a surprising fact is observed by an epistemic agent. Although the process returns an explicative hypothesis, the genuine result of an abductive inference is the plausibility of such hypothesis. The truth of the obtained hypothesis is thereby conjectured as plausible, which makes abduction an inferential process of a nonmonotonic character whose conclusion is rather a provisional proposal that could be revised in the light of new information.

When formalized within logical frameworks, the key concepts in abductive reasoning have traditionally taken the following form (Chap. 10). First, it is said that an abductive problem arises when there is a formula that does not follow from the current theory.

### Definition 13.1 Abductive problem

Let  $\Phi$  and  $\chi$  be a theory and a formula, respectively, in some language  $\mathcal{L}$ . Let  $\vdash$  be a consequence relation on  $\mathcal{L}$ :

- The pair  $(\Phi, \chi)$  constitutes a (*novel*) *abductive problem* when neither  $\chi$  nor  $\neg\chi$  are consequences of  $\Phi$ , that is, when

$$\Phi \not\vdash \chi \quad \text{and} \quad \Phi \not\vdash \neg\chi.$$

- The pair  $(\Phi, \chi)$  constitutes an *anomalous abductive problem* when, though  $\chi$  is not a consequence of  $\Phi$ ,  $\neg\chi$  is, that is, when

$$\Phi \not\vdash \chi \quad \text{and} \quad \Phi \vdash \neg\chi.$$

It is typically assumed that the theory  $\Phi$  is a set of formulas closed under logical consequence, and that  $\vdash$  is a truth-preserving consequence relation.

Consider a novel abductive problem. The observation of a  $\chi$  about which the theory  $\Phi$  does not have any opinion shows that  $\Phi$  is incomplete. Further information that completes  $\Phi$  making  $\chi$  a consequence of it solves the problem, as now the theory is strong enough to *explain*  $\chi$ . Consider now an anomalous abductive problem. The observation of a  $\chi$  whose negation is entailed by the theory shows that the theory contains a mistake. Now two steps are needed. First, perform a *theory revision* that stops  $\neg\chi$  from being a consequence of  $\Phi$ ; this turns the anomalous problem into a novel one, and now the search for further information that completes the theory, making  $\chi$  a consequence of it, can be performed. Here are the formal definitions.

### Definition 13.2 Abductive solution

- Given a *novel* abductive problem  $(\Phi, \chi)$ , the formula  $\eta$  is said to be an *abductive solution* when

$$\Phi \cup \{\eta\} \vdash \chi.$$

- Given an *anomalous* abductive problem  $(\Phi, \chi)$ , the formula  $\eta$  is an *abductive solution* when it is possible to perform a theory revision to get a *novel* problem  $(\Phi', \chi)$  for which  $\eta$  is a solution.

This definition of an abductive solution is often considered as too weak:  $\eta$  can take many trivial forms, as anything that contradicts  $\Phi$  (then everything, including  $\chi$ , follows from  $\Phi \cup \{\eta\}$ ) and even  $\chi$  itself (clearly,  $\Phi \cup \{\chi\} \vdash \chi$ ). Further conditions can be imposed in order to define more satisfactory solutions; here are some of them [13.1] (Chap. 10).

### Definition 13.3 Classification of abductive solutions

Let  $(\Phi, \chi)$  be an abductive problem. An abductive solution  $\eta$  is

consistent	iff	$\Phi, \eta \not\vdash \perp$
explanatory	iff	$\eta \not\vdash \chi$
minimal	iff	for every other solution $\zeta$ , $\eta \vdash \zeta$ implies $\zeta \vdash \eta$

The *consistency* requirement discards solutions that are inconsistent with the theory, something a reasonable explanation should not do. In a similar way, the *explanatory* requirement discards those explanations that would justify the problem by themselves, since it is preferred that the explanation only complements the current theory. Finally, the *minimality* requirement works as Occam's razor, looking for the simplest explanation: A solution is minimal when it is in fact logically equivalent to any other solution it implies. For further details on these definitions, the reader is referred to Chap. 10.

## 13.2 A Dynamic Epistemic Perspective

The present contribution proposes an approach to abductive reasoning from an epistemic and dynamic perspective. Instead of understanding abductive reasoning as a process that *modifies a theory* whenever *there is a formula that is not entailed by the theory under some particular consequence relation*, as the traditional definition of an abductive problem does, the proposed approach understands abductive reasoning as a process that *changes an agent's information* whenever, *due to some epistemic action, the agent has come to know or believe a fact that she could not have predicted otherwise*.

Such an epistemic and dynamic approach is natural. First, abduction, as other forms of nonmonotonic reasoning (e.g., belief revision, default reasoning), is classified as form of a common-sense reasoning rather than a mathematical one, and most of its classic examples involve *real* agents and their information (e.g., Mary observes that the light does not go on; Karen observes that the lawn is wet; Holmes observes that Mr. Wilson's right cuff is very shiny). Thus, even though abductive reasoning has been linked to scientific theories (as interpreted in philosophy of science), in its most basic forms it deals with an agent's (or a set of agents') information. Second, abductive reasoning implies a change in the agent's information (Mary assumes that the electricity supply has failed; Karen assumes it has rained; Holmes assumes Mr. Wilson has done a lot of writing lately), and thus it is essential to distinguish the different stages during the abductive process: the stage before the observation, the stage after the observation has raised the abductive problem (and thus the one when the agent starts looking for an explanation), and the stage in which the explanation that has been chosen is incorporated into the agent's information. This describes, of course, a dynamic process.

There is a final issue that is crucial for an epistemic approach to abductive reasoning. From this contribution's perspective, abductive reasoning involves not one epistemic attitude (as is typically assumed in most approaches) but rather (at least) two: that of those propositions about which the agent has full certainty; and that of those propositions that she considers very likely but she still cannot be certain about. The reason is that an agent typically tries to explain facts she has come to *know* due to some observation, but the chosen solution, being a *hypothesis* that might be dropped in the light of further observations, should not attain the full certainty status. The use of different epistemic notions also gives more flexibility to deal with a wider variety of abductive problems and abductive solutions,

making the analysis closer, from the authors' perspective, to Peirce's original formulation.

All in all, the abductive process can be studied by asking four questions:

1. What is an abductive problem?
2. What is an abductive solution?
3. How is the *best* solution(s) selected?
4. How does the agent assimilate the chosen solution(s)?

In the following, answers to these questions are discussed.

### 13.2.1 What Is an Abductive Problem?

There are, from an epistemic and dynamic perspective, two important concepts in the definition of an abductive problem. The first is what a formula  $\chi$  should satisfy in order to become an abductive problem. The second is the action that triggers the abductive problem, that is, the action that turns a formula  $\chi$  into an abductive problem.

For the former concept, a formula is typically said to be an abductive problem when it is surprising. There are different ways to define *a surprising observation of  $\chi$*  (some of them in a DEL setting [13.30]). Most of the approaches that define this notion in terms of what the agent knows (believes) understand a surprise as something that does not follow from such knowledge (beliefs). In other words, it is said that a given  $\chi$  is surprising whenever the agent does not know (believe) it, or, more radically, whenever the agent knows (believes)  $\neg\chi$ .

Now, note how in the context of abductive reasoning it is not reasonable to define a surprising observation in terms of what the agent knows (believes) *after such epistemic action*. The reason is that, after observing  $\chi$ , an agent would typically come to know (believe) it. Thus, if the mentioned definitions are followed focusing on the agent's information after the observation, no  $\chi$  would be surprising and there would be no abductive problems at all! It is more reasonable to define a surprising observation not in terms of what the agent knows (believes) as a result of the observation, but rather in terms of what she knew (believed) *before* it. More precisely, it will be said that a known (believed)  $\chi$  is surprising with respect to an agent whenever she could not have come to know (believe) it.

Of course, the meaning of the sentence *the agent could have come to know (believe)  $\chi$*  still needs to be clarified. This is a crucial notion, as it will indicate not only when a formula  $\chi$  is an abductive problem (the

agent could not have come to know (believe)  $\chi$ ), but also what a formula  $\eta$  needs in order to be an abductive solution (with the help of  $\eta$ , the agent could have come to know (believe)  $\chi$ ). Here the ability to come to know (believe) a given formula will be understood as the ability to infer it, and the simplest way to state this idea is the following: An agent could have come to know (believe)  $\chi$  if and only if there is an implication  $\eta \rightarrow \chi$  such that the agent knew both the implication and its antecedent. Other formulations that do not use the material implication  $\rightarrow$  are also possible (e.g., the agent may know both  $\neg\eta \vee \chi$  and  $\eta$  to come to know  $\chi$ ), but in the semantic model this contribution uses (Sect. 13.3), they are logically equivalent to the proposed one.

With respect to the action that triggers an abductive problem  $\chi$ , this action is typically assumed to be the observation of  $\chi$  itself. Here a more general idea will be considered: The action that triggers the abductive problem will be simply the observation of *some* formula  $\psi$ . Thus, though  $\psi$  should indeed be related to  $\chi$  (after all,  $\chi$  is an abductive problem because the agent comes to know  $\chi$  by observing  $\psi$ ), the agent will not be restricted to look for explanations of the formula that has been observed: She will also be able to look for explanations of *any* formula  $\chi$  she has come to know (believe) through the observation but could not have come to know (believe) by herself before. Note how other actions are also reasonable, as the agent might want to explain a belief she attained after a belief revision (Sect. 13.4.1).

Here is the intuitive definition of an abductive problem in full detail:

“Let  $s_1$  represent the epistemic state of an agent, and let  $s_2$  be the epistemic state that results from the agent observing some given  $\psi$ . A formula  $\chi$  constitutes an abductive problem for the agent at  $s_2$  whenever  $\chi$  is known and there is no implication  $\eta \rightarrow \chi$  such that the agent knew both the implication and its antecedent at  $s_1$ .”

It is important to emphasize how an abductive problem has been defined *with respect to an agent and stage* (i.e., *some epistemic situation*). Thus, whether a formula is an abductive problem depends on the formula *but also on the information* of that given agent at that given stage. The definition is given purely in terms of the agent’s knowledge, but it can also be given purely in terms of her beliefs, or even in terms of both, as it will be seen later.

The presented definition could seem very restrictive. Even if the reader agrees with the basic idea ( $\chi$  is an abductive problem for a given agent whenever she knows  $\chi$  but she could not have come to know (believe) it), she/he does not need to agree with the way key parts of it are understood. Nevertheless, as stated

in the introduction, this contribution does not intend on providing a full account of the many different understandings of what abductive reasoning does. Rather, its aim is to show how an epistemic and dynamic perspective can shed a new light on the way abductive reasoning is understood, even when assuming its simplest interpretation.

### 13.2.2 What Is an Abductive Solution?

In this proposal’s setting, an abductive solution for a given  $\chi$  will be defined in terms of what the agent could have been able to infer *before* the observation that raised the problem. As mentioned before, it will be said that  $\eta$  is a solution for the abductive problem  $\chi$  when the agent could have come to know (believe)  $\chi$  with the help of  $\eta$ . In this simple case in which the ability to come to know (believe) a given formula is understood as the ability to infer the formula by means of a simple modus ponens step, the following definition is obtained:

“A formula  $\eta$  constitutes an abductive solution for the abductive problem  $\chi$  at some given state  $s_2$  if the agent knew  $\eta \rightarrow \chi$  at the previous state  $s_1$ . Thus, the set of solutions for an abductive problem  $\chi$  is the set of antecedents of implications which have  $\chi$  as consequent and were known before the observation that triggered the abductive problem.”

Note how abductive solutions are looked for not when the agent has come to know (believe)  $\chi$ , but rather at the stage immediately before it. Thus,  $\eta$  is a solution when, had it been known (believed) before, would have allowed the agent to come to know (believe) (to predict/expect)  $\chi$ .

### 13.2.3 How is the Best Explanation Selected?

Although there are several notions of explanation for modeling the behavior of why-questions in scientific contexts (e.g., the law model, the statistical relevance model, or the genetic model), most of these consider a consequence (entailment) relation; *explanation* and *consequence* go typically hand in hand. However, finding suitable and reasonable criteria for selecting *the best* explanation has constituted a fundamental problem in abductive reasoning [13.31–33], and in fact many authors consider it to be the heart of the subject. Many approaches are based on logical criteria, but beyond requisites to avoid triviality and certain restrictions to the syntactic form, the definition of suitable criteria is still an open problem. Some approaches have suggested the use of *contextual aspects*, such as an ordering among formulas or among full theories. In particular,

for the latter, a typical option is the use of *preferential models* based on qualitative properties that are beyond the pure causal or deductive relationship between the abductive problem and its abductive solution. However, these preference criteria are seen as an external device which works on top of the deductive part of the explanatory mechanism, and as such they have been criticized because they seem to fall outside the logical framework.

Approaching abductive reasoning from an epistemic point of view provides a different perspective. It has been discussed already how the explanation an agent will choose for a given abductive problem does not depend on how the problematic formula could have been predicted, but rather on how *the agent* could have predicted it. In general, different agents have different information, and thus they might disagree in what each one calls *the best explanation* (and even in what each one calls *explanation* at all). This suggests that, instead of looking for criteria to select *the best explanation*, the goal should be a criterion to select *the agent's best explanation*. Now, once the agent has a set of formulas that explain the abductive problem from her point of view, how can she choose the best? This proposal's answer makes use of the fact that the considered agents have not only knowledge but also beliefs: Among all these explanations, some are more plausible than others *from her point of view*. These are precisely the ones the agent will choose when trying to explain a surprising observation: The best explanation can be defined in terms of a preference ordering among the agent's epistemic possibilities. It could be argued that this criterion is not *logical in the classic sense* because it is not based exclusively on the *deductive* relationship between the observed fact and different ways in which it could have been derived. Nevertheless, it is *logical in a broader sense* since it does depend on the agent's information: her knowledge and, crucially, her beliefs.

### 13.2.4 How is the Best Explanation Incorporated Into the Agent's Information?

Once the best explanation has been selected, it has to be incorporated into the agent's information. One of

the features that distinguishes abductive reasoning from deductive reasoning is its nonmonotonic nature: The chosen explanation does not need to be true, and in fact can be discarded in the light of further information. This indicates that an abductive solution cannot be assimilated as knowledge. Nevertheless, an epistemic agent has not only this hard form of information which is not subjected to modifications; she also has a soft form that can be revised as many times as it is needed: *beliefs*. Therefore, once the best abductive solution  $\eta$  has been chosen, the agent's information can be changed, leading her to *believe* that  $\eta$  is the case.

### 13.2.5 Abduction in a Picture

It is interesting to notice how the stated definitions of abductive problem and abductive solution rely on some form of *counterfactivity*, as in Peirce's original formulation (and also as discussed in [13.15]): A given  $\eta$  is a solution of a problem  $\chi$  if it would have allowed the agent to predict  $\chi$ . This can be better described with the following diagram.

The upper path is the real one: By means of an observation, the agent goes from the epistemic state  $s_1$  to the epistemic state  $s_2$  in which she knows  $\chi$ , and by accepting the abductive solution  $\eta$  she goes further to  $s_3$ . The existence of this path, the fact that  $\chi$  is an abductive problem and  $\eta$  is one of its abductive solutions, indicates that, at  $s_1$ , the lower path would have been possible: Incorporating  $\eta$  to the agent's information would have taken her to an epistemic state  $s'_2$  where she would have been able to infer  $\chi$ . Of course,  $s'_3$  is not identical to  $s_3$ : In  $s'_3$  both  $\eta$  and  $\chi$  are *equally reliable* because the second is inferred from the first, but in  $s_3$ ,  $\eta$  is less reliable than  $\chi$  since although the second is obtained via an observation, the first is just a hypothesis that is subject to revision in the light of further information.

### 13.3 Representing Knowledge and Beliefs

As mentioned, the most natural framework for formalizing the discussed ideas is that of DEL, the *dynamic extension of epistemic logic*. In particular, with the *plausibility models* of [13.34] it is possible to represent an agent’s knowledge and beliefs as well as acts of observation and belief revision, all of which are crucial to the stated understanding of the abductive process. This section introduces these needed tools; the discussed definitions will be formalized in Sect. 13.4.

#### 13.3.1 Language and Models

##### Definition 13.4 Language

Given a set of atomic propositions  $P$ , formulas  $\varphi$  of the language  $\mathcal{L}$  are given by

$$\varphi ::= p \mid \neg\varphi \mid \varphi \vee \varphi \mid \langle \leq \rangle \varphi \mid \langle \sim \rangle \varphi,$$

where  $p \in P$ . Formulas of the form  $\langle \leq \rangle \varphi$  are read as *there is a world at least as plausible (as the current one) where  $\varphi$  holds*, and those of the form  $\langle \sim \rangle \varphi$  are read as *there is a world epistemically indistinguishable (from the current one) where  $\varphi$  holds*. Other Boolean connectives ( $\wedge, \rightarrow, \leftrightarrow$ ) as well as the universal modalities,  $[\leq]$  and  $[\sim]$ , are defined as usual ( $[\leq]\varphi := \neg\langle \leq \rangle\neg\varphi$  and  $[\sim]\varphi := \neg\langle \sim \rangle\neg\varphi$  for the latter).

The modalities  $\langle \leq \rangle$  and  $\langle \sim \rangle$ , respectively, make it possible to define the notions of belief and knowledge within  $\mathcal{L}$ . The language’s semantic model, a *plausibility model*, is defined as follows.

##### Definition 13.5 Plausibility model

Let  $P$  be a set of atomic propositions. A *plausibility model* is a tuple  $M = \langle W, \leq, V \rangle$ , where:

1.  $W$  is a nonempty set of *possible worlds*
2.  $\leq \subseteq (W \times W)$  is a locally connected and conversely well-founded preorder, the agent’s *plausibility relation*, representing the plausibility order of the worlds from her point of view ( $w \leq u$  is read as *u is at least as plausible as w*)
3.  $V : W \rightarrow \wp(P)$  is an *atomic valuation function*, indicating the atoms in  $P$  that are true at each possible world.

A *pointed plausibility model*  $(M, w)$  is a plausibility model with a distinguished world  $w \in W$ .

Before proceeding, recall that a relation  $R \subseteq (W \times W)$  is *locally connected* when every two elements that are  $R$ -comparable to a third are also  $R$ -comparable. It is *conversely well-founded* when there is no infinite  $\bar{R}$ -

ascending chain of elements in  $W$ , where  $\bar{R}$ , the *strict* version of  $R$ , is defined as  $\bar{R}wu$  iff  $Rwu$  and not  $Ruw$ . Finally, it is a *preorder* when it is reflexive and transitive.

The key idea behind plausibility models is that an agent’s beliefs can be defined as what is true in the *most plausible worlds from the agent’s perspective*, and modalities for the plausibility relation  $\leq$  will allow this definition to be formed. In order to define the agent’s knowledge, the approach is to assume that two worlds are epistemically indistinguishable for the agent if and only if she considers one of them at least as plausible as the other (if and only if they are comparable via  $\leq$ ). The *epistemic indistinguishability relation*  $\sim$  can therefore be defined as the union of  $\leq$  and its converse, that is, as  $\sim := \leq \cup \geq$ . Thus,  $\sim$  is the symmetric closure of  $\leq$  and hence  $\leq \subseteq \sim$ . Moreover, since  $\leq$  is reflexive and transitive,  $\sim$  is an *equivalence* relation. This epistemic indistinguishability relation  $\sim$  should not be confused with the *equal plausibility* relation, denoted by  $\simeq$ , and defined as the *intersection* of  $\leq$  and  $\geq$ , that is,  $\simeq := \leq \cap \geq$ . For further details and discussion on these models, their requirements and their properties, the reader is referred to [13.34, 35].

##### Example 13.1

The following diagram represents a plausibility model  $M$  based on the atomic propositions  $P := \{l, e, b\}$ . Circles represent possible worlds (named  $w_1$  up to  $w_5$ ), and each one of them includes exactly the atomic propositions that are true at that world (e.g., at  $w_2$ , the atomic propositions  $l$  and  $e$  are true, but  $b$  is false). Arrows represent the plausibility relation, with transitive arcs omitted (so  $w_4 \leq w_5 \leq w_2 \leq w_1 \leq w_3$ , but also  $w_4 \leq w_2, w_4 \leq w_1, w_4 \leq w_3$  and so on). Moreover,  $\sim$  is then the full Cartesian product, that is, for every worlds  $u$  and  $v$  in the model,  $u \sim v$ .

For the semantic interpretation, the two modalities  $\langle \leq \rangle$  and  $\langle \sim \rangle$  are interpreted with the help of their respective relations in the standard modal way.

##### Definition 13.6 Semantic interpretation

Let  $(M, w)$  be a pointed plausibility model with  $M = \langle W, \leq, V \rangle$ . Atomic propositions and Boolean operators

are interpreted as usual. For the remaining cases,

$$(M, w) \Vdash \langle \leq \rangle \varphi \text{ iff } \exists u \in W \text{ s.t. } w \leq u \text{ \& } (M, u) \Vdash \varphi$$

$$(M, w) \Vdash \langle \sim \rangle \varphi \text{ iff } \exists u \in W \text{ s.t. } w \sim u \text{ \& } (M, u) \Vdash \varphi .$$

### Defining Knowledge and Beliefs

The notion of knowledge in plausibility models is defined by means of the epistemic indistinguishability relation in the standard way: The agent knows  $\varphi$  at some world  $w$  if and only if  $\varphi$  is the case in every world she considers to be epistemically possible from  $w$ . (This makes knowledge a very strong notion, corresponding to an “absolutely unrevisable belief” [13.34]). The modality  $[\sim]$  can be used to this end. For the notion of beliefs, the idea is, as stated before, that the agent believes  $\varphi$  at a given  $w$  if and only if  $\varphi$  is the case in the most plausible worlds from  $w$ . Thanks to the properties of the plausibility relation (a locally connected and conversely well-founded preorder),  $\varphi$  is true in the most plausible (i. e., the  $\leq$ -maximal) worlds from  $w$  if and only if, in accordance with the plausibility order, from some moment onward there are only  $\varphi$ -worlds (see [13.34, 36, 37] for the technical details). The modalities  $\langle \leq \rangle$  and  $[\leq]$  can be used to this end. Summarizing,

$$\begin{array}{ll} \text{The agent knows } \varphi & K\varphi := [\sim]\varphi \\ \text{The agent believes } \varphi & B\varphi := \langle \leq \rangle [\leq]\varphi \end{array}$$

Observe how, since  $\leq \subseteq \sim$ , the formula  $K\varphi \rightarrow B\varphi$  is valid (but its converse is not).

The dual of these notions, epistemic possibility and most likely possibility, can be defined as the correspondent modal duals

$$\hat{K}\varphi := \langle \sim \rangle \varphi \quad \hat{B}\varphi := [\leq] \langle \leq \rangle \varphi .$$

### Example 13.2

Consider the plausibility model  $M$  of Example 13.1, and take  $w_2$  as the evaluation point. Since  $w_2 \sim u$  holds for every possible world  $u$  in the model, every world is epistemically possible from  $w_2$ 's perspective. But every world in the model satisfies  $b \rightarrow l$  (the implication is true at  $w_2, w_1$ , and  $w_3$  because the antecedent  $b$  is false, and true at  $w_4$  and  $w_5$  because the consequent  $l$  is true), so  $[\sim](b \rightarrow l)$ , that is,  $K(b \rightarrow l)$  is true at  $w_2$ : *The agent knows  $b \rightarrow l$  at  $w_2$ .* On the other hand,  $\neg l$  is not true in every world, but it is true in  $w_3$ , the most plausible one from  $w_2$ 's perspective, so  $\langle \leq \rangle [\leq] \neg l$ , that is,  $B\neg l$ , is true at  $w_2$ : *The agent believes  $\neg l$  at  $w_2$ .* Moreover, observe how  $b$  is neither known (it is not true in every

epistemically indistinguishable world) nor believed (it is not true in the most plausible worlds) at  $w_2$ . Still, it is true in some epistemic possibilities from  $w_2$  (e.g.,  $w_5$ ); hence,  $\langle \sim \rangle b$  (i. e.,  $\hat{K}b$ ) holds at  $w_2$ : *At that world, the agent considers  $b$  possible.*

A more detailed description of this framework, a number of the epistemic notions that can be defined within it, its technical details and its axiom system can be found in [13.34].

Following the DEL idea, actions that modify an agent's information can be represented as operations that transform the underlying semantic model. In the rest of this section, operations that can be applied over plausibility models will be recalled, and extensions of the language that allow to describe the changes such operations bring about will be provided. These will be used in Sect. 13.4 to represent and describe abductive reasoning.

## 13.3.2 Operations on Models

### Update, Also Known as Observation

The most natural operation over Kripke-like semantic models is that of *update*. This operation reduces the domain of the model, and is typically given in terms of the formula the worlds should satisfy in order to survive the operation.

#### Definition 13.7 Update operation

Let the tuple  $M = \langle W, \leq, V \rangle$  be a plausibility model and let  $\psi$  be a formula in  $\mathcal{L}$ . The *update* operation yields the plausibility model  $M_{\psi!} = \langle W', \leq', V' \rangle$  where  $W' := \{w \in W \mid (M, w) \Vdash \psi\}$ ,  $\leq' := \leq \cap (W' \times W')$  and, for every  $w \in W'$ ,  $V'(w) := V(w)$ .

This operation reduces the domain of the model (preserving only those worlds that satisfy the given  $\psi$ ) and restricts the plausibility relation and the atomic valuation function accordingly. Since a submodel is obtained, the operation preserves the (universal) properties of the plausibility relation and hence it preserves plausibility models: If  $M$  is a plausibility model, then so is  $M_{\psi!}$ .

In order to describe the effects of an update within the language, existential modalities of the form  $\langle \psi! \rangle$  are used, for every formula  $\psi$ . Here is their semantic interpretation

$$(M, w) \Vdash \langle \psi! \rangle \varphi \text{ iff } (M, w) \Vdash \psi$$

$$\text{and } (M_{\psi!}, w) \Vdash \varphi .$$

In words, an update formula  $\langle \psi! \rangle \varphi$  holds at  $(M, w)$  if and only if  $\psi$  is the case (i. e., the evaluation point

will survive the operation) and, after the update,  $\varphi$  is the case. The universal modality  $[\psi!]$  is defined as the modal dual of  $\langle\psi!\rangle$ , that is,  $[\psi!]\varphi := \neg\langle\psi!\rangle\neg\varphi$ .

In addition to being the most natural operation over Kripke-like models, an update also has a straightforward epistemic interpretation: it works as an act of a public announcement [13.38, 39] or, as it will be called here, an act of *observation*. When the agent observes a given  $\psi$ , she can discard those epistemically possible worlds that fail to satisfy this formula, thereby obtaining a model with only worlds that satisfied  $\psi$  before the operation. More details on this operation and its modalities (including an axiom system) can be found in the papers [13.38, 39] or in the textbooks [13.18, 19].

### Example 13.3

Consider the model  $M$  in Example 13.1 again. Suppose the agent observes  $l$ ; this can be modeled as an update with  $l$ , which yields the following model  $M_l$

The most plausible world in  $M$  has been discarded in  $M_l$ . As explained in Example 13.2, the agent believes  $\neg l$  in  $M$ , but after the observation this is not the case anymore:  $\neg l$  does not hold in the unique most plausible world of the new model  $M_l$ . In fact,  $\neg l$  does not hold in any epistemically possible world, and thus after the observation the agent knows  $l$ ; in symbols

$$(M_l, w_2) \models Kl, \text{ that is, } (M, w_2) \models [l!]Kl.$$

### Upgrade, Also Known as Belief Revision

Another natural operation over plausibility-like models is the rearrangement of worlds within an epistemic partition. Of course, there are several ways in which a new order can be defined. The following rearrangement, taken from [13.40], is one of the many possibilities.

#### Definition 13.8 Upgrade operation

Let the tuple  $M = \langle W, \leq, V \rangle$  be a plausibility model and let  $\psi$  be a formula in  $\mathcal{L}$ . The *upgrade* operation produces the plausibility model  $M_{\psi\uparrow} = \langle W, \leq', V \rangle$ , which differs from  $M$  just in the plausibility order, given now by

$$\leq' := \{(w, u) \mid w \leq u \text{ and } (M, u) \models \psi\} \cup \{(w, u) \mid w \leq u \text{ and } (M, w) \models \neg\psi\}$$

$$\{(w, u) \mid w \sim u, (M, w) \models \neg\psi \text{ and } (M, u) \models \psi\}.$$

The new plausibility relation states that after an upgrade with  $\psi$ , all  $\psi$ -worlds become more plausible than all  $\neg\psi$ -worlds, and within the two zones the old ordering remains [13.40]. More precisely, a world  $u$  will be at least as plausible as a world  $w$ ,  $w \leq' u$ , if and only if they already are of that order and  $u$  satisfies  $\psi$ , or they already are of that order and  $w$  satisfies  $\neg\psi$ , or they are comparable,  $w$  satisfies  $\neg\psi$  and  $u$  satisfies  $\psi$ . This operation preserves the properties of the plausibility relation and hence preserves plausibility models, as shown in [13.35].

In order to describe effects of this operation within the language, an existential modality  $\langle\psi\uparrow\rangle$  is introduced for every formula  $\psi$ ,

$$(M, w) \models \langle\psi\uparrow\rangle\varphi \text{ iff } (M_{\psi\uparrow, w}) \models \varphi.$$

In words, an upgrade formula  $\langle\psi\uparrow\rangle\varphi$  holds at  $(M, w)$  if and only if  $\varphi$  is the case after an upgrade with  $\psi$ . The universal modality  $[\psi\uparrow]$  is defined as the modal dual of  $\langle\psi\uparrow\rangle$ , as in the update case.

This operation also has a very natural epistemic interpretation. The plausibility relation defines the agent's beliefs, and hence any changes in the relation can be interpreted as changes in the agent's beliefs [13.34, 40, 41]. In particular, an act of *revising* beliefs after a reliable and yet fallible source has suggested  $\psi$  can be represented by an operation that puts  $\psi$ -worlds at the top of the plausibility order. Moreover, each one of the different methods to obtain a relation with former  $\psi$ -worlds at the top can be seen as a different policy for revising beliefs. Details on the operation and its modalities (including an axiom system) can be found in the papers [13.34, 40] or in the textbook [13.19].

### Example 13.4

Consider the model  $M_l$  in Example 13.3, that is, the model that results from the agent observing  $l$  at the initial model  $M$  in Example 13.1. Suppose the agent performs a belief revision toward  $b$ ; this can be modeled as an upgrade with  $b$ , which yields the following model  $(M_l)_{b\uparrow}$ :

The ordering of the worlds has changed, making those worlds that satisfy  $b$  ( $w_4$  and  $w_5$ ) more plausible than

those that do not ( $w_2$  and  $w_1$ ), keeping the old ordering with these two zones ( $w_5$  strictly above  $w_4$  and  $w_1$  strictly above  $w_2$ ). In  $M_{!}$  the agent believed  $\neg b \wedge \neg e$ , as such formula was the case in the model's unique most plausible world  $w_1$ , but this is not the case anymore in  $(M_{!})_{b\uparrow}$ : The unique most plausible world,  $w_5$ , satisfies

$b \wedge e$ , and thus the formula is part of the agent's beliefs. In symbols,

$$\begin{aligned} ((M_{!})_{b\uparrow}, w_2) \Vdash B(b \wedge e), \\ \text{that is, } (M_{!}, w_2) \Vdash [! \uparrow]B(b \wedge e). \end{aligned}$$

## 13.4 Abductive Problem and Solution

Given the intuitive definitions discussed and the formal tools introduced, it is now time to formalize the ideas.

### 13.4.1 Abductive Problem

First, the definition of what an abductive problem is.

#### Definition 13.9 Abductive problem

Let  $(M, w)$  be a pointed plausibility model, and consider  $(M_{\psi!}, w)$ , the pointed plausibility model that results from observing a given  $\psi$  at  $(M, w)$ .

A formula  $\chi$  is an abductive problem at  $(M_{\psi!}, w)$  if and only if it is known at such stage but it was not known before, that is, if and only if

$$(M_{\psi!}, w) \Vdash K\chi \quad \text{and} \quad (M, w) \Vdash \neg K\chi.$$

Equivalently, a formula  $\chi$  can become an abductive problem at  $(M, w)$  if and only if it is not known at such stage but will be known after observing  $\psi$ , that is, if and only if

$$(M, w) \Vdash \neg K\chi \wedge [\psi!]K\chi.$$

Note again how the definition of an abductive problem is relative to an agent's information at some given stage (the one represented by the pointed model).

There are two points worth emphasizing. First, note again how the definition distinguishes between the formula that becomes the abductive problem,  $\chi$ , and the formula whose observation triggers the abductive problem,  $\psi$ . Although these two formulas are typically understood to be the same ( $\chi$  becomes an abductive problem after being observed), the choice in this contribution is to distinguish between them. One reason for this is technical: Here the idea is that the agent will look for explanations of formulas that she could not have known before the observation but knows afterward. However, stating this as *the agent knows  $\chi$  after observing it* is restrictive in the DEL setting as not every formula satisfies this condition. This is because the underlying EL framework is powerful enough to talk

about the knowledge an agent has not only about facts but also about her own knowledge, and so there are formulas expressing situations such as *it is raining and you do not know it* ( $r \wedge \neg Kr$ ), which can be observed but are not known afterward (now you know that it is raining!). Another reason is, as stated earlier, generality: The described agent will be able to look for explanations not only of the formulas she can observe, but also of those that she can come to know through an observation. Still, this choice does not imply that the observed formula and the one that becomes an abductive problem are unrelated: In order for the agent to know  $\chi$  after observing  $\psi$ , she must have known  $\psi \rightarrow [\psi!] \chi$  before the action. This is nothing but the *reduction axiom* for the knowledge modality in *public announcement logic*

$$[\psi!]K\chi \leftrightarrow (\psi \rightarrow K(\psi \rightarrow [\psi!] \chi)).$$

Second, the requirements Definition 13.9 asks for  $\chi$  to be an abductive problem are not exactly the ones stated in the previous section: The sentence *there is no implication  $\eta \rightarrow \chi$  such that, before  $\chi$  became an abductive problem, the agent knew both the implication and its antecedent* has been replaced by *the agent did not know  $\chi$  before  $\chi$  became an abductive problem*. The reason is that, in DEL, the agent's knowledge and beliefs are closed under logical consequence (still, small variations of the EL framework allows the representation of nonideal agents and their abductive reasoning; see Sect. 13.8), and in such setting the two statements are equivalent: If there is an  $\eta$  such that the agent knew  $\eta \rightarrow \chi$  and  $\eta$  before  $\chi$  became an abductive problem, then clearly she knew  $\chi$  too, and if she knew  $\chi$ , then there was a  $\eta$  such that  $\eta \rightarrow \chi$  and  $\eta$  were both known, namely  $\chi$  itself. In fact, the restatement of the requirement emphasizes that it is the observation of  $\psi$  what causes the agent to know  $\chi$  and hence what creates the abductive problem.

It is worthwhile to highlight how, although the definition of an abductive problem was given in terms of the agent's knowledge, it can also be given in terms of her beliefs: It also makes sense for her to look for explanations of what she has come to believe!

“A formula  $\chi$  is said to be an abductive problem at  $(M_{\psi \uparrow}, w)$  if and only if  $(M_{\psi \uparrow}, w) \Vdash B\chi$  and  $(M, w) \Vdash \neg B\chi$ .”

With this definition, a formula is a problem if it is believed now but was not believe before a belief revision with  $\psi$ . But not only that. The agent can also face abductive problems that combine knowledge and beliefs. For example, she can face an abductive problem with  $\chi$  if she does not know the formula at some stage but believes it after a belief revision with  $\psi$ :

“A formula  $\chi$  is said to be an abductive problem at  $(M_{\psi \uparrow}, w)$  if and only if  $(M_{\psi \uparrow}, w) \Vdash B\chi$  and  $(M, w) \Vdash \neg K\chi$ .”

The stated definition allows to describe several forms of abductive problems, all of which differ in the strength of the attachment of the agent to the problematic  $\chi$  (known, strongly believed, safely believed, believed, etc.) *after* the epistemic action (update, upgrade) and the strength of her attachment to the formula *before* the action.

### 13.4.2 Classifying Problems

As mentioned, some approaches classify an abductive problem  $\chi$  according to whether  $\chi$  or  $\neg\chi$  follows from the theory: If neither  $\chi$  nor  $\neg\chi$  follows, then  $\chi$  is called a *novel* abductive problem; if  $\chi$  does not follow but  $\neg\chi$  does, then  $\chi$  is called an *anomalous* abductive problem. Given the requirement *the agent did not know  $\chi$  before  $\chi$  became an abductive problem* ( $\neg K\chi$ ) in Definition 13.9, one could suggest *the agent knew  $\neg\chi$*  ( $K\neg\chi$ ) as an alternative, but since the definition also asks for  $\chi$  to be known after the observation in order to be an abductive problem, such suggestion turns out to be too strong for propositional formulas: If  $\neg\chi$  is propositional and the agent knows it at some stage, then every epistemic possibility satisfies  $\neg\chi$ . Thus, since no *epistemic* action can change the (propositional) formula's truth value, the only way for the agent to know  $\chi$  afterward is for the action to eliminate every epistemic possibility, making  $K\varphi$  true for *every* formula  $\varphi$  and thus turning the agent inconsistent. But even though it is not possible to classify abductive problems in terms of the knowledge the agent had about the formula before the observation, it is still possible (and more reasonable) to classify them by using weaker notions, such as beliefs. Here is one possibility.

#### Definition 13.10 Expected, novel and anomalous problems

Suppose  $\chi$  is an abductive problem at  $(M_{\psi \uparrow}, w)$ . Then  $\chi$  is said to be:

- An *expected* abductive problem if and only if  $(M, w) \Vdash B\chi$
- An *novel* abductive problem if and only if  $(M, w) \Vdash \neg B\chi \wedge \neg B\neg\chi$
- An *anomalous* abductive problem if and only if  $(M, w) \Vdash B\neg\chi$ .

Many people would not call the first case an abductive problem: The observation is a confirmation rather than a surprise, and thus it does not need to trigger any further epistemic action. Nevertheless, the case shows how this proposal allows for such situations to be considered. In fact, the classification can be refined by considering further attitudes, such as the *safe beliefs* of [13.34] or the *strong beliefs* of [13.42] (both definable in  $\mathcal{L}$ ).

### 13.4.3 Abductive Solutions

An abductive solution is now to be defined. Here is a version that uses only the notion of knowledge.

#### Definition 13.11 Abductive solution

Let  $(M, w)$  be a pointed plausibility model, and consider  $(M_{\psi \uparrow}, w)$ , the pointed plausibility model that results from observing  $\psi$  at  $(M, w)$ .

If at  $(M_{\psi \uparrow}, w)$  the formula  $\chi$  is an abductive problem, then  $\eta$  is an abductive solution if and only if the agent knew that  $\eta$  implied  $\chi$  before the observation, that is, if and only if

$$(M, w) \Vdash K(\eta \rightarrow \chi).$$

Equivalently, if at  $(M, w)$  the formula  $\chi$  can become an abductive problem, then  $\eta$  will be an abductive solution if and only if the agent knows that  $\eta$  implies  $\chi$ , that is, if and only if

$$(M, w) \Vdash K(\eta \rightarrow \chi).$$

Just as in the case of abductive problem, it is also possible to define an abductive solution in terms of weaker notions as beliefs. For example, while a very strict agent would accept  $\eta$  as explanation only when  $\eta \rightarrow \chi$  was known, a less strict agent could accept it when such implication was only believed.

It is worth emphasizing that, in the stated definition, a solution for a problem  $\chi$  (at some  $M_{\psi \uparrow}$ ) is a formula  $\eta$  such that  $\eta \rightarrow \chi$  is known not when the abductive problem has arisen (at  $M_{\psi \uparrow}$ ) but rather at the stage immediately before (at  $M$ ). This is because an explanation is a piece of information that would have allowed the agent to predict the surprising observation. In fact, if

an abductive solution for a problem  $\chi$  were defined as a formula  $\eta$  such that  $\eta \rightarrow \chi$  is known once  $\chi$  is an abductive problem (at  $M_{\psi!}$ ), then every formula  $\varphi$  would be a solution since (at  $M_{\psi!}$ )  $K\chi$  would be the case (because  $\chi$  is an abductive problem) and hence so would be  $K(\varphi \rightarrow \chi)$  for every formula  $\varphi$ .

Observe also how, again in the stated definition, if  $\eta$  is a solution for the abductive problem  $\chi$  (at some  $M_{\psi!}$ ), then  $\eta$  could not be known before the observation that triggered the problem (at  $M$ ). Otherwise, both  $K(\eta \rightarrow \chi)$  and  $K\eta$  would be the case at such stage ( $M$ ) and hence, by the closure under logical consequence of knowledge in EL, so would be  $K\chi$ , contradicting the fact that  $\chi$  is an abductive problem.

#### Proposition 13.1

Let  $\chi$  be an abductive problem and  $\eta$  be one of its abductive solutions, both at  $(M_{\psi!}, w)$ . Then,  $(M, w) \Vdash \neg K\eta$ .

### 13.4.4 Classifying Solutions

It is common in the literature to classify abductive solutions according to their properties (Chap. 10). For example (Definitions 13.2 and 13.3; again, see Chap. 10), given a surprising observation  $\chi$ , an abductive solution  $\eta$  is said to be:

- *Plain* when it is a solution
- *Consistent* when it does not contradict the agent's information
- *Explanatory* when it does not explain  $\chi$  by itself.

Similar properties can be described in the present setting. To begin with, the *plain* property simply states that  $\eta$  is an abductive solution; a definition that has been already provided (Definition 13.11).

For the *consistency* property, the intuitive idea is for the solution to be compatible with the agent's information. To this end, consider the following definition.

#### Definition 13.12 Consistent solution

Let  $\chi$  be an abductive problem and  $\eta$  be one of its abductive solutions, both at  $(M_{\psi!}, w)$ . It is said that  $\eta$  is a *consistent* solution if and only if the agent considers it possible at  $(M_{\psi!}, w)$ , that is, if and only if

$$(M_{\psi!}, w) \Vdash \hat{K}\eta.$$

Thus, a solution is consistent when it is epistemically possible. Note how this requirement is given in terms of the agent's information *after* the epistemic action that triggered the abductive problem, and not

before it. In fact, there are formulas that, in a given situation, are solutions according to the stated definition, and yet not epistemically possible once the abductive problem has been raised.

#### Fact 13.1

Not every abductive solution is consistent.

*Proof:* Let  $\eta$  and  $\chi$  be propositional formulas, and take a model  $M$  in which the agent considers at least one  $(\neg\eta \wedge \neg\chi)$ -world to be epistemically possible, with the rest of the epistemic possibilities being  $(\neg\eta \wedge \chi)$ -worlds. After observing  $\chi$ ,  $\neg\chi$ -worlds will be discarded and there will be only  $(\neg\eta \wedge \chi)$ -worlds left, thus making  $\chi$  itself an abductive problem (it is not known at  $M$  but it will be known at  $M_{\chi!}$ ) and  $\eta$  an abductive solution (every epistemic possibility at  $M$  satisfies  $\eta \rightarrow \chi$ , so the agent knows this implication). Nevertheless, there are no  $\eta$ -worlds at  $M_{\chi!}$ , and therefore  $\hat{K}\eta$  is false at such stage. ■

The *explanatory* property is interesting. The idea in the classic setting is to avoid solutions that imply the problematic  $\chi$  per se, such as  $\chi$  itself or any formula logically equivalent to it. In the current epistemic setting, this idea can be understood in a different way: A solution  $\eta$  is explanatory when the acceptance of  $\eta$  (which, as discussed, will be modeled via belief revision; see Sect. 13.6) changes the agent's information, that is, when the agent's information is different from  $(M_{\psi!}, w)$  to  $((M_{\psi!})_{\eta\uparrow}, w)$  (the model that results after integrating the solution  $\eta$ ). This assertion could be formalized by stating that the agent's information is the same in two pointed models if and only if the agent has the same knowledge in both, but this would be insufficient: The model operation representing an act of belief revision (the upgrade of Definition 13.8) is devised to change only the agent's beliefs (although certain knowledge, such as knowledge about beliefs, might also change). A second attempt would be to state that the agent's information is the same in two pointed models if and only if they coincide in the agent's knowledge and beliefs, but the mentioned operation can change a model without changing the agent's beliefs.

Within the current *modal* epistemic logic framework, a more natural way of specifying the idea of an agent having the same information in two models is via the notion of bisimulation.

#### Definition 13.13 Bisimulation

Let  $P$  be a set of atomic propositions and let  $M = \langle W, \leq, V \rangle$  and  $M' = \langle W', \leq', V' \rangle$  be two plausibility models based on this set. A nonempty relation  $Z \subseteq (W \times W')$  is called a *bisimulation* between  $M$  and  $M'$  (notation:  $M \leftrightarrow_Z M'$ ) if and only if, for every  $(w, w') \in Z$ :

- $V(w) = V'(w')$ , that is,  $w$  and  $w'$  satisfy the same atomic propositions
- If there is a  $u \in W$  such that  $w \leq u$ , then there is a  $u' \in W'$  such that  $w' \leq' u'$  and  $Zuu'$
- If there is a  $u' \in W'$  such that  $w' \leq' u'$ , then there is a  $u \in W$  such that  $w \leq u$  and  $Zuu'$ .

Two models  $M$  and  $M'$  are *bisimilar* (notation:  $M \leftrightarrow M'$ ) when there is a bisimulation between them, and two pointed models  $(M, w)$  and  $(M', w')$  are bisimilar (notation:  $(M, w) \leftrightarrow (M', w')$ ) when there is a bisimulation between  $M$  and  $M'$  containing the pair  $(w, w')$ .

This notion is significant because, under image-finiteness (a plausibility model is *image-finite* if and only if every world can  $\leq$ -see only a finite number of worlds), it characterizes modal equivalence, that is, it characterises models that satisfy exactly the same formulas in the modal language.

**Theorem 13.1**

Let  $P$  be a set of atomic propositions and let  $M = \langle W, \leq, V \rangle$  and  $M' = \langle W', \leq', V' \rangle$  be two image-finite plausibility models. Then  $(M, w) \leftrightarrow (M', w')$  if and only if, for every formula  $\varphi \in \mathcal{L}$ ,  $(M, w) \models \varphi$  iff  $(M', w') \models \varphi$ .

Now it is possible to state a formal definition of what it means for a solution to be explanatory.

**Definition 13.14 Explanatory solution**

Let  $\chi$  be an abductive problem and  $\eta$  be one of its abductive solutions, both at  $(M_{\psi!}, w)$ . It is said that  $\eta$  is an *explanatory* solution if and only if its acceptance changes the agent’s information, that is, if and

only if there is *no* bisimulation between  $(M_{\psi!}, w)$  and  $((M_{\psi!})_{\eta\uparrow}, w)$ .

This definition, devised in order to avoid solutions that explain the abductive problem per se, has pleasant side effects. In the abductive reasoning literature, a solution is called *trivial* when it is logically equivalent to the abductive problem  $\chi$  (i.e., when it is not explanatory) or when it is a contradiction (to the agent’s knowledge, or a logical contradiction). Under the given definition, every trivial solution is not explanatory: *Accepting any such solution will not change the agent’s information*. The reason is that, in both cases, the upgrade operation *will not make any change in the model*: In the first case because, after the observation, the agent knows the abductive problem formula, and hence every epistemically possible world satisfies it (as well as every formula logically equivalent to the problem); in the second case because *no* epistemically possible world satisfies it. In this way, this framework characterizes trivial solutions not in terms of their form, as is typically done, but rather in terms of their effect: *Accepting them will not give the agent any new information*.

In particular, this shows how the act of incorporating a contradictory explanation will not make the agent *collapse* and turn into someone that knows and believes everything, as happens in traditional approaches; thus, a logic of formal inconsistency (e.g., [13.43]; see also Chap. 15) is not strictly necessary. This is a consequence of two simple but powerful ideas:

1. Distinguishing an agent’s different epistemic attitudes
2. Assimilating an abductive solution not as knowledge, but rather as a belief.

## 13.5 Selecting the Best Explanation

Finding suitable and reasonable criteria for selecting the best explanation is a fundamental problem in abductive reasoning [13.32, 33], and in fact many authors consider this to be the heart of the subject. The so-called *thesis of purpose*, stated in [13.33], establishes that the aim of scientific abduction is:

1. To generate new hypotheses
2. To select hypotheses for further examination and testing.

Hence a central issue in scientific abduction is to provide methods for selecting. Because the true state of the world is unknown, selecting the best explanation requires more than just consistency with the available

information, and there are many proposals of what these extra criteria should be.

Some approaches are based on probabilistic measurements [13.44–46]. Even Sherlock Holmes advised that, in order to evaluate explanations, one should “balance probabilities and choose the most likely” (*The Hound of the Baskervilles*), but unfortunately explanations rarely come equipped with probabilities.

In abductive logic programming, a common strategy is to look for abductive solutions at the *dead ends* of prolog proofs [13.47]. Sound and complete procedures can be defined also by using stable models and answer sets [13.48, 49]. Apart from selection criteria based on consistency and integrity constraints, it is common to

start with a set of *abducible* predicates and select explanations built only from ground atoms using them (see Chap. 10 for more details on abductive logic programming).

There are also approaches that use logical criteria, but beyond the already mentioned requisites to avoid triviality, the definition of suitable criteria is still an open problem. One of the most pursued ideas is that of minimality, a concept that can be understood syntactically (e.g., [13.3] and [13.5] look for literals), semantically (a minimal explanation is equivalent to any other explanation it implies [13.1]), with respect to the set of possible explanations (the best explanation is the weakest, i.e., the one that is implied by the rest of them), and even with respect to the current information (the best explanation is the one that disrupt less the current information).

In fact, most logical criteria are based on restrictions on the logical form of the solutions but, as mentioned in [13.1], finer criteria to select between two equally valid solutions require contextual aspects. With this idea in mind some approaches have proposed to use an ordering among formulas [13.10, 50, 51] or among full theories (i.e., possible worlds [13.52, 53]). In particular, for the latter, a common option is the use of *preferential models* (e.g., [13.54]) in which preferential criteria for selecting the best explanation are regarded as qualitative properties that are beyond the pure causal or deductive relationship between the abductive problem and its abductive solution. But these preference criteria are normally treated as an external device, which works on top of the logical or deductive part of the explanatory mechanism, and thus it has been criticized because it seems to fall outside a logical framework.

The epistemic approach of this proposal provides with an interesting alternative. The concepts of an abductive problem and an abductive solution have been defined in terms of the agent's epistemic attitudes, so it is natural to use such attitudes as a criterion for selecting the best explanation. Consider, for instance, the following elaboration of an example presented in Chap. 10.

“Mary and Gaby arrive late to Mary's apartment; the light switch is pressed but the light does not turn on. Knowing that the apartment is old, Mary assumes a failure in the electric line as the explanation for the light not turning on. Gaby, on the other hand, does not have any information about the apartment, so she explains the light not turning on by assuming that the bulb is burned out.”

After pressing the switch, both Mary and Gaby observe that the light does not turn on. There are several explanations for this: It is possible that the electric line failed, as Mary assumed, but it can also be the case

that the bulb is burned out, as Gaby thinks, and it is even possible that the switch is faulty. Then, why do they choose a different explanation? The reason is that, though they both observe that the light does not turn on, they have different background information: Mary knows that the apartment is old, and hence she considers a failure in the electric line more likely than any other explanation, but Gaby does not have that piece of information, so for her a burned out bulb explains the lack of light better.

The example shows that, even when facing the same surprising observation (the light does not turn on), agents with different knowledge and beliefs may choose a different best explanation: While Mary assumes that the electric line has failed, Gaby thinks that the bulb is burned out. Both explanations are equally *logical* since either a failure on the electric line or else a burned out bulb is enough to explain why the light does not turn on. What makes Mary to choose the first and Gaby the second is that they have different knowledge and different beliefs. This suggests first, that, instead of looking for criteria to select *the* best explanation, the goal should be a criteria to select *the agent's* best explanation.

But there is more. The explanation an agent will choose for a given abductive problem depends not only on how the problematic formula could have been predicted, but also on what the agent herself knows and what she considers more likely to be the case. It could be argued that this criterion is not *logical in the classical sense* because it is not based exclusively on the *deductive* relationship between the observed fact and the different ways in which it could have been derived. Nevertheless, it is *logical in a broader sense* since it does depend on the agent's information: her knowledge and her beliefs. In particular, in the plausibility models framework, the agent's knowledge and beliefs are defined in terms of a plausibility relation among epistemic possibilities, so it is natural to use precisely this relation as a criterion for selecting each agent's best explanation(s).

This section presents a straightforward use of this idea. It discusses how the plausibility order among epistemic possibilities can be lifted to a plausibility order among formulas, thus providing a natural criterion to select the agent's best explanation. A generalization of this idea that works instead with all explanations will be discussed later (Sect. 13.7).

### 13.5.1 Ordering Explanations

A plausibility model provides an ordering among possible worlds. This order can be lifted to get an ordering among set of worlds, that is, an ordering among formulas of the language (with each formula seen as the set

of those worlds that make it true). The different ways in which such ordering can be defined has been studied in *preference logic* (see [13.55–57] or, for a more detailed exposition [13.58, Chap. 3.3]); this section recalls the main ideas, showing how they can be applied to the task of selecting the best explanation in abductive reasoning.

In general, an ordering among objects can be lifted to an ordering among sets of such objects in different ways. For example, one can say that the lifted ordering puts the set of objects satisfying the property  $\psi$  (the set of  $\psi$ -objects) over the set of objects satisfying the property  $\varphi$  (the set of  $\varphi$ -objects) when *there is a  $\psi$ -object that the original ordering among objects places above some  $\varphi$ -object* (a  $\exists\exists$  preference of  $\psi$  over  $\varphi$ ; see below). But one can be more drastic and say that the set of  $\psi$ -objects is above the set of  $\varphi$ -ones when the original ordering places *every  $\psi$ -object above every  $\varphi$ -one* (a  $\forall\forall$  preference of  $\psi$  over  $\varphi$ ). This quantification combination gives raise to the following possibilities

$\varphi \leq_{\exists\exists} \psi$	iff	<i>there is a <math>\varphi</math>-object <math>w</math> and there is a <math>\psi</math>-object <math>u</math> such that <math>w \leq u</math></i>
$\varphi \leq_{\forall\exists} \psi$	iff	<i>for every <math>\varphi</math>-object <math>w</math> there is a <math>\psi</math>-object <math>u</math> such that <math>w \leq u</math></i>
$\varphi \leq_{\forall\forall} \psi$	iff	<i><math>w \leq u</math> for every <math>\varphi</math>-object <math>w</math> and every <math>\psi</math>-object <math>u</math></i>
$\varphi \leq_{\exists\forall} \psi$	iff	<i>there is a <math>\varphi</math>-object <math>w</math> such that <math>w \leq u</math> for every <math>\psi</math>-object <math>u</math></i>

The first two orderings can be defined within the language  $\mathcal{L}$

$$\begin{aligned}\varphi \leq_{\exists\exists} \psi &:= \langle \sim \rangle (\varphi \wedge \langle \leq \rangle \psi) \\ \varphi \leq_{\forall\exists} \psi &:= [\sim] (\varphi \rightarrow \langle \leq \rangle \psi).\end{aligned}$$

The first formula indicates that there is a  $\psi$ -world that is at least as plausible as a  $\varphi$ -one,  $\varphi \leq_{\exists\exists} \psi$ , exactly when there is an epistemic possibility that satisfies  $\varphi$  and that can see an at least as plausible  $\psi$ -world. The second one only changes the first quantification (turning, accordingly, the conjunction into an implication): For every  $\varphi$ -world there is a  $\psi$ -world that is at least as plausible.

The last two orderings are not immediate. Given the formulas for the previous two orderings, one could propose  $[\sim](\varphi \rightarrow \langle \leq \rangle \psi)$  for the  $\forall\forall$  case, but this formula is not correct: It states that every world that is at least as plausible as any  $\varphi$ -world satisfies  $\psi$ , but it does not guarantee that *every  $\psi$ -world is indeed above every  $\varphi$ -world*:

1. There might be a  $\psi$ -world incomparable to some  $\varphi$ -one, and even if all worlds are comparable

2. There might be a  $\psi$ -world strictly below a  $\varphi$ -one ( $<$ , the strict version of  $\leq$ , is defined as  $w < u$  if and only if  $w \leq u$  and *not*  $u \leq w$ ).

The plausibility order is locally connected (i. e., inside each epistemic partition, every world is comparable to each other) so (1) cannot occur. Thus, a formula defining  $\leq_{\forall\forall}$  only needs to guarantee that no  $\psi$ -world is *strictly* below a  $\varphi$ -one; in other words, it needs to express that, given any  $\psi$ -world, every world that is strictly more plausible satisfies  $\neg\varphi$ . Such formula can be easily stated in a language that extends  $\mathcal{L}$  with a standard modality for the relation  $<$

$$\varphi \leq_{\forall\forall} \psi := [\sim](\psi \rightarrow \langle < \rangle \neg\varphi).$$

Finally, the  $\exists\forall$  ordering presents a similar situation. Following the first two cases one could propose  $\langle \sim \rangle (\varphi \wedge \langle < \rangle \psi)$ , but such formula is not appropriate, even in the current full-comparability case: It holds even when there are  $\psi$ -worlds below the chosen  $\varphi$ -one. In order to guarantee the existence of a  $\varphi$ -world that is at most as plausible as every  $\psi$ -world, the formula should state that every world that is strictly *less* plausible than the  $\varphi$ -world satisfies  $\neg\psi$ . Extending the language again, this time with a modality for  $>$ , makes such formula straightforward

$$\varphi \leq_{\exists\forall} \psi := \langle \sim \rangle (\varphi \wedge \langle > \rangle \neg\psi).$$

All in all, the important fact is that among these four orderings on sets of worlds (i. e., formulas), two are definable within  $\mathcal{L}$  and the other two only need simple extensions. This shows how the plausibility order among worlds that defines the agent's knowledge and beliefs (Sect. 13.3.1) also defines plausibility orderings among formulas (sets of worlds), and hence provides a criterion for selecting the best abductive solution *for a given agent*. It will now be shown how this criterion can be used, and how it leads to situations in which agents with different knowledge and beliefs choose different best explanations.

### Example 13.5

Recall Mary and Gaby's example. Both observe that after pressing the switch the light does not turn on, but each one of them chooses a different explanation: While Mary assumes that the electric line failed, Gaby thinks that the bulb is burned out. As it has been argued, the reason why they choose different explanations is that they have different knowledge and beliefs. Here is a formalization of the situation.

The following plausibility models show Mary and Gaby's knowledge and beliefs before pressing the

switch. They involve tree atomic propositions:  $l$  standing for lack of light,  $e$  standing for a failure in the electric line and  $b$  standing for a burned out bulb. Again, each possible world has indicated within it exactly those atomic propositions that are true in each one of them, and the arrows represent the plausibility relation (transitive arrows are omitted).

Observe how both Mary and Gaby know that both a failure on the electric line and a burned out bulb imply lack of light (both  $e \rightarrow l$  and  $b \rightarrow l$  hold in every world). In fact, the only difference in the models is the plausibility order between worlds  $w_2$  and  $w_4$ . Mary knows that the apartment is old so she considers a failure on the line ( $e$ ) more likely than a burned out bulb ( $b$ ), and hence the situation where the electric line fails but the bulb is not burned out ( $w_2$ ) is more likely than its opposite ( $w_4$ ). Gaby, on the other hand, does not know anything about the apartment, and hence for her a burned out bulb with a working electric line ( $w_4$ ) is more plausible than a working bulb and a failing electric line ( $w_2$ ). It is also assumed that, for both of them, the most likely possibility is the one in which everything works correctly ( $w_1$ ) and the least plausible case is the one in which everything fails ( $w_5$ ).

After they both observe that pressing the switch does not turn on the light, the unique world where  $l$  is

not the case,  $w_3$ , is eliminated, thus producing the following models.

As a result of the observation, Mary and Gaby know that there is no light ( $Kl$  holds in both models), something that they did not know before. Thus, following Definition 13.9, both have an abductive problem with  $l$ .

According to Definition 13.11, both  $e$  and  $b$  are abductive solutions for the abductive problem  $l$  for both Mary and Gaby: Both formulas are the antecedent of implications that have  $l$  as a consequent and that were known before the observation. So, how can each girl choose her own best explanation? For Mary, the unique ordering that puts  $b$  above  $e$  is the weakest one,  $\exists\exists$  (there is a  $b$ -world,  $w_4$ , at least as plausible as a  $e$ -one,  $w_5$ ). Nevertheless, from her point of view,  $e$  is above  $b$  not only in the weak  $\exists\exists$  way ( $w_2$  is at least as plausible as  $w_4$ ) but also in the stronger  $\forall\exists$  way (every  $b$ -world has a  $e$ -world that is at least as plausible as it). Thus, one can say that  $e$  is a more plausible explanation from Mary's perspective. In Gaby's case something analogous happens:  $b$  is above  $e$  not only in the weak  $\exists\exists$  way ( $w_4$  is at least as plausible as  $w_2$ ) but also in the strong  $\forall\exists$  way. Hence, it can be said that, for Gaby,  $b$  is the best explanation.

### 13.6 Integrating the Best Solution

Once the agent has selected the best explanation for her, she can incorporate it into her information. As discussed in Sect. 13.2, even though the nonmonotonic nature of abductive reasoning indicates that an abductive solution should not be assimilated as knowledge, the richness of the present framework allows the possibility to integrate it as a part of the agent's beliefs. Here is a modality describing such action.

**Definition 13.15 Modality for abductive reasoning**  
Let  $(M, w)$  be a pointed plausibility model and consider again  $(M_{\psi!}, w)$ , the pointed plausibility model

that results from observing  $\psi$  at  $(M, w)$ . Every pair of formulas  $\eta$  and  $\chi$  in  $\mathcal{L}$  define an existential modality  $\langle \text{Abd}_{\eta}^{\chi} \rangle \varphi$ , read as *the agent can perform an abductive step for  $\chi$  with  $\eta$  after which  $\varphi$  is the case*, and whose semantic interpretation is as follows

$$\begin{aligned}
 (M_{\psi!}, w) \models \langle \text{Abd}_{\eta}^{\chi} \rangle \varphi & \\
 \text{iff} & \\
 (1) (M_{\psi!}, w) \models K\chi \text{ and } (M, w) \models \neg K\chi, & \\
 (2) (M, w) \models K(\eta \rightarrow \chi), \text{ and} & \\
 (3) ((M_{\psi!})_{\eta \uparrow}, w) \models \varphi. &
 \end{aligned}$$

Equivalently,  $\langle \text{Abd}_\eta^x \rangle \varphi$ 's semantic interpretation can be defined as

$$\begin{aligned} (M_{\psi!}, w) \Vdash \langle \text{Abd}_\eta^x \rangle \varphi \\ \text{iff} \\ (M, w) \Vdash \neg K\chi \wedge K(\eta \rightarrow \chi) \wedge [\psi!](K\chi \wedge [\eta \uparrow]\varphi). \end{aligned}$$

The definition states that  $\langle \text{Abd}_\eta^x \rangle \varphi$  is true at  $(M_{\psi!}, w)$  if and only if:

1.  $\chi$  is an abductive problem at  $(M_{\psi!}, w)$
2.  $\eta$  is an abductive solution also at  $(M_{\psi!}, w)$
3. An upgrade (Definition 13.8) with  $\eta$  will make  $\varphi$  true.

The last part makes precise the idea of how an agent should incorporate the selected explanation: It cannot be incorporated as knowledge, but it can be incorporated as a belief.

**Example 13.6**

Returning to Example 13.5, once Mary and Gaby have selected their respective best explanation, they can perform an abductive step. In Mary's case, worlds satisfying  $e$  ( $w_5$  and  $w_2$ ) will become more plausible than worlds that do not satisfy it ( $w_4$  and  $w_1$ ); in Gaby's case, worlds satisfying  $b$  ( $w_5$  and  $w_4$ ) will become more plausible than worlds that do not satisfy it ( $w_2$  and  $w_1$ ). Applying these upgrades to the models  $Mary_{\eta!}$  and  $Gaby_{\eta!}$  produces the following models.

As a result of the abductive step, each agent believes her own explanation: Mary believes that the electric line has failed ( $e$  is true in her unique most plausible world  $w_2$ ), and Gaby believes that the bulb is burned out ( $b$  is true in her unique most plausible world  $w_4$ ). That is, for every  $w \in \{w_1, w_2, w_4, w_5\}$ ,

$$\begin{aligned} (Mary_{\eta!}, w) \Vdash \langle \text{Abd}_e^l \rangle Be \\ (Gaby_{\eta!}, w) \Vdash \langle \text{Abd}_b^l \rangle Bb. \end{aligned}$$

**13.6.1 Abduction in a Picture, Once Again**

The definitions that have been provided allow more precision in the diagram of abductive reasoning presented in Sect. 13.2.5. Here is the updated version for the case in which the definitions are given just in terms of the agent's knowledge. Note how the *inferring*  $\chi$  step has been dropped, as it is not needed in an omniscient setting such as DEL. Again, circles represent the agent's epistemic states (i. e., full plausibility models) and arrows are labeled with the operations that modify the agent's information.

Again, the upper path represents what really happened. After observing  $\psi$ , the agent reaches the epistemic state  $s_2$  in which she knows  $\chi$ . But before the observation, at  $s_1$ , she did not know  $\chi$ , and thus this formula is an abductive problem at  $s_2$ . Observe how  $\eta \rightarrow \chi$  was known at  $s_1$ : hence,  $\eta$  is an abductive solution at  $s_2$  and the agent can perform an abductive step with it to reach state  $s_3$ . This abductive solution  $\eta$  would have helped the agent to infer (and hence to come to know)  $\chi$ , and the lower path represents this alternative situation. In general, it cannot be guaranteed that the agent would have known  $\chi$  (or even  $\eta$ ) at state  $s'_2$ : these formulas could have had epistemic modalities, and hence the observation could have changed their truth value. However, if both formulas are propositional,  $K\chi$  and  $K\eta$  hold at  $s'_2$ .

**13.6.2 Further Classification**

Section 13.4.4 presented an epistemic version of the the common classification of abductive solutions. But the current DEL setting allows further possibilities and hence a finer classification. For example, here are two straightforward ideas. First, a solution  $\eta$  has been defined as the antecedent of an implication that has  $\chi$  as a consequent and that was known *before* the epistemic action that triggered the problem. Nevertheless, given that both formulas might contain epistemic operators, the agent can go from knowing the implication to not knowing it. Second, it has been stated that the agent incorporates the selected explanation via a belief revision (i. e., an upgrade). Nevertheless, since the solution might contain epistemic operators, the upgrade does not guarantee that the agent will believe the solution after the operation.

**Definition 13.16 Adequate solution and successful solution**

Let the formula  $\eta$  be an abductive solution for the abductive problem  $\chi$  at  $(M_{\psi!}, w)$ . Then:

- $\eta$  is an *adequate* solution if and only if the agent still knows  $\eta \rightarrow \chi$  at  $(M_{\psi!}, w)$ , that is, if and only if  $(M_{\psi!}, w) \Vdash K(\eta \rightarrow \chi)$ .
- $\eta$  is a *successful* solution if and only if it is believed after the abductive step, that is, if and only if  $(M_{\psi!}, w) \Vdash \langle \text{Abd}_{\eta}^{\chi} \rangle B\eta$ .

Here it is a result about the adequacy property.

**Proposition 13.2**

Every abductive solution is *adequate*.

*Proof:* More precisely, suppose that at  $(M_{\psi!}, w)$  the formula  $\chi$  is an abductive problem and  $\eta$  is one of its abductive solutions. Since  $\chi$  is an abductive problem,  $(M_{\psi!}, w) \Vdash K\chi$  and hence  $(M_{\psi!}, w) \Vdash K(\eta \rightarrow \chi)$ . ■

Given this result, this property is of little interest in the current setting. However, it becomes interesting in settings with nonomniscient agents. In such frameworks, it is possible for the agent not to know  $\eta \rightarrow \chi$  even when she knows  $\chi$  and she knew  $\eta \rightarrow \chi$  before.

Here it is another result, now about the property of being a successful solution.

**Fact 13.2**

Not every abductive solution is successful.

*Proof:* Let  $P = \{p, q\}$  be the set of atomic propositions, and consider the pointed plausibility models below (reflexive and transitive arrows omitted) in which the evaluation points are double circled.

Observe how  $q$  is an abductive problem at  $M_{q!}$  since it is not known at  $M$  (there is an epistemically possible world where  $q$  fails, namely,  $w_3$ ) but it is known at  $M_{q!}$ . Observe also how  $p \wedge \neg Bp$  is an abductive solution since  $K((p \wedge \neg Bp) \rightarrow q)$  holds at  $M$  (it is true at  $w_1$  and  $w_2$  because  $q$  is true in those worlds, and also true at  $w_3$  because  $p \wedge \neg Bp$  fails in this world). Furthermore,  $p \wedge \neg Bp$  is a consistent solution since it is epistemically possible in  $M_{q!}$  ( $p$  and  $\neg Bp$  are both true at  $w_1$ , the latter because there is a most plausible world,  $w_2$ , where  $p$  is not the case, and hence the agent does not believe  $p$ ). Nevertheless, after an upgrade with  $p \wedge \neg Bp$  this very formula is not believed. It fails at the unique most plausible world  $w_1$  because  $\neg Bp$  fails at it: the most plausible world ( $w_1$  itself) satisfies  $p$  and hence the agent now believes  $p$ , that is,  $Bp$  is the case. ■

Nevertheless, if a propositional solution  $\eta$  is also consistent, then it is successful.

**Proposition 13.3**

Suppose that at  $(M_{\psi!}, w)$  the formula  $\eta$  is an abductive solution for the abductive problem  $\chi$ . If  $\eta$  is a propositional and consistent solution, then it is successful.

*Proof:* If  $\eta$  is a consistent solution, then at  $(M_{\psi!}, w)$  there is at least one epistemically possible  $\eta$ -world. Therefore, an upgrade with  $\eta$  will put worlds that satisfied  $\eta$  in  $(M_{\psi!}, w)$  on top of the plausibility order. Now,  $\eta$  is propositional, and hence its truth value depends only on the valuation of each possible world; since the upgrade operation does not affect the valuation, then any world satisfying  $\eta$  in  $M_{\psi!}$  will still satisfy it in  $(M_{\psi!})_{\eta\uparrow}$ . Hence, after the operation, the most plausible worlds will satisfy  $\eta$ , and thus  $((M_{\psi!})_{\eta\uparrow}, w) \Vdash B\eta$  will be the case. This, together with the fact that at  $M_{\psi!}$  the formula  $\chi$  is an abductive problem and the formula  $\eta$  is an abductive solution, yield  $(M_{\psi!}, w) \Vdash \langle \text{Abd}_{\eta}^{\chi} \rangle B\eta$ . ■

It has been already stated that a solution is explanatory when it changes the agent's information. A further classification of abductive solutions can be provided according to *how much* they change the agent's information, that is, according to the attitude of the agent toward the solution *before* it was incorporated.

**Definition 13.17**

Suppose that  $\chi$  is an abductive problem at  $(M_{\psi!}, w)$ . An explanatory abductive solution  $\eta$  is:

- *Weakly explanatory* when  $(M_{\psi!}, w) \Vdash B\eta$

- Neutral when  $(M_{\psi!}, w) \models \neg B\eta \wedge \neg B\neg\eta$
- Strongly explanatory when  $(M_{\psi!}, w) \models B\neg\eta$ .

Again, there are more possibilities if further epistemic attitudes are considered.

### 13.6.3 Properties in a Picture

Consider an anomalous abductive problem  $\chi$  (i. e.,  $B\neg\chi$  holds at  $s_1$ ) whose abductive solution  $\eta$  is consistent ( $\hat{K}\eta$  holds at  $s_2$ ) and successful ( $B\eta$  holds at  $s_3$ ), recalling also that every solution is adequate (so  $K(\eta \rightarrow \chi)$  holds at  $s_2$ ). This extends the diagram of Sect. 13.6.1 in the following way.

Moreover, consider the case in which both  $\chi$  and  $\eta$  are propositional, the typical case in abductive reasoning in which the agent looks for explanations of facts, and not of her own (or, in a multiagent setting, of other agents') epistemic state. First, in such case,  $\eta$  should be an epistemic possibility not only at  $s_2$  but also at  $s_1$ . But not only that; it is possible now to state the effects of the abductive step at  $s_2$  (the agent will believe  $\eta$  and will still know  $\eta \rightarrow \chi$ ) and of the hypothetical announcement of

$\eta$  at  $s_1$  (she would have known both  $\eta$  and  $\chi$ , and she would have still known  $\eta \rightarrow \chi$ ). Therefore,

This diagram beautifully illustrates what lies behind this proposal's understanding of abductive reasoning. In the propositional case, if  $\eta$  is a consistent and successful abductive solution for the abductive problem  $\chi$ , then, after abductive reasoning, the agent will know  $\chi$  and will believe  $\eta$ . In fact, when the observed formula  $\psi$  is actually the same  $\chi$  that becomes an abductive problem, the epistemic effect of abductive reasoning, from knowledge to beliefs, can be described with the following validity [13.59],

$$K(\eta \rightarrow \chi) \rightarrow [\chi!](K\chi \rightarrow \langle \text{Abd}_\eta^\chi \rangle B\eta) .$$

What makes  $\eta$  a reasonable solution is the existence of an *alternative reality* in which she observed  $\eta$  and, thanks to that, came to know  $\chi$ . Similar diagrams can be obtained for the cases in which the definitions of an abductive problem and an abductive solution are given in terms of epistemic attitudes other than knowledge.

## 13.7 Working with the Explanations

The reason why abductive solutions are incorporated as beliefs and not as knowledge is because the selected explanation (in fact, *any* explanation) is just a hypothesis, subject to change in light of further information. Consider the following continuation of the Mary and Gaby's situation.

### Example 13.7

After their respective abductive steps (models  $(Mary!_l)_{e\uparrow}$  and  $(Gaby!_l)_{b\uparrow}$  of Example 13.6), Mary and Gaby take a closer look at the bulb and observe that it is not burned out ( $\neg b$ ). Semantically this is simply an observation operation that eliminates  $w_4$  and  $w_5$ , exactly those epistemic possibilities where the bulb is burned out (i. e., where  $b$  holds). The resulting models

are the following.

This observation does not affect Mary's explanation: She still believes that the electric line has failed ( $e$  is true in her unique most plausible world  $w_2$ ). But Gaby's

case is different: She does not have an explanation for  $l$  anymore. Although she knows it ( $Kl$  holds at the model on the bottom, that is,  $l$  is true in every epistemic possibility), she neither knows nor believes the antecedent of a known implication with  $l$  as a consequent (besides, of course, the trivial ones); she needs to perform a further abductive step in order to explain it.

There is, nevertheless, a way to avoid the extra abductive reasoning step. Recall that after applying the defined upgrade operation (Definition 13.8), all the worlds satisfying the given formula become more plausible than the ones that do not satisfy it, *and within the two zones the old ordering remains*. If the *lifted* worlds are not those that satisfy the agent's most plausible explanation but rather those that satisfy *at least one* of her explanations, the resulting model will have two layers: the lower one with worlds that do not satisfy any explanation, and the upper one with worlds that satisfy at least one. But inside the upper layer the old ordering will remain. In other words, the most plausible worlds in the resulting model (i. e., the most plausible ones in the upper layer) will be the ones that satisfy at least one explanation and that were already more plausible than the rest. Thus, with respect to the most plausible explanation, the same result is achieved: After such upgrade, roughly, the agent will believe the explanation that was the most plausible for her.

The difference with respect to the approach of the previous section is that the worlds that appear below the most plausible ones are not arbitrary. Worlds on the second best layer satisfy already some explanation; an explanation that was not chosen because it was not the most plausible one. Then, if further observations make the original best explanation obsolete, once that the correspondent (and now also obsolete) worlds have been discarded, the ones that will be at the top of the plausibility ordering will be the previously second best. Thus, an explanation will be already present and no further abductive steps will be needed.

### 13.7.1 A Modality

The idea just described is formalized now by introducing a modality that, given an abductive problem  $\chi$ , upgrades those worlds that satisfy at least one of its abductive explanations.

#### Definition 13.18 Modality for formula-based abduction

Let  $(M, w)$  be a pointed plausibility model and consider again  $(M_{\psi!}, w)$ , the pointed plausibility model that results from observing  $\psi$  at  $(M, w)$ . Every formula  $\chi$  in

$\mathcal{L}$  defines an existential modality of the form  $\langle \text{Abd } \chi \rangle \varphi$ , read as *the agent can perform a complete abductive step for  $\chi$  after which  $\varphi$  is the case*, and whose semantic interpretation is as follows

$$\begin{aligned} (M_{\psi!}, w) \Vdash \langle \text{Abd } \chi \rangle \varphi \\ \text{iff} \\ (1) (M_{\psi!}, w) \Vdash K\chi \text{ and } (M, w) \Vdash \neg K\chi, \\ (2) ((M_{\psi!})_{(\bigvee \Sigma_\chi) \uparrow}, w) \Vdash \varphi, \end{aligned}$$

where  $\Sigma_\chi$  is the set of abductive solutions for  $\chi$ , that is,

$$\Sigma_\chi := \{\eta \mid (M, w) \Vdash K(\eta \rightarrow \chi)\}.$$

Equivalently,  $\langle \text{Abd } \chi \rangle \varphi$ 's semantic interpretation can be defined as

$$\begin{aligned} (M_{\psi!}, w) \Vdash \langle \text{Abd } \chi \rangle \varphi \\ \text{iff} \\ (M, w) \Vdash \neg K\chi \wedge [\psi!](K\chi \wedge [\bigvee \Sigma_\chi \uparrow] \varphi). \end{aligned}$$

The correspondent universal modality,  $[\text{Abd } \chi]$ , is defined as usual.

The definition states that  $\langle \text{Abd } \chi \rangle \varphi$  is true at  $(M_{\psi!}, w)$  if and only if (1)  $\chi$  is an abductive problem at  $(M_{\psi!}, w)$ , and (2) an upgrade with  $\bigvee \Sigma_\chi$  will make  $\varphi$  true. The last part makes precise the idea of working with all the solutions:  $\Sigma_\chi$  contains all abductive solutions for  $\chi$ , so  $\bigvee \Sigma_\chi$  is a disjunction characterising those worlds that satisfy at least one of them and hence an upgrade with it will move such worlds to the topmost layer. But inside this layer, the former plausibility order will persist, and hence worlds at the top of it will be precisely those that satisfy at least one solution for  $\chi$  and, among them, were already the most plausible ones.

#### Remark 13.1

The set  $\Sigma_\chi$  contains, among others,  $\chi$ ,  $\chi \wedge \chi$ , and so on, and hence  $\bigvee \Sigma_\chi$  is an infinite disjunction. Syntactic restrictions can be imposed in order to avoid such situations (e.g., asking for solutions that are also minimal conjunctions of literals). Another possibility, closer to the semantic spirit of this approach, is to work with finite plausibility models, and then look for solutions among the formulas that characterize each possible world.

The following example shows how this new operation allows the agent to have ready another explanation in case the initially *best* one turns out to be incorrect.

**Example 13.8**

Let us go back to Mary and Gaby’s example all the way to the stage after which they have observed that the light does not turn on (models  $Mary_{!}$  and  $Gaby_{!}$  of Example 13.5, repeated here).

Suppose that, instead of selecting their respective most plausible explanation and assimilating it (as they did in Example 13.5), Mary and Gaby work with all their explanations: Instead of an upgrade with  $e$  for Mary and an upgrade with  $b$  for Gaby, both of them perform an upgrade with  $e \vee b$ . This produces the following models.

The worlds satisfying  $e \vee b$  ( $w_2$ ,  $w_4$ , and  $w_5$ ) have been upgraded. As a result of this, both Mary and Gaby have an explanation for  $l$ , but each one of them has *her own* explanation: While Mary believes that the electric line

has failed ( $e$  is the case in the most plausible world at the model on the top), Gaby believes that the bulb is burned out ( $b$  holds in the most plausible world at the model on the bottom).

So far the result of the upgrade is, with respect to Mary and Gaby beliefs, exactly the same as with the previous proposal where only worlds that satisfy the most plausible explanation are upgraded (in both cases,  $w_2$  and  $w_4$  are Mary’s and Gaby’s most plausible worlds, respectively). But note what happens now when they both observe that the bulb is in fact not burned out ( $\neg b$ ): Such action produces the following situation.

Again, the observation does not affect Mary’s explanation ( $e$  still holds in the most plausible world at model on the top), but it does change Gaby’s since her previous explanation  $b$  is not possible anymore. The difference is that now she does not need to perform an extra abductive step because she has already another explanation: She now believes that the electric line has failed ( $e$  holds in the most plausible world at model on the bottom).

Thus, after an upgrade with all explanations, what the agent will be lead to believe depends on her plausibility order, just as with the first proposal. Nevertheless, if further information invalidates such best explanation, the agent will believe the next to best one without the need of further abductive steps.

**13.8 A Brief Exploration to Nonideal Agents**

As most (if not all) proposals for representing a given phenomena, the presented epistemic and dynamic approach to abduction has made some assumptions for the sake of simplicity. One of the most important of these is the fact that agents whose information is represented within the plausibility framework are *ideal*: Their knowledge and beliefs are closed under logical consequence. This supposition is not exclusive of this approach; the classic logical definitions of abductive reasoning assume not only that the given set of formulas  $\Phi$ , the theory, is closed under logical con-

sequence, but also that  $\vdash$  is the logical consequence relation.

The present proposal highlights the epistemic nature of abductive reasoning, and so it is natural to ask how such reasoning process works for a different kind of agents, in particular, for those whose information does not need to have *ideal* properties and thus are, in that sense, closer to real computational agents with limited resources (and also closer to us human beings). This final section briefly discusses some ideas; further developments in this direction can be found in [13.60].

### 13.8.1 Considering Inference

Suppose Karl is in his dining room and sees smoke coming out of the kitchen. This seems unjustified at first, but then he realises that the chicken he placed on the fire has been there for a long time. Initially Karl did not have any explanation for the smoke, but after a moment he realized that such event was actually not surprising at all.

This case is different from the discussed ones because Karl is not an ideal agent: He does not have at hand all logical consequences of his information, and therefore he did not realize that the information he had before seeing the smoke was enough to predict it (i. e., to infer that there would be smoke). Described in more technical terms, seeing the smoke raised an abductive problem for Karl, but such problem arose because he did not have, at the time of the observation, all the logical consequences of the information he actually had (otherwise there would have been no abductive problem at all). Accordingly, in such case the abductive solution is not necessarily a piece of information that would have allowed Karl to predict the smoke; it might be a simple inference step that made *explicit* what was only *implicit* before.

This shows not only how agents whose information is not closed under logical consequence can face at least a new kind of abductive problem, but also how such problems give rise to a different kind of solutions.

### 13.8.2 Different Reasoning Abilities

In the previous example, the abductive solution was a simple inference step because Karl had the needed

reasoning tools to infer *there is smoke in the kitchen from the chicken has been on the fire for a long time*. But what if that was not the case? That is, what if, besides not having at hand all the logical consequences of his information, Karl did not have the required reasoning tools to infer some of them?

In such new situation, Karl faces again an abductive problem, but this time of a different nature. The surprising observation could have been predicted in the sense that it is a logical consequence of Karl's information *the chicken has been on the fire for a long time*, just as in the initial version of this example. The difference is that such observation is not something that Karl could have predicted by himself: He did not have the needed tools. One can say that, even though *there is smoke in the kitchen* is *objectively* derivable from the initial information, it is not *subjectively* derivable in the sense that Karl could not have done it. To put it in other words, besides not having at hand all the logical consequences of her actual information, Karl might not even be able to reach them.

Accordingly, the simple inference step of before cannot be a solution to the problem now, as Karl does not have the needed tools to perform it. One possible solution is, as in the traditional case, a piece of information that would have allowed Karl to predict the smoke from some other previously known fact, but a more interesting one is some reasoning tool that would have helped him to predict the fire from the known fact *the chicken has been on the fire for a long time*.

New cases arise when further kinds of agents are considered. A systematic study of such cases can be found in [13.61].

## 13.9 Conclusions

This chapter has proposed an epistemic and dynamic approach to abductive reasoning, understanding this form of reasoning as a process that:

1. Is triggered by an epistemic action through which the agent comes to know or believe certain  $\chi$  that otherwise she could not have been able to know or believe
2. Looks for explanations for  $\chi$  in the set of formulas that could have helped the agent to come to know or believe  $\chi$
3. Incorporates the chosen explanation as a part of the agent's beliefs.

Besides providing formal definitions of what an abductive problem and an abductive solution are in terms

of an agent's knowledge and beliefs, the present proposal has discussed:

1. A classification of abductive problems in terms of both how convinced the agent is of the problematic formula after the observation (she *knows* it, or just *believes* it) and how plausible the formula was *before* the epistemic action that triggered the problem
2. A classification of abductive solutions based not only on their deductive relation with the abductive problem or their syntactic form, but also in terms of both their plausibility *before* the problem was raised and the way it will affect the agent's information once they are incorporated
3. A new perspective that looks not for *the best* explanation but rather for *the agent's best* explanation,

and the possibility to carry out this search in terms of which explanations are more likely from the agent's point of view, that is, in terms of the agent's beliefs

4. The possibility of integrating the chosen solution into the agent's information as part of her beliefs, which allows not only to identify trivial solutions because of their effect rather than their form, but also to revise and eventually discard solutions that become obsolete in the light of further information.

Crucial for all these contributions has been the use of plausibility models and, in general, the DEL guidelines, which puts emphasis in the representation of both epistemic attitudes and the actions that affect them.

It is worthwhile to compare, albeit briefly, the present proposal to other epistemic approaches to abductive reasoning. Besides immediate differences in the respective semantic models (while other approaches follow the Alchourrón–Gärdenfors–Makinson (AGM) belief revision, using a set of formulas for representing the agent's information, here possible worlds are used), there are two main points that distinguish the presented ideas from other proposals. First, here several epistemic attitudes are taken into account, thus making a clear difference between what the agent holds with full certainty (knowledge) and what she considers very likely but still cannot guarantee (beliefs); this allows to distinguish between the certainty of both the previous information and the surprising observation, and the mere plausibility of the chosen solution (recall the validity  $K(\eta \rightarrow \chi) \rightarrow [\chi!](K\chi \rightarrow \langle \text{Abd}_\eta^x \rangle B\eta)$ , briefly discussed at the end of Sect. 13.6). Second, this approach goes one step further by making explicit the different stages of the abductive process, thus making also explicit the epistemic actions involved. This highlights the importance of actions such as *belief revision*, commonly understood in epistemic approaches to abduction as the one *triggered* by the abductive problem [13.12, 62], and also such as *observation*, understood here as the one that *triggers* the abductive process.

This chapter presents only the first steps toward a proper study of abductive reasoning from an epistemic and dynamic perspective, and several of the current proposals can be refined. For example, the specific definition of an abductive problem (Definition 13.9) relies on the fact that, within the DEL framework, agents are logically omniscient. As it has been hinted at in Sect. 13.8, in a nonomniscient DEL setting [13.35, 63] the ideas discussed in Sect. 13.2 would produce a different formal definition (which, incidentally, would allow to classify abductive problems and abductive solutions according to some *derivability* criteria). Moreover, it would be possible to analyze the full abductive picture presented in Sect. 13.2.1, which requires inference steps

in the alternative reality path. These extensions are relevant: They would allow a better understanding of the abductive process as performed by *real* agents.

But it is also possible to do more than just follow the traditional research lines in abductive reasoning, and here are two interesting possibilities (whose development exceeds the limits of this chapter). First, the DEL framework allows multiagent scenarios in which abductive problems would arise in the context of a community of agents. In such setting, further to the public observation and revision used here, actions that affect the knowledge and beliefs of different agents in different ways are possible. For example, an agent may be privately informed about  $\psi$ : If this raises an abductive problem  $\chi$  for her and another agent has private information about  $\eta \rightarrow \chi$ , they can interact to obtain the abductive solution  $\eta$ . Second, the DEL framework deals with high-order knowledge, thus allowing to study cases in which an agent, instead of looking for an explanation of a fact, looks for an explanation of her own epistemic state. Interestingly, explanations might involve epistemic actions as well as the lack of them.

According to those considerations, this logical approach takes into account the dynamics aspects of logical information processing, and one of them is abductive inference, one of the most important forms of inference in scientific practices. The aforementioned multiagent scenarios allow to model concrete practices, particularly those that develop a methodology based on observation, verification, and systematic formulation of provisional hypotheses, such as in empirical sciences, social sciences, and clinical diagnosis. The epistemological repercussions of this DEL approach is given by the conceptual resources that it offers, useful to model several aspects of explanatory processes. If known theories of belief revision, at the last resort, say nothing about context of discovery, by means of DEL the accessibility of this context to rational epistemological and logical analysis is extended, further on classical logical treatment of abduction. From the perspective of game theoretic semantics, for example, now it is easier to determine what rules are strategic and what are operatories when abductive steps were given. But applications should also be considered to tackle certain philosophical problems. For example, abductive scenarios within multiagent settings can be used to study the implications of different forms of communication within scientific communities.

# 14. Argumentation and Abduction in Dialogical Logic

Cristina Barés Gómez, Matthieu Fontaine

This chapter advocates for a reconciliation of argumentation theory and formal logic in an agent-centered theory of reasoning, that is, a theory in which inferences are studied as human activities. First, arguments in favor of a divorce between the two fields are presented. Those arguments are not so controversial. However, rather than forcing a radical separation, they urge logicians to rethink the object of their studies. Arguments cannot be analyzed as objects independent from human activity, whether it is dealt with deductive or nondeductive reasoning. The present analysis naturally takes place in the context of dialogical logic in which the proof process and the semantics are conceived in terms of argumentative games, which involve the agents, their commitments and their actions. This work focuses first on deductive reasoning and then takes abduction as a case of nondeductive reasoning. By relying on some relevant ideas of the Gabbay-Woods (GW) schema of abduction and Aliseda's approach, a new dialogical explanation of abduction in terms of *concession-problem* is proposed. This notion of *concession problem* will be defined thereafter. With respect to the topics of the model-based sciences, the question of the specificity of the speech act by means of which a hypothesis is conjectured is set more specifically.

## 14.1 Reasoning as a Human Activity

In this chapter, it is argued against the radical dissociation of formal logic and argumentation advocated by *Toulmin* [14.1] and *Perelman and Olbrechts-Tyteca* [14.2]. It is proposed to bring formal logic and argumentation together in the field of dialectical interaction in which the *human being* and the *action* of the agent are given a central role. In this contribution, a unified theory of reasoning is thus advocated, the key concept of which is not something as a *universal logic* but rather the notion of *commitment*, that is, what a speaker is ready to defend on uttering a sentence or

in making use of a particular argument. Indeed, from the perspective of dialectical interactions, the crucial question is: *What are we committed to when we utter a sentence in a dialectical interaction?* In other words, when an agent performs a claim, it is never for free, and further justifications may be demanded for by the speaker's argumentative partners. The commitment to providing further justifications precisely constitutes the ground in order to distinguish between various kinds of speech acts relevant for the specification of different forms of reasonings. This study takes place within

the dialogical framework in which the proof is conceived in terms of a dialectical process. The specificity of deductive and abductive reasonings is clarified by identifying different kinds of speech acts specific to each of these forms of reasoning. The aim is to show that abductive dialogues involve specific speech acts, namely certain conjectural claims that differ from usual assertions and questions of deductive dialogues. A more exhaustive study of commitment and its role in the definition of different kinds of speech acts in dialogical interaction which can also be found in *Walton and Krabbe* [14.3]. However, this study focuses here on some aspects of commitment related to assertions and questions in deductive dialogues and considers how to extend the picture to abductive dialogues. The context of this study is first explained. In order to defend a practical logic to study the fallacies, *Woods* [14.4] identifies what he calls *third-way reasoning*, which operates beyond the usual standards of deduction and induction. According to *Woods*, logicians have missed the target concerning the study of fallacies because they have failed to invoke the right standards of reasoning. The mistake is linked to an ostracism with respect to the human being when the task should be to describe reasoning. Indeed, in most logical studies of reasoning, the human being has simply been left out of the story! In *Woods*' own words, "there are no people in the models of mainstream mathematical logic" [14.4, p. 12].

*Toulmin* [14.1] also reports that logicians left out the human being while they were modeling reasoning. As a solution, he urges for the divorce between logic and argumentation by claiming that logic was too narrow to study argumentation. *Toulmin* was right in thinking that formal logicians had forgotten the human being. He was wrong in thinking that the solution was to dissociate logic and argumentation. Independently of how some logicians might have led their investigations, the point of view endorsed in this chapter is that an agent-centered logic (that is, a logic built around human activity) is possible. Logic and argumentation should again be brought together. Human beings play a fundamental role in third-way reasoning as well as in deductive reasoning.

A study centered on the role of the agent constitutes the condition of possibility of a unified theory of reasoning, that is, a theory in which logic and argumentation are analyzed together. What is to be considered is not a mere relation of consequence-having but a relation of consequence drawing. As stressed by *Woods* [14.4], while the former is a mere relation between propositions, the latter is to be linked with agent-based inferences, that is, actions by means of which an agent draws conclusions. The latter is the ba-

sis of what has been called an *agent-centered logic*. The position defended in this chapter, which is perhaps stronger than that of *Woods*, is that focusing on a consequence-having relation is also a mistake with respect to deductive reasoning. Reasoning, in general, must be studied in a general framework in which particular attention is paid to the action of the agents and their commitments.

More precisely, it is argued that deductive as well as nondeductive reasoning should be understood within argumentative practices, taking into account the interaction between agents. This can be achieved by means of dialogical logic, a semantics based on argumentative practices and presented as a game between a proponent of a thesis and an opponent to this thesis. More precisely, dialogical logic is grounded on speech acts and commitments related to these speech acts. That is, a dialogue is a sequence of speech acts, questions and assertions, in order to justify or challenge an initial thesis. Moreover, utterances are not free of further justifications: When we utter something, we are committed to providing justification of what we are saying. This is the basis of the rules which say how to challenge and how to defend an utterance. Deductive validity is thus conceived in terms of strategy by means of which a proponent of a thesis defends her initial claim against every attack of her opponent.

However, this is just deduction! Is it possible to generalize the picture to nondeductive reasoning? To answer this question, abductive reasoning will be considered as a case of nondeductive reasoning. A relevant conceptual question is therefore the following: What is the difference and the specificity of abduction with respect to other inference kinds? If it makes sense to talk about abduction as a third kind of inference, it is because it is neither a deductive nor an inductive inference.

According to *Gabbay and Woods* [14.5, p. 192], "[w]hereas deduction is truth-preserving and induction is probability-enhancing, abduction is ignorance-preserving." An abduction is triggered by an ignorance problem that arises when a fact cannot be explained by the current knowledge of an agent. The inability to solve an ignorance problem is a cause of discomfort, which *Gabbay and Woods* [14.5, p. 190] call a *cognitive irritant*. Such an unpleasant situation is sometimes overcome by conjecturing a hypothesis on the basis of which further actions are made possible. Even if such a conjecture allows the agent to overcome the irritant situation, it does not constitute a solution to the ignorance problem: It is only a defeasible hypothesis. This precisely grasps the specificity of abduction.

Rather than an explanation in terms of *ignorance problem*, the specificity of abduction is set from a di-

logical perspective in terms of *concession problem*. A *concession problem* is overcome by a conjecture on the basis of which the dialogue is continued. In contrast with the usual deductive dialogues, such a conjecture is settled in a new kind of move allowed by an additional rule. The difficulty is thus to specify which kind of speech act is at stake while performing such conjectural moves. Indeed, under the view endorsed in this chapter, conjectural moves are performed by means of speech acts which are neither assertions nor questions of usual deductive dialogues.

Reasons why Toulmin argues in favor of a radical separation between formal logic and argumentation are given in the first section. Although it is true that some aspects of argumentation such as the role of the agent, the dynamic of the contexts, and the defeasibility are to be taken into account, it is not a reason to conclude that formal logic and argumentation should be studied

separately. First, it is not true that those aspects are completely missing in formal logic. It is shown in the rest of this section that numerous formal logics deal with these aspects, although they have yet to be brought all together. Second, in this contribution, it is thought that even deduction is to be understood within argumentative practices. Hence, the dialogical framework is introduced in the third section, where it is come back to the key concept of commitment. It is also shown how dialogical logic enables to grasp the central role of the agent as well as the dynamics of the contexts in terms of a pluralist attitude. After having presented abductive reasoning in the fourth section, the scene for a dialogical understanding of abduction is set in the fifth section. All the details of dialogical pluralism, dynamics of contexts, and dialogical defeasibility cannot be given here. However, the relevant related works on each of these points will be systematically mentioned.

## 14.2 Logic and Argumentation: The Divorce

Heavy criticism against the formal logic approach to natural human reasoning has been raised by theoreticians of argumentation who have stressed the importance of the context, the plausibility and the defeasibility of arguments, the commitments and the actions of the agents, and so on. Some of the most virulent of these theoreticians were perhaps *Toulmin* [14.1] (see also [14.6] for recent studies about Toulmin Model) and *Perelmann* and *Olbrechts-Tyteca* [14.2]. This chapter focuses on Toulmin, who defined a model of argumentation based on the analysis of microarguments. This model will be called the *Toulmin Model* of argumentation whose general idea is that some data leads to the claim (or conclusion). The data is supported by a war-

rant. The whole process is qualified by an adverb such as *plausibly*, *probably*, or *necessarily*, that may be rebutted. An important insight of Toulmin’s work was to emphasize the role of the agent and the persuasive feature of argument. Arguments are used to persuade someone to believe something. An agent puts forward an argument in order to defend a thesis and the inferences are defeasible, that is, they might be rebutted when new information is encountered. Schematically, the Toulmin Model may be represented as in Fig. 14.1.

This schema represents the process that consists in defending a claim against a challenger. First, the agent asserts a *Claim* (C) and then defends this claim by appealing to relevant available facts, the so-called *Data*

Fig. 14.1 Toulmin Model

(D). Next, the challenger may ask for the bearing of the data and this is exactly what is called the *Warrant* (W). The warrant influences the degree of force on the conclusion it justifies and this is signaled by the qualifying of the conclusion with the *Qualifier* (Q): *necessarily*, *probably*, or *presumably*. The qualifier *presumably* renders the argument defeasible, and the condition of *Rebuttal* (R) should be specified. The process ends in a question that consists in asking what is thought about the general acceptability of the argument: what Toulmin calls *Backing* (B). In different fields, warrant and backing might be of different kinds.

According to the Toulmin Model, an argument is assumed to be used by a practical agent. Inferences are not conceived in terms of the relationship between propositions independent from any act. And the act of inferring is linked with the agent who expresses a claim, by means of which a commitment to a thesis is in fact expressed. The underlying methodological thesis is that the study of reasoning must be related to real-life reasoning. This kind of reasoning is never perfect (as in an ideal model of formal logic) because we never have all the information needed to defend a claim and we might always find a rebuttal that changes it. Hence, the right standard of a good argument cannot be the deductive standard of validity. An argument succeeds or fails only in relation to an agent's target. Toulmin's schema enriches the traditional premises–conclusion relationship of the deductive reasoning model of arguments by distinguishing additional elements, such as warrant, backing, and rebuttal. It is an interesting fact that the Toulmin Model and argumentation theory call up not only the matter of the burden of proof, but also the matter of the burden of questioning, which is of importance for the beginning of the process. A consequence of this action- and agent-centered analysis is that an account of the defeasibility of reasoning is now required. The fact that none of these features appeared in formal logic constituted the core of Toulmin's criticism, that led him to consider argumentation theory and formal logic as radically different disciplines.

There is nothing really controversial in Toulmin's critics of formal logic or in his model of argumentation. Nevertheless, following *van Benthem* [14.7], in this chapter, it is believed him to be wrong in pronouncing the divorce of argumentation theory and formal logic. Indeed, it might be true that classical formal logic is insufficient to deal with reasoning as a human activity. Classical formal logic is not the only way to do logic, however. Although Toulmin's work has the virtue of emphasizing the role of human being, the defeasible feature of everyday life reasoning, and the dynamic of argumentative contexts, it is worth noting that those features were not completely lacking in formal logic.

With respect to the agent, intuitionism initiated by the Dutch mathematician *Brouwer* [14.8] is motivated by the need of taking the importance of the agent into account. More recently, agent-centered dialogical logic initiated by *Lorenzen* [14.9, 10] conceives the notion of proof itself in terms of interactions between agents. It remains true that further efforts are still required to deal with nondeductive reasoning. Before pronouncing the divorce between logic and argumentation theory, it should be recognized that many logicians had already widened the range of argumentative schemas in formal logic, by adding the agent, thinking otherwise the premises–conclusion relation, and defining several kinds of consequence relations.

Certain cognate aspects of reasoning must be grasped. For example, inference is a process which involves a flow of information, changes of belief, knowledge or even desires. Logicians have to take the “dynamic turn”, in the words of *Gochet* [14.11]. That is why the agent has sometimes been introduced explicitly in the object language in order to express intentional relations by means of specific operators. The enterprise does not always head in the same direction as an agent-centered analysis (in fact it almost never goes in that direction) but the enterprise does provide new tools on how to implement the agent in the study of reasoning. *Hintikka's* explicit epistemic logic [14.12], and more recently *Priest's* intentional logic [14.13], among others, define useful tools to describe the intentional states of an agent. In addition, dynamic approaches, such as the AGM-Belief Revision Theory [14.14] (and see Chap. 10), are meant to give an account of how to incorporate new pieces of beliefs into an agent's belief set, conceived as a set of sentences. In the same spirit, dynamic studies coming from natural language semantics [14.15–18] and dynamic epistemic logic [14.17–19] add operators to deal with the flow of information and the transmission of information between groups of agents. The study of dynamic inferences is not restricted to model theory and to the change in information. From a pluralistic point of view, a change of logic might occur with respect to a given context of argumentation. For example, dialogical logic is a pluralist enterprise in which the context of argumentation is defined by means of rules governing the general organization of a dialectical game (more precision on this point below). Although this fails to provide Toulmin with an answer to each critic he addresses on formal logic, it does reveal how formal studies are sufficiently rich to consider the possibility of a more practical logic in which reasoning is conceived as a human activity.

Another aspect of argumentation stressed by Toulmin is the imperfect feature of human reasoning, which

he deals with by means of the notion of *rebuttal*. Thinking of reasoning as defeasible means that an agent never draws conclusions definitively, that is, whatever she infers from a given base of information might be revised when faced with new information. In other words, the conclusions drawn by an agent might be defeated. It is worth noting that defeasibility does not need to be studied in the context of nonmonotonic logics. If nonmonotonic reasoning is defeasible, the converse does not hold. Interesting ways of defeasible cases come from the context [14.20]. What characterizes defeasible reasoning is the possibility to defeat, or to change a previously drawn consequence. Again, this feature cannot be claimed to be completely missing in formal logic. Indeed, defeasible reasoning has been studied from various perspectives [14.21]. As already mentioned, one well-known approach is the epistemic approach such as that in the context of belief revision theory. The formal epistemology of *Pollock* [14.22], who differentiates between fundamental knowledge and inferred knowledges, provides another example. In this theory, inferred knowledge is precisely a knowledge which might be defeated. Another approach is centered on the notion of logical consequence, that is, dealing with defeasibility in the context of nonmonotonic logics (Chap. 10). Some of the most important proposals are Default Logic by *Reiter* [14.23] and Circumscription by *McCarthy* [14.24]. In both of these frameworks, the conclusion follows defeasibly or nonmonotonically from a set of premises, just in the case that it will hold in almost all models that verify the premises. (For a relevant survey, see for example [14.25–27]. See also the third-way reasoning in [14.4].) It is also important to mention *Batens'* adaptive logic [14.28], a formal logic in which the application of inference

rules may be subject to conditions with respect to the context of the proof (e.g., in the context of contradictory premises, disjunctive syllogism might be rejected).

The three main aspects of the Toulmin Model of argumentation that have been highlighted are the central role of the agent, the dynamics related to the action and changes of contexts, and defeasibility. In what follows, it will be argued for a reconciliation of formal logic and argumentation, and deduction will be also defined in argumentative practices. Note that it is not the purpose of this chapter to deal exhaustively with all the relevant aspects of argumentation. Indeed, every facet of the dialogical pluralism (although the general principles are explained and relevant related works are mentioned) or defeasible reasoning cannot be presented here. The designation *defeasible reasoning* gathers together aspects of default logic, nonmonotonic logics, truth maintenance systems, defeasible inheritance logics, autoepistemic logics, circumscription logics, logic programming systems, preferential reasoning logics, abductive logics, theory revision logics, belief change logics, and so on. In fact, all of this relates to what is called by *Woods* the *third-way reasoning* [14.4]. Various systematic approaches to defeasible argumentation that make use of formal tools originating from computational sciences and artificial intelligence can be found in [14.29].

The main thesis of this contribution is that a unified study of reasoning may be achieved by focusing on the key notion of commitment in argumentative interaction. Indeed, this notion forms the basis for a distinction between various kinds of speech acts that are significant for the specification of different kinds of reasonings, such as deduction and abduction.

## 14.3 Logic and Argumentation: A Reconciliation

It is true that a study of logic that is not centered on human activity is not sufficient to deal with reasoning in general. However, it is a mistake to conclude that the divorce between argumentation and logic is to be pronounced. Logic and argumentation must be brought together within a general framework in which a consequence–drawing relation, conceived as a human practice, is taken into account, and not a consequence–having relation conceived as a mere calculus between propositions. In the rest of this section, deduction is modeled inside an argumentation theory and the standard (deductive) dialogical logic is defined by giving the rules for the propositional level.

### 14.3.1 What is Dialogical Logic?

The dialogical logic referred to in this chapter has its roots in the works of *Lorenzen* and *Lorenz* [14.10], and more recently in *Rahman* [14.30] and his collaborators (see for example *Rahman* and *Keiff* [14.31], *Fontaine* and *Redmond* [14.32], and *Clerbout* [14.33]). Different works on dialogical logic have also been developed by *Barth* and *Krabbe* [14.34, 35], among others, and by the Pragma-dialecticians from an informal point of view [14.36, 37].

Dialogical logic is considered to be an alternative semantics, that is neither a model-theoretic semantics

nor a proof-theoretic semantics, and is grounded in the argumentative practices. It is a semantics based on the “meaning is use” of *Wittgenstein* [14.38, p. 43] and the description of specific language games governed by the rules defined below. Although it was first developed to deal with intuitionist logic, it has since then taken a pluralist turn. Indeed, different kinds of rules enable a sharp distinction between different semantic levels and this enables the definition of a wider range of logics in a unified framework.

Roughly speaking, dialogical logic is a framework in which the proof process is conceived as a dialectical game between two players: the *Proponent* of a thesis and the *Opponent*. The Proponent utters an initial thesis and tries to defend it against challenges performed by the Opponent, who criticizes the thesis. The two players make moves alternately. Those moves consist of specific speech acts by means of which they perform challenges and defences. A thesis is valid if and only if the Proponent is able to defend it against every attack of the Opponent. In order to criticize an assertion of her argumentation partner, a move in which a formula has been uttered has to be challenged with respect to its main connective. Such sequences of utterances, challenges, and defences are regulated by the particle rules by means of which the local meaning of the logical constant is given. In addition, structural rules give the general organization of the dialogue and determine the global level of semantics. In fact, these structural rules dictate how the particle rules may be applied and allow to define different games for different contexts of argumentation, for different underlying logics. In the following sections, the particle rules are given, then the structural rules, and finally, the notion of winning strategy which is necessary for the definition of the dialogical notion of validity is presented.

### 14.3.2 Particle Rules

In a dialogical games, moves are of two different kinds: challenges and defences (plus the utterance of the initial thesis as a special move), and are performed by means of two kinds of speech acts: assertive utterances and interrogative utterances. Note that challenges are not necessarily performed by means of interrogative utterances (as shown later below). An utterance is challenged with respect to its main connective. How to challenge and how to defend an utterance is prescribed by the particle rules, which therefore gives the local meaning of logical constants. More precisely, particle rules are abstract descriptions of how an assertion may be challenged and defended with respect to its main connective. They are abstract because they are not related to any specific context of argumentation and are

defined independently of the identity of **P** and **O** (hence they are defined making use of player variables **X** and **Y**). It is fundamental that when agents perform utterances, they are committed to justify their claims. This commitment is essential in the characterization of different kinds of speech acts and in giving the meaning of what is said.

The language used to define the rules of dialogical logic is defined as follows. Let *L* be the language of standard propositional logic:

- Two labels, **O** and **P**, stand for the players of the game: the Opponent and the Proponent, respectively.
- To define particle rules, variables **X** and **Y** are required, with  $X \neq Y$ , that hold for players (regardless of their identity with **O** or **P**).
- Force symbols, ! and ?, are used to specify the kind of speech act at stake: ! for declarative utterances, and ? for interrogative utterances.
- The conjunction can be indexed yielding  $\wedge_i$ , where  $i \in \{1, 2\}$ , such that  $\wedge_1$  stands for the first conjunct, and  $\wedge_2$  the second.
- $r := n$  indicates the rank chosen by the player at the beginning of a dialogue, as pointed out by the rule [SR0]. For example,  $n := 1$  means that the rank is 1. (The notion of rank is explained and defined in Sect. 14.3.3)

A *move* is an expression of the form  $X-f-e$ , where **X** is a player variable, *f* a force symbol, and *e* is either a well-formed formula of *L* or a question of the form  $? \vee$  or  $? \wedge_i$ . Note that the dash – has no meaning, it is used only in order to distinguish in a clear way the element of a dialogical expression. A sequence of such moves will be called a *play*, and a sequence of plays a (dialogical) *game*.

Particle rules (Table 14.1) are abstract descriptions that consist of sequences of moves such that the first member of the sequence is an assertive utterance, the second says how to challenge that utterance with respect to its main connective, and the third says how to answer the challenge.

Rules are *abstract descriptions* that are formulated by making use of variables **X** and **Y** (and not **O** and **P**).

**Table 14.1** Particle rules

Assertion	Challenge	Defence
$X-!-\varphi \wedge \psi$	$Y-?- \wedge_1$ or $Y-?- \wedge_2$ ,	$X-!-\varphi$ or $X-!-\psi$ respectively
$X-!-\varphi \vee \psi$	$Y-?-?\vee$	$X-!-\varphi$ or $X-!-\psi$
$X-!-\neg\varphi$	$Y-!-\varphi$	No defence
$X-!-\varphi \rightarrow \psi$	$Y-!-\varphi$	$X-!-\psi$

They are independent of any specific context of argumentation. They are the same no matter the presupposed logic and are applied in the same way by both players. The formulation of particle rules is symmetric.

Symmetry is an essential feature of dialogical particle rules and this is the reason why dialogical logic is immune to trivializing connectives such as *Prior's* tonk [14.39], even if there is no reference to any model or to any truth condition. *Rahman* et al. [14.40] and *Rahman* [14.41] show that defining a rule for a tonk operator would lead to a formulation of particle rule which is not symmetric. This would involve player-dependent rules, which is not possible in dialogical logic because, at the local level, the identity of the players has not been yet defined. As rightly stressed by *Clerbout* [14.33], it does not even make sense to talk of Opponent and Proponent at the local level. Indeed, the identity of the players is defined at the level of structural rules, when it is said, for example, that the Proponent is the player who utters the initial thesis.

Note how commitment is essential to the meaning of an assertion. An agent, on uttering a conjunction, is committed to give a justification for both of the conjuncts. Hence the challenger has the choice of which subformula to defend. That is, if **X** utters  $\varphi \wedge \psi$ , **Y** challenges this move by asking either  $?\wedge_1$  (the first conjunct) or  $?\wedge_2$  (the second conjunct). In the case of a disjunction, it is the defender (**X**) who chooses. Indeed, an agent uttering a disjunction is committed to give a justification for (at least) one of the disjuncts, that is, **Y** asks  $?\vee$  and **X** chooses to answer either  $\varphi$  or  $\psi$ .

Note that a challenge on a negation cannot be answered. The challenge consists in a switch in the burden of the proof: If a player **X** utters a formula  $\neg\varphi$ , a player **Y** challenges that formula uttering  $\varphi$  and has to defend it thereafter. For the conditional, **Y** takes the burden of the proof of the antecedent. It might be said that when an agent **X** utters a conditional  $\varphi \rightarrow \psi$ , then **X** is committed to justifying  $\psi$  with the proviso that the argumentation partner **Y** concedes  $\varphi$ .

### 14.3.3 Structural Rules

Now structural rules are needed in order to define the general organization of a dialogue by explaining how to apply the particle rules, that is, how to start a dialogue, who has to play, when, who wins, and so on. The global level of meaning is defined by these rules, that is, a level of meaning that arises from the application of the particle rules in specific contexts of argumentation.

#### [SR0] [Starting Rule]

Let  $\varphi$  be a complex formula. Every dialogical game

$D(\varphi)$  starts with the assertion of  $\varphi$  by **P** ( $\varphi$  is called the *initial thesis*). **O** and **P** then choose a positive integer called *repetition rank*.

#### [SR1-c] [Classical Gameplay Rule]

After the ranks have been chosen, moves are alternately performed by **O** and **P** and every move is either a challenge or a defence. Let  $n$  be the repetition rank of a player  $X$ : When it is  $X$ 's turn to play,  $X$  can challenge a preceding utterance or defend herself against a preceding challenge at most  $n$  times by the application of particle rules.

#### [SR1-i] [Intuitionistic Gameplay Rule]

After the ranks have been chosen, moves are alternately performed by **O** and **P** and every move is either a challenge or a defence. Let  $n$  be the repetition rank of a player  $X$ : When it is  $X$ 's turn to play,  $X$  can challenge a preceding utterance or defend herself against *the last challenge which has not yet been defended*, at most  $n$  times by the application of particle rules.

#### [SR2] [Formal Rule]

**P** is not allowed to utter an atomic formula unless **O** uttered the same atomic formula before. Atomic formulae cannot be challenged.

#### [SR3] [Winning Rule]

A player **X** wins the game if and only if the game is finished and **X** made the last move. It is said that a game is finished if and only if there are no more moves allowed according to the particle rules.

The first rule [SR0] sets the identity of the players by claiming that the Proponent is the one who utters the initial thesis and introduces asymmetry. Once the initial thesis is uttered, the players have to choose a rank of repetition. That rank of repetition prevents them from infinitely repeating the same moves. In fact, they indicate how many times a player can challenge or defend a formula. For example, if a player chooses rank 1, then this player is allowed to challenge a formula at most once. Ranks are used to ensure that every game ends after a finite number of moves. Rules [SR1-c] and [SR1-i] regulate the gameplay and distinguish classical from intuitionistic games. Note that a game is never played with both of them. The classical rule [SR1-c] does not impose any restriction with respect to the defences. While playing with the intuitionistic rule [SR1-i], it is forbidden to defend the same move twice or to give a defence against a challenge that is not the last one. This is related to the intuitionistic requirement of having a direct justification for the uttered formula.

The formal rule, [SR2], might be understood as a rule that prevents the Proponent from making any supposition which might be used to win. Without that rule, dialogues would be trivial and the Proponent would al-

ways be in a situation to win. Finally, the winning rule, [SR3], gives the conditions of victory.

### 14.3.4 Winning Strategy and Validity

Hitherto, nothing has been said about the notion of validity. In dialogical logic, validity is not defined in terms of truth preservation but rather in terms of winning strategy. It is said that a player has a winning strategy if and only if she is able to win regardless of the moves and the choices made by her argumentation partners. This leads to the strategic level which is not involved at the level of particle and structural rules. Indeed, nothing in those rules indicate how to play strategically and in no way do they indicate how to win; neither do they prevent anybody from playing badly. Note then that it is not one play of the game which is to be taken into account to determinate the validity of a formula: The validity of a formula is determined by the existence of a winning strategy.

Now, it is reasonable to ask whether a generally good strategy exists. First a comment about the choice of rank. As explained by Clerbout [14.33,42], it is sufficient to consider the case in which the Opponent chooses rank 1 and the Proponent rank 2 in order to obtain a significant range of winning strategies to deal with deductive validity. Second, trained dialogicians know in fact that the best way to play is always to let the Opponent choose first when it is possible and thereafter to repeat the same choices. This is the well-known copy-cat strategy based on a clever use of the formal rule.

An illustration of a dialogue is given in Table 14.2 by taking the elimination of double negation principle  $\neg\neg p \rightarrow p$  as an example. In Table 14.2, the moves of the players are written down in the column **O** for the **O**-moves, and in the column **P** for the **P**-moves. The number of a move is indicated in the outer column whereas those of the challenges moves are indicated in the inner columns. The game runs by applying the classical rule [SR1-c].

At move 0, **P** states the initial thesis. At move 1, **O** chooses rank 1 and **P** chooses rank 2. At move 3, **O** challenges the initial thesis uttering the antecedent of the conditional, namely  $\neg\neg p$ . **P** cannot answer immediately by giving the consequent  $p$  because **P** cannot utter an atomic formula. Therefore, at move 4, **P** challenges the double negation  $\neg\neg p$  by uttering  $\neg p$ . No defence is allowed and **O** has to counter-attack by uttering  $p$ . **P** uses that concession to answer to the attack 3 at move 6. Again, **P** wins. However, this game has been

Table 14.2 Dialogue 1

	<b>O</b>		<b>P</b>		
			$\neg\neg p \rightarrow p$	0	
1	$r := 1$		$r := 2$	2	
3	$\neg\neg p$	0	$p$	6	
	---		3	$\neg p$	4
see o 5	$p$	4	---		

played with classical rule [SR1-c]. If it had been played with the intuitionistic rule [SR1-i], **P** would have lost. **P** could not have performed move 6 because the last challenge of **O** is 5, not 3 ([SR2]). Thus the dialogue would have ended at move 5 with a victory by **O**.

These two different possible gameplays illustrate the difference between classical and intuitionistic negation. Quine’s claim “change of logic, change of subject” [14.43, pp. 80–94] must be thought otherwise. Indeed, the dialogical setting displays that negation has the same local meaning in every logic, and its global meaning is changing according to its use in different contexts of argumentation. Both the semantic levels are significant in fully defining the meaning of an expression.

Beyond the classical and intuitionistic logics, the sharp distinction between the particle rules and the structural rules allows a development of dialogical logic as a pluralistic tool. The pluralistic aspect of dialogical logic allows us to deal with various kinds of argumentation contexts and their dynamics, the importance of which has been stressed by argumentation theoreticians. Indeed, more expressive languages may be introduced by means of the introduction of new symbols, the (local) meaning of which will be given by a particle rule. A language may be used in different contexts of argumentation, with various underlying logics. Dialogically, this means that a language may be used in different kinds of games distinguished by their structural rules.

As stated earlier, it is not the purpose of this contribution to present all the varieties of dialogical logics which nevertheless should be taken into account in order to deal with the contextual aspect of argumentation. More details on first-order dialogical logic are to be found in Clerbout [14.42]. With different structural rules it is also possible to define a dialogical free logics as in Rahman et al. [14.44], Fontaine and Redmond’s paper in [14.45] and an application to the logic of fiction is to be found in Fontaine [14.46]. For the introduction of modal operators (and explicit contexts of argumentation) and their use in different modal frames, see [14.47] and [14.31].

## 14.4 Beyond Deductive Inference: Abduction

Within dialogical logic, an analysis of the relation of consequence–drawing in terms of argumentative games in which the action of the agents and their interactions are taken into account has been proposed. Until now, it has been focused on deductive reasoning. However, if the aim is to bring together logic and argumentation, it is necessary to extend the dialogical approach to nondeductive reasoning. This is performed by taking abduction as a case of nondeductive reasoning. After having defined the conception of abduction that will be defended here, the basis for abductive dialogues will be described. While relying on existing proposals in this field, the aim is to offer a new and different understanding of abduction in the context of a dialogical interaction.

As explained by *Magnani* [14.48], the *knowledge assimilation theory* of *Kowalski* [14.49], in which the assimilation of new information into a knowledge base is described, might explain the role of the agent in abduction in terms of the generation of hypotheses. *Aliseda* also explores an epistemic study of abduction in which a more important role would be given to the agent. She defines abduction in terms of epistemic changes in the context of Belief Revision Theory [14.50, pp. 179] (see also Chap. 10). The role of the agents might be strengthened by developing that approach in the context of dialogical logic, and more precisely in the context of the dialogical approach to belief revision of *Fiutek* [14.51]. In a similar way, *Nepomuceno* et al. [14.52] (see also Chap. 13 by *Nepomuceno* et al.) define abduction in the context of dynamic epistemic logic and its public announcement operator. This might be dialogically understood on the basis of *Magnier* [14.53]. However, this is not the path followed in this contribution, because the agent would be introduced into the language and abduction would still be understood in terms of consequence–having relation, despite some kind of interaction in a dialogical reconstruction. Moreover, an epistemic understanding of abduction would lead to consider hypothetical *abductive solutions* as new pieces of knowledge; something that is not defended in this chapter, as clarified in the following.

Essentially, the challenge consists in explaining what is specific to abduction in a dialogue. As shown below, while studying abduction, the concepts of *abductive problem* and *abductive solution* are fundamental (Chap. 10). In order to define dialogues based on these concepts, a new kind of move performed by means of a specific type of speech act is needed. Therefore, the problem is to clarify this type of speech act and the rules which govern it. Again, the key question

is related to commitment: What are we committed to when we state an *abductive problem* or an *abductive solution*? The purpose is to understand abduction in terms of consequence–drawing and to study the key step of such an inference in terms of interactions in relation to the question of commitment. Therefore, although there exists different approaches to abduction, in this chapter, the GW schema (following *Gabbay* and *Woods* [14.5]), in which a central role is given to the agent, constitutes a landmark. This contribution will also rely on *Aliseda*'s insights [14.50] when a dialogical reconstruction of abduction is proposed, thereby benefitting from her clear and formal systematization of this kind of inference.

### 14.4.1 The GW Model of Abduction

What is characteristic to abduction and is not characteristic to other reasoning kinds, such as deduction and induction? When is an abduction triggered? Why does an agent begin an abductive process? How does an agent draw abductive conclusions and what is the (cognitive or epistemic) status of those conclusions? According to *Gabbay* and *Woods* [14.5, 54], and more recently *Woods* [14.4], abduction is first to be understood as an inference triggered by an ignorance problem and, second, the relation between the premises and the conclusion is to be understood as an ignorance–preserving relation.

Abduction is an inference triggered in response to an ignorance problem, in particular, there is an ignorance problem when, with respect to a (surprising) fact or state of affairs, there is a question (a problem),  $Q$ , we cannot answer with our present knowledge. We assume that there is a sentence  $\alpha$  such that if we knew it, it would help us to answer  $Q$ . With respect to such a  $Q$ , three situations are possible:

- Subduance, that is, new knowledge removes ignorance (e.g., by discovering an empirical explanation)
- Surrender, that is, we give up and do not look for an answer
- Abduction, that is, we set a hypothesis as a basis of new actions.

Abduction is thus an inference by means of which we do not solve the ignorance problem, but we overcome it in a certain way by setting a hypothesis. This hypothesis can then be released in further reasoning, something which allows for specific kinds of actions. In *Woods*' words, abduction “is a response that offers the agent a reasoned basis for new action in the presence of that ignorance” [14.4, p. 368]. Therefore, what

must be grasped here is that the conclusion of an abduction is not (necessarily) a true sentence or a new piece of knowledge; it is a hypothesis that can be used in further reasoning. The ignorance contained at the level of the premises is inherited by the conclusion. What is specific in the relation between premises and conclusions here is not a gain of knowledge, but rather an ignorance-preserving relation.

For reasons of clarity, the GW schema is formally presented following Woods' latest version in [14.4, p. 369]. Let  $T$  be an agent's epistemic state at a specific time,  $K$  the agent's knowledge base at that time,  $K^*$  an immediate successor base of  $K$ ,  $R$  an attainment relation for  $T$  (that is,  $R(K, T)$  means that the knowledge-base  $K$  is sufficient to reach the target  $T$ ),  $\rightsquigarrow$  a symbol denoting the subjunctive conditional connective, for which no particular formal interpretation is assumed, and  $K(H)$  the revision of  $K$  upon the addition of  $H$ .  $C(H)$  denotes the conjecture of  $H$  and  $H^c$  its activation. Let  $T!Q(\alpha)$  denote the setting of  $T$  as an epistemic target with respect to an unanswered question  $Q$  to which, if known,  $\alpha$  would be the answer. According to the GW schema, the general structure of abduction is as follows:

1.  $T!Q(\alpha)$
2.  $\neg(R(K, T))$  [fact]
3.  $\neg(R(K^*, T))$  [fact]
4.  $H \notin K$  [fact]
5.  $H \notin K^*$  [fact]
6.  $\neg R(H, T)$  [fact]
7.  $\neg R(K(H), T)$  [fact]
8.  $H \rightsquigarrow R(K(H), T)$  [fact]
9.  $H$  meets further conditions  $S_1, \dots, S_n$  [fact]
10. Therefore,  $C(H)$  [subconclusion, 1-7]
11. Therefore,  $H^c$  [conclusion, 1-8]

The aim, here, is to characterize what is specific to abductive inference, by taking into account what triggers such an inference, and to describe the subsequent process. At the beginning, a cognitive target  $T!Q(\alpha)$  is set (1): something we aim to reach in response to an ignorance problem. The ignorance problem triggers an abduction because it is a cognitive irritant, that is, it places us in an unpleasant situation of lack of knowledge which can be overcome by action and reasoning.

Step (2)  $\neg(R(K, T))$  says that the current knowledge is insufficient to attain the cognitive target. This is essential if we face an ignorance problem. Step (3),  $\neg(R(K^*, T))$ , says that there is no immediate successor of  $K$  by means of which the target would be attained. This is a crucial step. If there were such a  $K^*$ , we would just extend our knowledge by adding new information and would refrain from triggering anything such as an abduction. This would be subduance, that is, new knowledge would remove the initial ignorance.

If there is no  $K$  or  $K^*$  relating to the cognitive target, a hypothesis  $H$  is sought by the agent in order to set a plausible solution to the ignorance problem. Such a hypothesis is not knowledge, it is a hypothesis. This is represented in steps (4) and (5). Since it is only a hypothesis, it cannot relate to the cognitive target either, because it is not a solution. Even combined with the knowledge set, the cognitive target is not attained. This is expressed in steps (6) and (7).

What is the purpose of the hypothesis  $H$  if it does not solve the problem? In step (8), it is settled as a hypothesis that *subjunctively* relates to the cognitive target in combination with our knowledge base. What does this mean that it *subjunctively* relates to the cognitive target? This is how Gabbay and Woods understand Peirce's, *hence*, in the schema laid down by Peirce [14.55, 5.189] (see also Chap. 10 for the original formulation). It means that it is not a true sentence, it is not a piece of knowledge either, but if it were, it would give an acceptable solution to the cognitive problem. As in step (9), some additional conditions should be added for the acceptability of  $H$ .

Having set hypothesis  $H$  as a *subjunctive* solution of the cognitive problem, abduction first consists in concluding that we are right in conjecturing that hypothesis. This is the first subconclusion at step (10).  $C(H)$  means that the hypothesis  $H$  is conjectured. It is important to notice here that abduction does not end at step (10). Indeed, by taking seriously the fact that abduction is triggered by a cognitive problem, we trigger an abduction not to conjecture a hypothesis, but in order to find a possibility of further actions despite the lack of knowledge. Therefore, the abduction should not end before step (11), that is, when the conjecture is released and when the hypothesis is used in further reasoning as a basis for new action.  $H^c$  represents the hypothesis released in a further reasoning, that is, in a reasoning in which we act on the hypothesis  $H$  and the superscript  $c$  indicates the conjectural origin of the hypothesis. Following Woods [14.4, p. 371] an inference that ends at step (10) will be called a *partial abduction*, and an inference continuing with step (11) a *full abduction*.

For the purpose of clarity, in step (10) we face two possibilities. First, we do not test the hypothesis but we use it in a further reasoning (as in step (11)). This is precisely what is called *full abduction*. Second, we test the hypothesis, by empirical methods, for example. This presents us with three possibilities. First, the hypothesis is confirmed and we obtain a new piece of knowledge; this would lead to a situation similar to the  $K^*$  situation above. In this case, no full abduction is triggered, that is, we do not act on the hypothesis in an ignorance-preserving way. In fact, we would end with

new knowledge and this is subduance, or hypothetico-deductive reasoning, induction or even a mix, but this is not abduction. Second, we do not have confirmation and give up on the hypothesis: again this would end in a partial abduction. Third, we do not have confirmation but we continue with the hypothesis and perform a full abduction.

This is what leads Woods [14.4] to claim that abduction should not be understood as an inference to the best explanation (that would consist of the first part of the abduction schema, with respect to certain aspects), but rather as an inference *from* the best explanation. That is, we opt for a hypothesis and make an inference by activating that hypothesis. The following example of daily reasoning illustrates this point:

*Shahid* and *Ángel* are in Mexico City at the *Baranca del Muerto* underground station (Fig. 14.2). They want to go to a conference near *Universidad*. On their map, the new line (dotted line on the map) between *Mixcoac* and *Zapata* is missing. They do not know the existence of this line and decide to travel first to *Tacubaya*. During the trip to *Tacubaya*, they see a workmate disembarking the train at *Mixcoac*. They think their workmate will be late and they proceed to change in *Tacubaya*. There, they board another train to *Centro Médico* where they will change again to go to *Universidad*. When they arrive at the conference they are surprised to see their workmate already there. The fact to be disclosed is now that there is a faster way to go to *Universidad* which cannot be explained on the basis of the information contained on the incomplete map.

With respect to the previously detailed GW schema, step (1)  $T!Q(\alpha)$  is such that  $Q$  is the question of knowing how their workmate might have arrived so early. The cognitive target  $T$  would be a situation in which an  $\alpha$  is known such that  $\alpha$  would be the answer to that question. With respect to step (2), their knowledge base is insufficient to answer the question because their map does not show any another way to reach *Universidad* ( $\neg(R(K, T))$ ). In step (3), they receive no further knowledge (e.g., an updated map) to answer the question ( $\neg(R(K*, T))$ ). There are three possibilities: First, they do not care and follow the same trip as the day before (surrender). Second, they search for more information and obtain an updated map in which the line between *Mixcoac* and *Universidad* appears (subduance). Note that in this last case, no abduction is triggered, a new piece of information is added to the knowledge base (such that the new knowledge-base  $K^*$  explains why the workmate went faster the day before  $\neg R(K*, T)$ ). Third, they perform an abduction. That is, they conjecture the existence of the line and, therefore, they can leave half an hour later the following day. The exist-

Fig. 14.2 México City Metro

tence of such a line is a hypothesis,  $H$ , and is such that  $H \notin K$  (step (4)) and  $H \notin K^*$  (step (5)), and is not part of any knowledge set. Therefore, step (6) holds because  $H$  is not an established fact and does not relate to the target ( $\neg R(H, T)$ ). Moreover, step (7) also holds because even combined with their knowledge-base  $K$ , it does not relate to the cognitive target ( $\neg R(K(H), T)$ ). Step (8) is crucial because  $H$  only subjunctively relates to the cognitive target, that is, the effective existence of another line might be such that, when added to the knowledge-base  $K$ , it would allow the cognitive target  $T$  to be reached. However,  $H$  is only a hypothesis and without further information, it does not constitute an  $\alpha$  answer to  $Q$  that would relate to the cognitive target  $T$ . If  $H$  meets further conditions ( $S_1, \dots, S_n$ ) it might be considered as a good or plausible explanation, perhaps the *best* one, as expressed in step (9), and that hypothesis would be conjectured as in step (10) ( $C(H)$ ). The following day, *Sahid* and *Ángel* stop at *Mixcoac* as if they knew the existence of this line, but in fact they do not. That is, step (11), they release the conjectured hypothesis ( $H^C$ ) and act upon it despite their persisting ignorance with respect to the genuine explanation of the initial problem.

The fact that an epistemic view of the abductive inference thus described would not grasp the specificity of abduction has to be emphasized. Indeed, the new hypothesis is not to be considered as a new piece of knowledge or belief. It might be accepted as an abductive conclusion and as a good explanation without being believed or accepted as *the* good explanation. What is

characteristic of an abduction is the conjectural aspect of its conclusion and the activation of the hypothesis in further reasoning. What is essential to an abduction is

that the cognitive target is not attained by a definitive solution of the initial problem at the level of the conclusion.

## 14.5 Abduction in Dialogical Logic

It is time to propose a dialogical understanding of abduction and its basic concepts. In previous work, Keiff [14.56, pp. 200ff] defines *abductive problems* in the context of substructural dialogues, namely dialogues in which optimal rules to defend a thesis are sought. Roughly speaking, in the context of substructural dialogue for modal logic for example, the Proponent is allowed to conjecture the accessibility relations that are needed for the defence of her thesis, while this kind of move is forbidden in modal dialogical logic. The framework now outlined is rather different and more general, even if some basic problems remain similar.

Although some given explanations have their roots in the GW model and Aliseda's characterization of abduction, the aim is not to give a faithful dialogical formalization of these approaches. The point is rather to identify the general features of abductive dialogues following these three main questions:

- How can a surprising fact, an *abductive problem* and (or) an ignorance problem be characterized?
- How can the guessing step, in which a hypothetical explanation is conjectured, be characterized?
- How can the ignorance-preserving feature of abduction be characterized?

The first question relates to the conditions under which an *abductive problem* may be stated in a game, that is, the *triggering* of an abductive dialogue must be described. The second question relates to the possibility of conjecturing an explicative hypothesis during the dialogue, that is, the act of *guessing* specific to an abductive dialogue must be described. The third question relates to the conjectural status of the explicative hypothesis in a dialogue, that is, the question of the *commitment* must be asked. Indeed, what are we committed to when we conjecture a hypothesis? This last question is more complicated and involves in-depth considerations about the defeasible aspect of conjectures. In this chapter, this difficulty will be explained in terms of *not-conceded preservation*, that is, a hypothesis that has not been conceded by the opponent, remains not conceded at the end of an abductive dialogue even if the Proponent has conjectured it. In fact, it is the general point of this contribution to propose a dialogical explanation of abduction in terms of what is called a *concession problem*.

The leading idea is to allow the Proponent to claim *I am facing an abductive problem* when this agent has no winning strategy for a thesis  $\Phi$  given some shared knowledge or an accepted theory  $\Theta$ . As explained below, the theory  $\Theta$  is represented as a set of initial concessions of the Opponent.  $\Phi$  is the thesis that the Proponent cannot explain on the basis of the initial concessions, that is,  $\Phi$  holds for a *surprising* fact. If the Proponent is able to justify which kind of *abductive problem* she is being faced, then she triggers a subdialogue in which she is allowed to conjecture a hypothetical explanation  $\alpha$ .

The Proponent then has to show that this conjecture is such that if it had been conceded, it would have enabled her to explain the surprising fact expressed by  $\Phi$ . However, the hypothetical explanation  $\alpha$  remains not-conceded at the end of the dialogue and the Proponent only *subjunctively* and *defeasibly* wins. To parallel the explanation to the GW model, let the target  $T$  of the Proponent be the situation in which she wins the dialogue, the question  $Q$  be a set of challenges she is unable to answer, and  $\alpha$  that which would enable her to defend herself against those challenges. When the Proponent conjectures a hypothesis  $\alpha$ , the target is only subjunctively attained. In other words, the Proponent is in a situation, such that *if  $\alpha$  had been conceded, she would have explained  $\Phi$* . The explicative feature of the conjectured  $\alpha$  may thus be interpreted in the spirit of the *subjunctive attainment relation* ( $\rightsquigarrow$ ) of the GW model of abduction. The situation also parallels the  $\neg R(H, T)$  and  $\neg R(K(H), T)$  of the GW model because the Proponent does not actually reach the target. Note that this process, which will be described in this section, is simply partial abduction. In order to attain a characterization of full abduction, it should be explained how to release the conjectured hypothesis in a further dialogue and how to act upon it. This requires in-depth considerations about the specificity of the speech act by means of which such a hypothesis is conjectured. This issue will be dealt with in Sect. 14.6.

### 14.5.1 Triggering

The triggering of an abductive dialogue is characterized within what is called by Rahman and Keiff [14.31] and Rahman and Tulenheimo [14.57] *material dialogues*,

**Table 14.3** Dialogue 2

	O		P	
$\Theta_1$	$A \rightarrow B$			0
$\Theta_2$	$B \rightarrow (C \wedge \neg E)$		$C \wedge \neg E$	
$\Theta_3$	$D \rightarrow (C \wedge \neg E)$			
1	$m := 1$		$n := 2$	2
3	$? \wedge_1$			

that is, dialogues with the standard rules plus initial concessions of the Opponent. For example, let  $\Theta$  be a theory or a knowledge base consisting of several sentences, and  $\Phi$  be the initial thesis. A material dialogue begins with **O** conceding all the formulae contained in  $\Theta$  and with the initial thesis uttered by **P**. The dialogue then runs as usual. The following example, with  $\Theta = \{A \rightarrow B, B \rightarrow (C \wedge \neg E), D \rightarrow (C \wedge \neg E)\}$  and  $\Phi = C \wedge \neg E$ , is given in Table 14.3.

In Dialogue 2 (Table 14.3), **O** concedes the formulae of  $\Theta$  numbered  $\Theta_1, \dots, \Theta_n$ . **P** states the initial thesis  $C \wedge \neg E$ . Both choose a rank. At move 3, **O** challenges the initial thesis by asking for the first conjunct. **P** cannot answer because the required  $C$  is an atomic formula. There is no winning strategy for **P** for  $\Phi$ , given the initial concessions  $\Theta_1, \dots, \Theta_n$ . If  $\Theta_1, \dots, \Theta_n$  is interpreted as the shared (assumed) knowledge and  $\Phi$  as holding for a fact, then it might be said that  $\Phi$  represents a surprising fact which cannot be explained by the current knowledge. The idea is now that in such a situation, **P** has to be allowed to claim that she is facing an *abductive problem*. In fact, as it is clear in the dialogue (Table 14.3), an *abductive problem* is triggered by a *concession problem*: **P** cannot explain her thesis on the basis of the concessions.

The notion of *abductive problem* is dialogically defined following Aliseda's [14.50, p.47] definitions of abductive novelty and abductive anomaly (see also Chap. 10): **P** will now be allowed to claim *I am facing an abductive novelty* or *I am facing an abductive anomaly*, as in the rules [SR-AN] and [SR-AA] below. In the first case, **P** is committed to show that neither  $\Phi$  nor  $\neg\Phi$  is entailed by  $\Theta$ . In other words, **P** has no winning strategy for  $\Phi$  nor for  $\neg\Phi$ , given  $\Theta$ . In the second case, **P** is committed to show that  $\Phi$  is not entailed by  $\Theta$  while  $\neg\Phi$  is. That is, **P** has a winning strategy for  $\neg\Phi$  but not for  $\Phi$  given  $\Theta$ . Here, the technical difficulty is that the Proponent would need a *losing strategy* in order to justify she is facing an abductive novelty or an abductive anomaly. How strange such a game would be!

**Table 14.4** Particle rule for  $\mathcal{F}$  operator

Assertion	Challenge	Defence
$X \text{--}! \text{--} \mathcal{F}_\Theta \Phi \text{--} d_1$	$Y \text{--}? \mathcal{F}_\Theta \text{--} d_{1,i}$	$X \text{--}! \text{--} \neg(\Theta \rightarrow \Phi) \text{--} d_{1,i}$
	$Y$ opens a subdialogue $d_{1,i}$ .	

The difficulty is easily overcome by making use of the *attackability* operator  $\mathcal{F}$  introduced by Rahman and Rückert [14.58] in their dialogical connexive logic. This  $\mathcal{F}$  operator allows the Proponent to claim that under some conditions, the formula in the scope of that operator cannot be defended. Here a subscript is used in order to apply this operator in material dialogues. That is, if **X** says  $\mathcal{F}_\Theta \Phi$ , then she is claiming that  $\Phi$  may be attacked given the premises  $\Theta$ . The rule is stated in Table 14.4.

Note that the rule is formulated with an indication for what is called *section of a dialogue*, i. e. main dialogue ( $d_1$ ) and subdialogue ( $d_{1,i}$ ), in accordance with the following definitions:

**[D2] [Main Dialogue  $d_1$ ]**

The first section of a game in which **P** defends an initial thesis is called *main dialogue*  $d_1$ .

**[D3] [Subdialogue]**

The subdialogue triggered by the challenge of an  $\mathcal{F}$  operator in a section  $d_1$  or the subdialogue triggered by an *AS-challenge* is called *subdialogue*  $d_{1,i}$ . Note that this rule allows subdialogues of subdialogues (i. e., a subdialogue  $d_{1,i,i}$  triggered in a subdialogue  $d_{1,i}$ , for example in the case of an *AS-challenge*, as defined in the next section).

The main idea is that **X** justifies  $\mathcal{F}_\Theta \Phi$  by showing that  $\Phi$  cannot be justified, given  $\Theta$ . This supposes a device that allows switches of the burden of proof, in addition to the particle rule for the  $\mathcal{F}$  operator. This presupposes a generalization of the formal rule by means of a structural rule which says that the player who plays formally (i. e., the player who cannot introduce atomic formula) is the player who challenges an  $\mathcal{F}$  operator (or the player who defends an *AS-move*). In other words, the argumentation partner who challenges a formula such as  $\mathcal{F}_\Theta \Phi$  will have to take the burden of the proof by defending  $\Phi$  under the formal restriction.

**[SR2.1] [Formal Restriction]**

Let  $d_n$  be a section of a dialogue (main dialogue or subsection): If **X** plays under formal restriction in  $d_n$ , then **X** is not allowed to utter an atomic formula unless **Y** uttered the same atomic formula before in the same section  $d_n$ .

The rule governing the application of the formal restriction is now defined as follows:

**Table 14.5** Dialogue 2.1

O		$d_1$		P	
...	...	...	...	...	...
3	? $\wedge_1$				
				$\mathcal{F}_\Theta(C \wedge \neg E) \wedge \mathcal{F}_\Theta \neg(C \wedge \neg E)$	4
5	? $\wedge_1$	4		$\mathcal{F}_\Theta(C \wedge \neg E)$	6
$d_{1,1}$					
7	? $\mathcal{F}_\Theta$	6		$\neg(\Theta \rightarrow (C \wedge \neg E))$	8
9	$\Theta \rightarrow (C \wedge \neg E)$	8		---	
11	$C \wedge \neg E$		9	$\Theta$	10
...	...	...	...	...	...

**[SR2.2] [Application of the Formal Restriction]**

The application of the formal restriction is regulated by the following conditions:

1. In the main dialogue  $d_1$ , if  $\mathbf{X} = \mathbf{P}$ , then  $\mathbf{X}$  plays formally.
2. If  $\mathbf{X}$  opens a subdialogue  $d_{1,i}$  by challenging an  $\mathcal{F}$  operator, then  $\mathbf{X}$  plays formally.
3. If  $\mathbf{X}$  opens a subdialogue  $d_{1,i}$  by challenging an AS-move, then  $\mathbf{Y}$  plays formally.

Now, structural rules that allow the Proponent to claim she is facing an *abductive problem* are added. She has the choice between the two kinds of *abductive problems* previously defined:

**[SR-AN] [Utterance of Abductive Novelty]**

When  $\mathbf{P}$  loses a game playing deductively (i. e., with the standard rules of dialogical logic), then  $\mathbf{P}$  is allowed to claim that she is facing an abductive novelty by saying  $\mathcal{F}_\Theta \Phi \wedge \mathcal{F}_\Theta \neg \Phi$ .

In the same way, the *Proponent* is allowed to choose between the claim that she is facing an abductive novelty or an abductive anomaly. The following rule is therefore added:

**[SR-AA] [Utterance of Abductive Anomaly]**

When  $\mathbf{P}$  loses a game playing deductively (i. e., with the standard rules of dialogical logic), then  $\mathbf{P}$  is allowed to claim that she is facing an abductive novelty by saying  $\mathcal{F}_\Theta \Phi \wedge \neg \Phi$ . Note here that the second conjunct does not trigger any subdialogue  $d_{i,i}$  and that  $\neg \Phi$  has to be defended in the same context as the initial thesis, namely when the concession of  $\Theta$  is given by  $\mathbf{O}$ .

Without going into excessive details, this point is explained with an example based on Dialogue 2, (Table 14.3).

In Dialogue 2.1 (Table 14.5),  $\mathbf{P}$  loses and now claims she is facing an abductive novelty at move 4.  $\mathbf{O}$  challenges that move at move 5,  $\mathbf{P}$  answers by giving the first conjunct.  $\mathbf{O}$  then challenges the  $\mathcal{F}$  operator

at move 7 by opening a subdialogue in which she now plays formally.  $\mathbf{P}$  answers by saying  $\neg(\Theta \rightarrow (C \wedge \neg E))$ , where  $\Theta$  is the same set of initial concessions as before, and the dialogue runs as usual. It is easy to verify that  $\mathbf{O}$  will lose (for the same reasons  $\mathbf{P}$  lost in Dialogue 2, Table 14.3). In the same way,  $\mathbf{O}$  will lose even if she challenges the second conjunct in move 4, and  $\mathbf{P}$  will have justified that she was facing an abductive novelty.

**14.5.2 Guessing**

After having shown she was facing an *abductive problem*, the Proponent has to guess what is missing in order to solve it. The Proponent has to be allowed to conjecture a hypothetical *abductive solution*. Such a conjecture is made by means of a subjunctive speech act, that is, a speech act that does not rely on the concessions of the Opponent. In fact, such a move should be rendered as a feasible move. Note that it will not be explained how an *abductive solution* is generated or chosen. Instead, the present proposal will be to describe the conditions under which such a conjectural move is performed.

This contribution relies again on *Aliseda* [14.50] who proposes a calculus for abduction, based on the semantic trees of deductive logic, but with some nuances with respect to the status of the abductive explanation. Roughly speaking, the idea is to construct the tree for  $\Theta \rightarrow \Phi$  and identify its open branches together with such formulae that may close those branches (in a consistent way). Several formulae may do the job. These formulae are called by *Aliseda* *abductive solutions* to *abductive problem* consisting of the pair  $\Theta, \Phi$ . Therefore, an abduction consists in guessing (or discovering) what the possible *abductive solutions* are. To put it in *Aliseda's* own words, consistent abductions are those formulae which “if they had been in the theory before, they would have closed those branches that remain open after  $\neg \Phi$  is incorporated into the tableau” [14.50, p. 110].

**Table 14.6** AS-challenge 1

Utterance	Challenge	Defence
$X-!-SA : \alpha - d_{1,i}$	$Y-?-?Plain_{AS} - d_{1,i,i}$	$X-!- (\Theta \wedge \alpha) \rightarrow \Phi - d_{1,i,i}$
	Y opens a subdialogue $d_{1,i,i}$	

**Table 14.7** AS-challenge 2

Utterance	Challenge	Defence
$X-!-SA : \alpha - d_{i,i}$	$Y-?-?Explanatory_{SA} - d_{i,i,i}$	$X-!- ((\Theta \wedge \alpha) \rightarrow \Phi)$ $\wedge (\neg(\Theta \rightarrow \Phi) \vee (\alpha \rightarrow \Phi)) - d_{i,i,i}$
	Y opens a subdialogue $d_{1,i,i}$	

Even if, from a dialogical viewpoint, it is not looked for any *true* formula, what is an *abductive solution* may be defined following a similar process. Indeed, after having shown that she was facing an *abductive problem*, the Proponent should be allowed to put forward a hypothesis. What the Proponent has to look for is a formula, not conceded by the Opponent, that enables her to win the dialogue previously lost. Therefore, a rule that allows the Proponent to conjecture the hypothesis of an explanation called *abductive solution* is added:

#### [SR-SA] [Abductive Solution Rule]

When the Proponent has won the subdialogue triggered by the challenge of the  $\mathcal{F}$  operator, whether it be novelty or anomaly, the Opponent is allowed to ask her ?AS (i. e., she claims *do you have an abductive solution to propose?*). If so, the Proponent answers  $AS : \alpha$  (i. e., she claims  $\alpha$  is my abductive solution).

What does it mean that  $\alpha$  is an *abductive solution* for the Proponent, and why is that *abductive solution* the conjecture of a hypothesis? In fact, this move consists in claiming that there is a plausible explanation to the surprising fact  $\Phi$  given  $\Theta$ . This specific move,  $AS : \alpha$ , is the move that forces to reconsider dialogical games to fit in with abductive reasoning. Indeed, it may consist of the utterance by the Proponent of an atomic formula not previously conceded by the Opponent. Nevertheless, the introduction of this new piece of information is to be understood as a subjunctive explanation. That is, the Proponent introduces  $\alpha$  as she would say *if you had conceded me  $\alpha$ , I would have been able to explain  $\Phi$* . In no way is  $\alpha$  introduced as an **O**-concession to be incorporated into  $\Theta$  or into a  $\Theta'$ , a successor of  $\Theta$  containing the initial concessions and the other concessions made during the dialogue.  $\alpha$  is a new formula that may be used in further reasoning, but only temporarily, and that temporarily nature requires further justification. Indeed, as a hypothesis,  $\alpha$  is defeasible, that is, it is a conclusion *faute de mieux* guessed by the Proponent. If it is shown later that this is not a good explanation or if a counter-example is encountered, then  $\alpha$  will be defeated and removed. Its

conditions of use are not the same as the usual assertions of the standard dialogical logic because it is subject to further justification, no matter whether it is an atomic or a complex formula: Would it be a new kind of utterance?

### 14.5.3 Committing

The dialogues defined here only describe a partial abduction, that is, an *abductive problem* is set and a plausible answer is guessed. However, in order to characterize a full abduction, it should be explained how the conjecture might be released in a further dialogue and how the players might act upon it. As already explained, Gabbay and Woods characterize abduction as an ignorance-preserving inference. It has been shown that abductive dialogues are not-conceded-preserving: The explicative conjecture remains not-conceded and the Proponent only gives a subjunctive explanation for the surprising fact. The difficulty at this point involves the clarification of the commitment carried by such conjectural moves, which are rather different from the usual assertions.

Even if the question of the commitment of the conjectural move is very complex (it might even vary according to the argumentation contexts), a rule to deal with the consequence requirement of the type of abduction called “plain abduction” by *Aliseda* [14.50, Part II] can be defined. In a dialogue, this consists in adding the possibility of a challenge on the  $AS$ -move, called an  $AS$ -challenge. The Opponent makes the request to justify that it is sufficient to consider the conjunction of  $\Theta$  and  $\alpha$  to derive  $\Phi$  by means of the rule in Table 14.6.

Under this rule, the challenger opens a subdialogue in which the defender will have to defend the condition  $(\Theta \wedge \alpha) \rightarrow \Phi$ . The act of  $Y$  opening a subdialogue means that  $X$  will play under formal restriction. The formal restriction is applied in accordance with the rules [SR2.1] and [SR2.2] given earlier. More kinds of such challenges should be defined to complete the picture. Adding the explanatory character of  $\alpha$  might also be required. Thus, the possibility to chose another attack against an  $AS$ -move is offered to  $Y$  (Table 14.7).

Other requirements, such as consistency ( $\Theta, \alpha \not\vdash \perp$ ), minimality and so on (Chap. 10), might be added in the same way. It would also be possible to rely on these rules in order to deal with the defeasibility of AS-moves. Indeed, if a player is not able to answer the AS-challenges performed by her argumentation partner, then her conjectural move should be removed and considered as null. In the same way, if some counterexamples or a better explanation are found, the AS-moves should also be cancelled. However, defeasibility is a very wide topic and cannot be dealt with in detail in this chapter. A nonmonotonic account of abduction that makes use of adaptive logic is given by *Meheus and Batens* [14.59] and *Beirlaen and Aliseda* [14.60] (see also Chap. 12 by *Gauderis*). For a dialogical study of defeasible reasoning, see the work of *Nzokou* [14.61]. For a nonmonotonic treatment of inconsistencies in the context of an adaptive dialogical logic, see *Rahman and Van Bendegem* [14.62].

What has been characterized in this section is only partial abduction. In order to attain a full abduction, the framework over which dialogues are obtained and in which the hypothesis  $\alpha$  is released in the defence of

another thesis *as if* it had been conceded, should be developed. Indeed, full abductive dialogue should be not-conceded-preserving, that is, the agents act upon the hypothesis although it has not been conceded by the Opponent. This is the dialogical understanding of ignorance-preservation in the GW model of abduction defended in this contribution. In the GW schema, it was said that neither  $R(K(H), T)$  nor  $R(K * (H), T)$  were the case. Here, this parallels the fact that **P** does not actually attain the target. **P** only encounters something similar to a subjunctive winning strategy, a strategy which would lead to the victory if **O** had conceded  $\alpha$ ; similarly in the GW model, it is only a subjunctive attainment relation expressed by  $H \rightsquigarrow R(K(H), T)$ . Now, the challenge faced in order to complete the picture and to define the conditions of use of a hypothetical explanation  $\alpha$  in a full abduction, consists in providing an in-depth analysis of the commitment carried by such a conjecture. This relates to the following question: What kind of speech act is at stake when a hypothesis is conjectured? Without a precise answer to this question, no precise rule of victory for abductive dialogues can be yet formulated.

## 14.6 Hypothesis: What Kind of Speech Act?

In the previous section, a new kind of move specific to abductive dialogues, the so-called AS-move, by means of which a hypothetical *abductive solution* is conjectured, has been introduced. Such a move is considered as a subjunctive move, that is, a move stated hypothetically with an assumption such as *if you had conceded me  $\alpha$ , I would have been able to justify  $\Phi$* . The conditions under which it is possible to conjecture an *abductive solution* and how such a hypothetical *abductive solution* might be challenged have been clarified. However, by means of what kind of speech act is an AS-move performed? What kind of speech act is the conjecture of a hypothetical *abductive solution* if  $\alpha$  can be used in the defence of another thesis (in a full abduction)?

An epistemic explanation might have seemed attractive, relying for example on the notion of subjunctive knowledge defined by *Rückert* [14.63]. Subjunctive knowledge is defined in a modal frame as the knowledge people of another world would have about the actual world. Abduction might thus be thought of in terms of subjunctive epistemic change, namely if some people of another world had the knowledge of what is expressed by the hypothesis, they would be able to explain a surprising fact in the actual world. This would smartly explain the subjunctive status of the

explanatory relation conjectured in a hypothetical *abductive solution*. However, it would have ended up in an account explicitly involving the epistemic states of the agents instead of taking into account their actions. Moreover, such an account would yield an excessively strong commitment on the part of the agent with respect to the belief or the knowledge of the truth of the hypothetical *abductive solution*. However, as explained earlier, this is not necessary. An *abductive solution* can be conjectured as being plausible without any commitment to the belief of the truth of what is expressed.

This last point brings back the problem of the status of an AS-move. Is it an assertive speech act? How could it be? An assertive speech act is usually characterized by the commitment (of the speaker) to its truth. In his theory of speech acts, *Searle* [14.64, p. 12] defines the class of assertive speech act as follows:

“The point or purpose of the members of the assertive class is to commit the speaker (in varying degrees) to something being the case, to the truth of the expressed proposition.”

Although, in dialogical logic, the commitment to the truth is irrelevant in the characterization of an assertion, assertion can be thought of in terms of com-

mitment to justify what is said (by defending it against further challenges or by relying on the concessions of the Opponent). What about the AS-move? It is conjectured and might be released in another dialogue without being conceded by the Opponent or fully justified by the Proponent. Therefore, is the conjecture of a hypothesis an assertive utterance in the dialogical sense of the term? In Searle's terms, is conjecturing an assertive act? It seems that it cannot be. Answering these questions is crucial if the aim is to succeed in introducing the AS-move defeasibly and to release the conjectures in further reasoning in the same way as in the GW schema of abduction in a dialogical framework.

If the speech act, by means of which a hypothetical *abductive solution* is conjectured, is not an assertion, would it be a commissive speech act? Beyond the question of the commitment to the truth or to belief, or even to the acceptance of what is uttered, an *abductive solution* commits the speaker to a subsequent series of actions. First, the speaker is committed to answer the AS-challenges. Second, the use of the hypothesis in a full abduction without knowing whether it is true or not, might be seen as a peculiar kind of commitment. Does such a peculiar commitment relate to what Searle has called the commissive speech acts? More precisely, Searle defines the commissives as "those illocutionary acts whose point is to commit the speaker (again in varying degree) to some future course of action" [14.64, p. 14]. In the dialogical approach, which has been outlined in the previous section, the underlying idea is that the Proponent conjectures a hypothetical *abductive solution* which is such that, if it had been conceded, it would have explained the surprising fact. However, this should not be the end of the story because the aim would be to release the hypothesis in a further reasoning: in another dialogue in which the Proponent defends another thesis by acting on the hypothesis at stake. That is why the commitment carried out by the speech act, by means of which an AS-move is performed, indicates that it could be understood in terms of a commissive speech act. In addition to further justification, it also commits the agent to further dialectical actions. Nevertheless the commissives are usually speech acts in which the agents commit themselves to an action over which they have full control. That is to say, the commissive speech act commits to something that depends only on the agents, as it happens in the case of promises and oaths. However, the agent who performs an abduction does not have full control of the explanatory force of an *abductive solution*. Indeed, while in the first case

the failure of the promise is dependent upon the agent herself, the failure of an abductive explanation includes a wider range of factors which do not exclusively depend on the agent activity. So, it does not seem that the speech act by means of which an AS-move is performed, is a commissive speech act.

If it consists in neither an assertive nor a commissive act, would a conjectural move be a fictional speech act? Indeed, according to Searle [14.65], fictional discourse is not composed of genuine assertions but instead of pretended assertions. The point is that in fiction, even if the author is not committed to the truth of what she says, she does not have the intention to lie. Therefore, the author does not tell the truth but neither is the author lying. The author tells a story doing *as if* she were asserting. When a player performs an AS-move and uses it in a further reasoning, she does *as if* it were conceded. She does not have to believe what she says but neither is she trying to mislead the interlocutor. However, beyond the fact that Searle's theory of fictionality is not shared by this contribution, it is thought that abduction has a practical dimension, which is not necessary to the fictional discourse. Hence, in this chapter, it is not believed that the hypothetical speech act should be explained in terms of fictional discourse. Moreover, what is to be explained while studying fiction is its double aspect, the fact that while we know it is not true we react to such a discourse without experiencing any kind of cognitive dissonance. Also there is no such tension to be explained in the conjecture of a hypothetical *abductive solution*. (For more details on these points, see [14.66–68].)

An alternative, though tentative solution, would be to reconsider the taxonomy of speech acts. For example, Bach [14.69] defines the wider category of constative, which the conjecturing act would be part of. Other inspirations might be found in the work of Barés Gómez [14.70] who distinguishes between different kinds of assertions in natural language (assertive paradigm, negative paradigm, and evidentiality) by making use of Dynamic Epistemic Logic and by focusing on the transmission of information. These different kinds of assertions might also be understood as different types (talking thus about hypothetical judgement); see the recent work of Rahman and Clerbout [14.71], on Constructive Type Theory in the context of dialogical logic follows in this respect. The question is left as a challenge for further investigations. Is a hypothetical speech act a particular kind of assertive or commissive act? Is it a mix of both? Is it a completely new kind of speech act?

## 14.7 Conclusions

In this chapter, it is first advocated for a reconciliation of argumentation theory and formal logic in an agent-centered theory of reasoning, that is, a theory in which inferences are studied in terms of human activities. More precisely, the dialogical approach to logic, in which reasoning is studied through a dialectical interaction between the Proponent of a thesis and the Opponent of it, is defended. In this context, the necessity of taking into account, not only the actions of the agents, but also the importance of the notion of commitment is stressed. Beginning with deductive dialogues, the picture has been extended to abduction, which is considered as a case of nondeductive reasoning.

The starting point to deal with abduction is the agent-centered analysis of the GW model. While Gabbay and Woods identify abduction as an ignorance-preserving inference triggered by an ignorance problem, abductive dialogues have been defined here as not-conceded-preserving dialogues triggered by a *concession problem*. The specificity of abductive dialogues has been identified at the level of the so-called AS-moves by means of which hypothetical *abductive solutions* are conjectured. To allow such moves, new rules have been put forward. The challenge for dialogicians now consists in exploring the release of such hypotheses in further dialogues in which they remain not-conceded. However, the difficulty of defining the

nature of such a hypothetical speech act is being faced, which leads to the key question of commitment. What are we committed to when we conjecture a hypothetical explanation of a surprising fact and when we release such a hypothesis in further reasoning? A definite answer to this question is left for further investigations.

# 15. Formal (In)consistency, Abduction and Modalities

Juliana Bueno-Soler, Walter Carnielli, Marcelo E. Coniglio, Abilio Rodrigues Filho

This chapter proposes a study of philosophical and technical aspects of logics of formal inconsistency (LFIs), a family of paraconsistent logics that have resources to express the notion of consistency inside the object language. This proposal starts by presenting an epistemic approach to paraconsistency according to which the acceptance of a pair of contradictory propositions  $A$  and  $\neg A$  does not imply accepting both as true. It is also shown how LFIs may be connected to the problem of abduction by means of tableaux that indicate possible solutions for abductive problems. The connection between the notions of modalities and consistency is also worked out, and some LFIs based on positive modal logics (called *anodic modal logics*), are surveyed, as well as their extensions supplied with different degrees of negations (called *catholic modal logics*). Finally, *swap structures* are explained as new and interesting semantics for the LFIs, and shown to be as a particular important case of the well-known *possible-translations semantics* (PTS).

## 15.1 Paraconsistency

Paraconsistency is the study of logical systems in which the presence of a contradiction does not imply triviality, that is, logical systems with a nonexplosive negation  $\neg$  such that a pair of propositions  $A$  and  $\neg A$  does not (always) trivialize the system. In paraconsistent logics the *principle of explosion* does not hold

$$A, \neg A \not\vdash B. \quad (15.1)$$

But what would be the reason for devising a paraconsistent logic? Or more precisely, if avoiding contradictions is a fundamental criterion of thought and reason, what is the point of a formal system that tolerates contradictions? It will be argued here that to have available a logical formalism capable of dealing with contradictions does not imply any sympathy with the thesis that

there are true contradictions, nor that reality is, in some sense, contradictory.

It is a fact that contradictions appear in a number of real-life contexts of reasoning. From databases to scientific theories, we often have to deal with contradictory information. There are several scientific theories, however successful in their areas of knowledge, that yield contradictions, either by themselves or when combined with other efficacious and compelling theories [15.1, Chap. 5]. The presence of contradictions is not a sufficient condition for discarding interesting theories. In order to deal rationally with contradictions, explosion cannot be valid without restrictions, since triviality, that is, a circumstance such that everything holds, is obviously unacceptable. Given that, in classical logic, explosion is a valid principle of inference, the underly-

ing logic of a contradictory context of reasoning cannot be classical.

Indeed, the occurrence of contradictions in both scientific theories and everyday contexts of reasoning is being increasingly recognized. Notice that, as a general rule, these theories have been successful in describing and predicting a wide range of phenomena. The realist (and naive) assumption that scientific theories provide correct descriptions of reality would unavoidably imply that there are ontological contradictions, but this would be a careless and hasty conclusion, since these contradictions are better taken as provisional [15.2, p. 2]. If contradictions are provisional, they should not be taken as *true* contradictions. From a strictly logical point of view, the problem is how to formulate an account of logical consequence capable of identifying, in contradictory contexts, the inferences that are allowed, distinguishing them from those that must be blocked. It is clear that such an account of logical consequence must be paraconsistent.

## 15.2 Logics of Formal Inconsistency

There are two different but classically equivalent notions of consistency with respect to a deductive system  $S$  with a negation  $\sim$ .  $S$  is consistent if and only if:

1. There is a formula  $B$  such that  $\not\vdash_S B$ ;
2. There is no formula  $A$  such that  $\vdash_S A$  and  $\vdash_S \sim A$ .

What (1) says is that  $S$  is not trivial; and (2) says that  $S$  is noncontradictory. In classical logic both are (provably) equivalent.

A theory is a set of propositions (or sentences, if one prefers) closed under logical consequence. Given a set of propositions  $\Gamma$  in the language of a given logic  $L$ , let  $T = \{A: \Gamma \vdash_L A\}$  be the theory whose nonlogical axioms are the propositions of  $\Gamma$  and the underlying logic is  $L$ . Suppose the language of  $T$  has a negation  $\sim$ . We say that  $T$  is:

- *Contradictory*: if and only if there is a proposition  $A$  in the language of  $T$  such that  $T$  proves  $A$  and  $T$  proves  $\sim A$ ;
- *Trivial*: if and only if for any proposition  $A$  in the language of  $T$ ,  $T$  proves  $A$ ;
- *Explosive*: if and only if  $T$  trivializes when exposed to a pair of contradictory formulas – i. e., for all  $A$  and  $B$ ,  $T \cup \{A, \sim A\} \vdash B$ .

A theory whose underlying logic is classical is contradictory if and only if it is trivial. But it is the case precisely because such a theory is explosive, since the principle of explosion holds in classical logic. It is clear,

The question about the nature of contradictions accepted by paraconsistent logics is where a great deal of the debate on the philosophical significance of paraconsistency has been concentrated. In philosophical terminology, we say that something is ontological when it has to do with reality, with the world in the widest sense, and that something is epistemological when it has to do with knowledge and the process of its acquisition. A central question for paraconsistency is the following: Are the contradictions that paraconsistent logic deals with ontological or epistemological? Do contradictions have to do with reality proper? Or do contradictions have to do with knowledge and thought? Contradictions of the latter kind, called here epistemological contradictions, have their origin in our cognitive apparatus, in the failure of measuring instruments, in the interactions of these instruments with phenomena, in operations of thought, or even in simple mistakes that in principle could be corrected later on.

then, that *it is contradictoriness together with explosiveness that implies triviality*. The obvious move in order to deal with contradictions is thus to reject the unrestricted validity of the principle of explosion by means of adopting a *nonexplosive negation* (that is, a negation  $\neg$  such that  $A, \neg A \not\vdash B$ ). This is a necessary condition if one wants a contradictory but nontrivial theory.

For classical negation  $\sim$  the following conditions hold

$$A \wedge \sim A \vDash , \quad (15.2)$$

$$\vDash A \vee \sim A . \quad (15.3)$$

According to (15.2), there is no model  $M$  such that  $A \wedge \sim A$  holds in  $M$ . Equation (15.3) says that for every model  $M$ ,  $A \vee \sim A$  holds in  $M$ . A negation is para-complete if it disobeys (15.3), and is paraconsistent if it disobeys (15.2). Now, given classical consequence,  $A \vee \sim A$  follows from anything, and anything follows from  $A \wedge \sim A$ . From the point of view of rules of inference, the duality is not between noncontradiction and excluded middle, but rather between explosion and excluded middle.

The principle of noncontradiction is usually taken as a claim that there can be no contradictions in reality. But we may well understand the principle of explosion as a stronger way of saying precisely the same thing:  $A$  and  $\sim A$  cannot hold together, otherwise we get triviality. From the above considerations, it is clear that in

order to give a counterexample to the principle of explosion, we need a weaker negation and a semantics in which there is a model  $M$  such that  $A$  and  $\neg A$  holds in  $M$ .

In classical logic the values 0 and 1 are understood respectively as false and true, but in nonclassical logics this does not need to be the case. It is not necessary that a paraconsistent logic takes a pair of formulas  $A$  and  $\neg A$  as both true. The semantic value 1 attributed to a formula  $A$  may be read as *A is taken to be true*, *A is possibly true*, *A is probably true*, or perhaps better as *there is some evidence that A is true* in the sense of there being reasons for believing that  $A$  is true. Thus, the attribution of the value 1 to a pair of propositions  $A$  and  $\neg A$ , does not need to be understood as if both propositions are true in the sense that there is something in the world that makes them true. Rather, it is better to consider that  $A$  and  $\neg A$  are both being taken in a sense weaker than true, perhaps waiting for further investigations that will decide the issue, and discard one of them.

*Logics of formal inconsistency* are a family of paraconsistent logics that have resources to express the notion of consistency inside the object language by means of a sentential unary connective:  $\circ A$  means (informally) that *A is consistent*. As in any other paraconsistent logic, explosion does not hold in LFIs. But this is handled in a way that allows distinguishing between contradictions that can be accepted from those that cannot. In LFIs, negation is explosive only with respect to consistent formulas

$$A, \neg A \not\vdash_{\text{LFI}} B, \text{ while } \circ A, A, \neg A \vdash_{\text{LFI}} B. \quad (15.4)$$

An LFI is thus a logic that separates the propositions for which explosion holds from those for which it does not hold. The former are marked with  $\circ$ . For this reason, they are called *gently explosive*.

In the  $C_n$  hierarchy, introduced by *da Costa* in [15.3], the so-called *well-behavedness* of a formula  $A$ , in the sense that it is not the case that  $A$  and  $\neg A$  hold, is also expressed inside the object language. However, in  $C_1$ ,  $A^\circ$  is an abbreviation of  $\neg(A \wedge \neg A)$ , which makes the *well-behavedness* of a proposition  $A$  equivalent to saying that  $A$  is noncontradictory. A full hierarchy of calculi  $C_n$ , for  $n$  natural, is defined and studied in [15.3].

The first step in paraconsistency is the distinction between triviality and contradictoriness. But there is a second step, namely, the distinction between consistency and noncontradictoriness. In LFIs the consistency connective  $\circ$  is not only primitive, but it is also not always logically equivalent to noncontradiction. This is the most distinguishing feature of the logics of formal inconsistency. Once we break up the equivalence

between  $\circ A$  and  $\neg(A \wedge \neg A)$ , some very interesting developments become available. Indeed,  $\circ A$  may express notions different from consistency as freedom from contradiction.

The circumstance in which both  $A$  and  $\neg A$  receive the value 1 may be understood as the presence of simultaneous but nonconclusive evidence that  $A$  is true and  $\neg A$  is true. *Evidence for A* in the sense proposed here are *reasons to believe in A*. One may be justified in believing that  $A$  is true inasmuch one has evidence available that  $A$  is true. But of course it may be that there are also reasons for believing  $\neg A$ , and in this case the evidence is not conclusive.

Suppose that according to some empirically testable criteria, an atomic proposition  $A$  is true if and only if a condition  $c$  is fulfilled and on the other hand, there is also a condition  $d$ , independent of  $c$ , such that obtaining  $d$  implies the truth of  $\neg A$ . In some critical circumstances, it may happen that both criteria  $c$  and  $d$  are obtained [15.4, pp. 9–10]. Although  $c$  and  $d$  have been conceived initially as criteria of truth, it seems far more reasonable at this point to not draw the conclusion that  $A$  and  $\neg A$  are both true. It is better to be more careful and to take the contradiction as a provisional state, a kind of excess of information that should, at least in principle, be eliminated by means of further investigation. The criteria  $c$  and  $d$  provide reasons for believing (i. e., provide evidence) that  $A$  and  $\neg A$  are true, but do not establish conclusively that both are true. Thus, a counterexample for explosion is straightforward: there may be nonconclusive evidence for both  $A$  and  $\neg A$ , but no evidence for some  $B$ .

This intuitive interpretation for the paraconsistent negation justifies the invalidity of explosion. However, it is not possible yet to express that some proposition is true, because the notion of evidence is weaker than truth. With the help of the consistency operator this problem can be solved. The following intuitive meaning for the consistency operator is proposed:  $\circ A$  means informally that the truth value of  $A$  has been conclusively established. Now one has resources to express not only that there is evidence that  $A$  is true but also that  $A$  has been established (by whatever means) as true:  $\circ A \wedge A$ . Notice that how the truth or falsity of a proposition is established is not a concern of logic. The establishment of the truth of a given proposition  $A$  comes from outside the formal system.

A very good example of a provisional contradiction in physics, better understood in terms of conflicting evidence rather than truth, is the problem faced by Einstein just before he formulated the special theory of relativity. It is well known that there was an incompatibility between classical Newtonian mechanics and Maxwell's theory of electromagnetic field. This is a typical case of

two (supposedly) noncontradictory theories that yield contradictory results.

A friendly presentation of the problem may be found in *Einstein* [15.5] and *Feynman et al.* [15.6]. Briefly, with respect to the same hypothetical situation, with  $c$  being the velocity of light in vacuum and  $w$  the velocity of light in a particular circumstance [15.5, Sects. 6 and 7], Newtonian mechanics and Maxwell's theory provide that  $\neg(w = c)$  and  $w = c$  respectively. So, combining the two theories yields a contradiction, and if the underlying logic is classical, triviality follows.

In such a scenario, two contradictory propositions hold in the sense that both may be *proven* from theories that were supposed to be correct. This fact may be represented by the attribution of the semantic value 1 to both  $\neg(w = c)$  and  $w = c$ . But clearly, the meaning of this should not be that both are true – actually, we know it is not the case, and nobody has ever supposed that it could be the case. The meaning of the simultaneous attribution of the value 1, as we suggest, is that at that time there was evidence for both in the sense, mentioned above, of some *reasons for believing* that both were true, because there was evidence that the results yielded by both classical mechanics and theory of the electromagnetic field were true. The *contradiction* has been solved (roughly speaking) in the following way: As velocity grows, time *slows down* and *space shortens*. So, the relation between space and time that gives velocity remains the same, because both have decreased (for details, see [15.6, Sect. 15]). This is an example of what we call *epistemic contradictions*. We want to call attention to the fact that the general logical framework Einstein was working in was not classical. He had two different theories at hand: classical mechanics and the theory of electromagnetic field, which, when combined, yielded a nonexplosive contradiction. Later, according to the special theory of relativity, the *contradiction* disappeared. Although there were some reasons to believe that both  $\neg(w = c)$  and  $w = c$  were true, only one, the latter, has been established as true. The value 1 attributed to  $\neg(w = c)$  later became 0.

### 15.2.1 mbC: A Minimal LFI

Let us present *mbC*, a basic LFI. This name stands for a *minimal logic with the axiom bc1*, and *bc* stands for *basic property of consistency*. *mbC* is an extension of classical positive propositional logic (CPL+) enriched with a nonexplosive negation and a *consistency* operator, the unary operator  $\circ$ . *mbC* is interesting because it has a minimal apparatus and several technical properties that illustrate the main features of logics of formal inconsistency. As we shall see, *mbC*:

- i. Permits us to define classical negation, and thus can be seen as an extension of classical logic
- ii. Permits recovering classical consequence by means of a derivability adjustment theorem (DAT)
- iii. Distinguishes the consistency of a formula  $A$  from the noncontradiction of  $A$ , i. e.,  $\circ A$  and  $\neg(A \wedge \neg A)$  are not equivalent
- iv. Is gently explosive in the sense that it tolerates some pairs of formulas  $A$  and  $\neg A$ , while it is explosive with respect to others; and
- v. Has a sound and complete bivalued semantics.

#### The Syntax of mbC

Let  $L_1$  be a language with a denumerable set of sentential letters  $\{p_1, p_2, p_3, \dots\}$ , the set of connectives  $\{\circ, \neg, \wedge, \vee, \rightarrow\}$ , and parentheses. The consistency operator  $\circ$  is a primitive symbol and  $\neg$  is a nonexplosive negation. The set of formulas of  $L_1$  is obtained recursively in the usual way; and Roman capitals stand for metavariables for formulas of  $L_1$ .

The logic *mbC* is defined over the language  $L_1$  by the following Hilbert system:

Axiom-schemas:

- Ax.1.  $A \rightarrow (B \rightarrow A)$ ,
- Ax.2.  $(A \rightarrow (B \rightarrow C)) \rightarrow ((A \rightarrow B) \rightarrow (A \rightarrow C))$ ,
- Ax.3.  $A \rightarrow (B \rightarrow (A \wedge B))$ ,
- Ax.4.  $(A \wedge B) \rightarrow A$ ,
- Ax.5.  $(A \wedge B) \rightarrow B$ ,
- Ax.6.  $A \rightarrow (A \vee B)$ ,
- Ax.7.  $B \rightarrow (A \vee B)$ ,
- Ax.8.  $(A \rightarrow C) \rightarrow ((B \rightarrow C) \rightarrow ((A \vee B) \rightarrow C))$ ,
- Ax.9.  $A \vee (A \rightarrow B)$ ,
- Ax.10.  $A \vee \neg A$ ,
- Ax.bc1.  $\circ A \rightarrow (A \rightarrow (\neg A \rightarrow B))$ ,

Inference rule: modus ponens.

Positive classical propositional logic, CPL+, is given by axioms Ax. 1 to Ax. 9 plus modus ponens. *mbC* is thus an extension of CPL+.

The definition of a derivation of  $A$  from a set of premises  $\Gamma$  ( $\Gamma \vdash_{\text{mbC}} A$ ) is the usual one: a finite sequence of formulas  $B_1 \dots B_n$  such that  $A$  is  $B_n$  and each  $B_i$ ,  $1 \leq i \leq n$  (that is, each line of the proof) is an axiom, a formula that belongs to  $\Gamma$ , or a result of modus ponens. A theorem is a formula derived from the empty set of premises.

#### Lemma 15.1

The logic *mbC* satisfies the following properties:

- P1. Reflexivity: if  $A \in \Gamma$ , then  $\Gamma \vdash_{\text{mbC}} A$ ;

- P2. Monotonicity: if  $\Gamma \vdash_{\text{mbC}} B$ , then  $\Gamma, A \vdash_{\text{mbC}} B$ , for any  $A$ ;
- P3. Cut: if  $\Delta \vdash_{\text{mbC}} A$  and  $\Gamma, A \vdash_{\text{mbC}} B$ , then  $\Delta, \Gamma \vdash_{\text{mbC}} B$ ;
- P4. Deduction theorem: if  $\Gamma, A \vdash_{\text{mbC}} B$ , then  $\Gamma \vdash_{\text{mbC}} A \rightarrow B$ ;
- P5. Compactness: if  $\Gamma \vdash_{\text{mbC}} A$ , then there is  $\Delta \subseteq \Gamma$ ,  $\Delta$  finite,  $\Delta \vdash_{\text{mbC}} A$ .

*Proof:* The properties P1, P2, P3 and P5 come directly from the definition of  $\Gamma \vdash_{\text{mbC}} A$ . The deduction theorem comes from axioms Ax. 1 and Ax. 2 plus modus ponens. ■

Since the properties P1, P2 and P3 hold, *mbC* is thus a standard logic [15.7, p. 6]. Due to the axiom *bc1*, *mbC* is gently explosive, that is

For some  $A$  and  $B$ :

$A, \neg A \not\vdash_{\text{mbC}} B$ ,

$\circ A, A \not\vdash_{\text{mbC}} B$ ,

$\circ A, \neg A \not\vdash_{\text{mbC}} B$ ,

While for every  $A$  and  $B$ :  $\circ A, A, \neg A \vdash_{\text{mbC}} B$ .

Thus, the formal system is able to distinguish the contradictions that do not lead to explosion from those that do. The axiom *bc1* is also called the *gentle explosion law*, because it is explosive only with respect to formulas marked with  $\circ$ .

Classical logic may be recovered in *mbC* in two ways: by defining a negation that has the properties of the classical negation and by means of a derivability adjustment theorem (DAT).

#### Fact 15.1

Classical negation is definable in *mbC*.

*Proof:* We define  $\perp \stackrel{\text{def}}{=} \circ A \wedge A \wedge \neg A$  and  $\sim A \stackrel{\text{def}}{=} A \rightarrow \perp$ . Now, we get explosion,  $A \rightarrow (\sim A \rightarrow B)$ , as a theorem, in a few steps from *bc1*. From the axiom 9, excluded middle is obtained,  $A \vee \sim A$ . Classical propositional logic (CPL) is obtained by axioms 1–8 plus explosion, excluded middle and modus ponens. ■

The general purpose of a derivability adjustment theorem is to establish a relationship between two logics, *L1* and *L2*, in the sense of restoring inferences that are lacking in one of them. The basic idea is that some *information* has to be added to the premises to restore the inferences that are lacking. DATs are especially interesting because they show what is needed to restore the classical consequence in a paraconsistent scenario.

For the sake of precisely stating the DAT between *mbC* and CPL, we need to take into account the differ-

ence between the respective languages. The first step is to translate one language into another. Let  $L_2$  be a language with the set of connectives  $\{\sim, \vee, \wedge, \rightarrow\}$ . Instead of a paraconsistent negation  $\neg$ ,  $L_2$  has classical negation  $\sim$ .

#### Fact 15.2

Let  $t$  be a mapping that replaces  $\sim$  by  $\neg$ . Then, the following holds:

For all  $\Gamma$  and for all  $B$ ,  $\Gamma \cup \{B\} \subseteq L_2$ , there is a  $\Delta$ ,  $\Delta \subseteq L_1$  such that  $\Gamma \vdash_{\text{CPL}} B$  iff  $t[\Gamma], \circ \Delta \vdash_{\text{mbC}} t[B]$ , where  $\circ \Delta = \{\circ A : A \in \Delta\}$ .

*Proof:* From left to right, suppose there is a derivation  $D$  of  $\Gamma \vdash_{\text{CPL}} B$  (in the language  $L_2$  of CPL). If we simply change the classical negations  $\sim$  to  $\neg$ , such a derivation does not hold in *mbC*. We need to be concerned only with occurrences of explosion. The relevant point is that some information must be available in order to reconstruct classical reasoning. An occurrence of a line:

1.  $A \rightarrow (\sim A \rightarrow B)$

in the derivation  $D$  has to be substituted by the following lines, obtaining a derivation  $D'$ :

2.  $\circ A$

3.  $\circ A \rightarrow (A \rightarrow (\neg A \rightarrow B))$

4.  $A \rightarrow (\neg A \rightarrow B)$ .

From right to left, suppose there is a derivation  $D'$  of  $t[\Gamma], \circ \Delta \vdash_{\text{mbC}} t[B]$ . We get a derivation  $D$  of  $\Gamma \vdash_{\text{CPL}} B$  just by deleting the occurrences of  $\circ$  and changing  $\neg$  to  $\sim$ . ■

The reader should notice the difference between restoring classical consequence by means of a definition of a classical negation inside *mbC* and by means of a DAT. In the latter case, the central issue is the information that has to be available to restore classical reasoning. In each occurrence of classical explosion,  $A \rightarrow (\sim A \rightarrow B)$ , the information needed from the viewpoint of *mbC* is the consistency of  $A$ , represented by  $\circ A$ .

#### A Semantics for *mbC*

The sentential connectives of classical logic are truth functional. This means that the truth-value of a molecular formula is functionally determined by its structure and by the truth-values of its components, which reduce to the truth-values of the atomic formulas. Truth functionality as a property of the semantics of certain logics is a mathematical rendering of the *principle of compositionality*, which says that the meaning of a complex expression is functionally determined by the meanings of its constituent expressions and the rules used

to combine them. This principle is also called Frege's principle, since it has been traced back to Frege. The truth-value of molecular formulas may be determined by using the familiar matrices (truth-tables) that any logic student is familiar with. These matrices have only two values (*true* and *false*, or 1 and 0) in the case of classical propositional logic, but the idea can be generalized to any number of *truth-values*.

A logic can be *truth functional* even if it is characterized semantically by a finite, or even by an infinite, number of *truth-values*. Indeed, in most many-valued logics the *truth-value* of a molecular formula is also functionally determined by the values of the atomic formulas.

However, instead of talking about truth-values, it would be better to talk about *semantic values*, since, as we have argued earlier, the values 0 and 1 attributed to formulas need not be *always* interpreted as false and true. The point is that we do not want to commit ourselves from the start to just the values true and false attributed to formulas.

Now let us put things in a more neutral and precise way. Let us say that a semantics for a logic  $L$  is called *matrix functional* (instead of truth functional) if the semantic value of a formula of  $L$  is functionally determined by means of a finite matrix. This is the case for classical logic, but not for intuitionistic logic, as Gödel has proven in [15.8], nor is the case for *mbC*. In fact, not only *mbC* but all logics of the da Costa hierarchy  $C_n$ , and most LFIs, are not characterizable by finite matrices [15.7, theorem 121].

A non-matrix-functional semantics for paraconsistent logics was proposed by *da Costa* and *Alves* in [15.9]. There, a bivalued semantics for the logic  $C_1$  is found. The semantic clause for the paraconsistent negation has only *half* of the clause for classical negation: if  $v(\neg A) = 0$ , then  $v(A) = 1$ . The idea is that it cannot be the case that  $A$  and  $\neg A$  simultaneously receive the value 0. But the possibility is open for both to receive the value 1. This kind of semantics is described by the so-called *quasi-matrices*. The quasi-matrix for negation is as follows

$A$	$\neg A$
1	0
	1
0	1

It is clear that the semantic value of  $\neg A$  is not functionally determined by the semantic value of  $A$ : when  $v(A) = 1$ ,  $v(\neg A)$  may be 1 or 0. For this reason, this semantics is clearly nonfunctional, and in this case we say also that the semantics is *nondeterministic*. A bivalued sound and complete semantics for *mbC*, is as follows:

### Definition 15.1

An *mbC-valuation* is a function that assigns the values 0 and 1 to formulas of the language  $L_1$ , satisfying the following clauses:

- (i)  $v(A \wedge B) = 1$  iff  $v(A) = 1$  and  $v(B) = 1$
- (ii)  $v(A \vee B) = 1$  iff  $v(A) = 1$  or  $v(B) = 1$
- (iii)  $v(A \rightarrow B) = 1$  iff  $v(A) = 0$  or  $v(B) = 1$
- (iv)  $v(\neg A) = 0$  implies  $v(A) = 1$
- (v)  $v(\circ A) = 1$  implies  $v(A) = 0$  or  $v(\neg A) = 0$ .

A valuation  $v$  is a model of a set  $\Gamma$  if and only if every proposition of  $\Gamma$  receives the value 1 in  $v$ , and  $v$  is a model of a proposition  $A$  if and only if  $A$  receives the value 1 in  $v$ .

The notion of logical consequence is defined as usual: A formula  $A$  is an *mbC-consequence* of a set  $\Gamma$  ( $\Gamma \models_{\text{mbC}} A$ ), if and only if for every valuation  $v$ , if  $v$  is a model of  $\Gamma$ , then  $v$  is a model of  $A$  (when there is no risk of ambiguity, we simply write  $\models$  and  $\vdash$  without subscripts).

Soundness and completeness proofs for the semantics above are to be found in [15.7, pp. 38ff]. Notice that the clauses for  $\wedge$ ,  $\vee$  and  $\rightarrow$  are exactly the same as in classical logic. By clause (iv), the system is paraconsistent but not paracomplete, since the excluded middle (for paraconsistent negation) holds. We suggest that the values 0 and 1 are not to be understood as false and true respectively, but rather as absence and presence of evidence. Accordingly:  $v(A) = 1$  means *there is evidence that  $A$  is true*;  $v(A) = 0$  means *there is no evidence that  $A$  is true*;  $v(\neg A) = 1$  means *there is evidence that  $A$  is false*; and  $v(\neg A) = 0$  means *there is no evidence that  $A$  is false*. The same counter example invalidates explosion and disjunctive syllogism:  $v(A) = 1$ ,  $v(B) = 0$  and  $v(\neg A) = 1$ . Noncontradiction is also invalid:  $v(A) = v(\neg A) = 1$ , hence  $v(A \wedge \neg A) = 1$ , but  $v(\neg(A \wedge \neg A))$  may be 0. Due to clause (v), it may be the case that  $v(A) = 1$ ,  $v(\neg A) = 0$  (or vice versa) but  $v(\circ A) = 0$ . In this valuation,  $v(\neg(A \wedge \neg A)) = 1$ , hence the nonequivalence between  $\circ A$  and  $\neg(A \wedge \neg A)$ . Also, due to clause (v), it is clear that *mbC* does not admit a trivial model, i. e., a model such that  $v(A) = 1$  for every formula  $A$ .

We would like to make some comments with respect to the validity of the excluded middle in *mbC*, given the intended interpretation in terms of evidence. Indeed, in some circumstances there may be a situation such that there is no evidence at all, neither for the truth nor for the falsity of a proposition  $A$ , but this scenario cannot be represented in *mbC*. In fact, in the next section, it will be shown that *mbC* may be easily modified in order to be able to represent such a situation. On the other hand, the validity of the excluded middle may be justified when one, by default, attributes evi-

dence for  $A$  or for  $\neg A$  when there is no evidence at all. This happens, for instance, in a criminal investigation in which one begins by considering everyone (in some group of people) not guilty until proof to the contrary (see Example 15.5 in Sect. 15.3.1). In fact, any context of reasoning such that a final decision must be made in a finite amount of time demands that  $A$  or  $\neg A$ , or even both, have to be in some sense accepted. Whether the excluded middle should be valid from the start, or be recovered once some information has been added may be seen as a methodological decision that depends on the reasoning scenario we want to represent.

### 15.2.2 A Logic of Evidence and Truth

The logic  $mbC$  may be slightly modified to be able to express a scenario such that no evidence is available. The duality between the principles of explosion and excluded middle that corresponds to a duality between paraconsistency and paracompleteness has been mentioned in Sect. 15.2. Now, in a way analogous to that by which we recover the explosion with respect to a formula  $A$ , in a paracomplete logic, the validity of the excluded middle with respect to a formula  $A$  may be recovered by means of the following axiom

$$\text{Ax. bd1. } \circ A \rightarrow (A \vee \neg A) .$$

A semantic clause for the axioms  $bc1$  and  $bd1$  is defined as follows:

(vi) if  $v(\circ A) = 1$ , then  $[v(A) = 1 \text{ iff } v(\neg A) = 0]$ .

If the excluded middle holds for  $A$ , we say that  $A$  is determined.  $bd$  stands for *basic property of determinedness* (bd). A system in which both  $bd1$  and  $bc1$  holds is thus paracomplete and paraconsistent. It is better to call  $\circ$ , in this context, not a consistent operator but rather a *classicality operator*, since  $\circ A$  recovers classical truth conditions with respect to  $A$ . But  $\circ A$  still may be informally understood as meaning that the truth value of  $A$  has been conclusively established. In fact, the basic idea of restricting the validity of the principle of explosion may be generalized. The validity of some inference rule (or axiom) may be restricted in such a way that some *logical property* does not hold unless some information is added to the system. In particular, the excluded middle may be restricted in a way analogous to the restriction imposed to the explosion.

Now, with  $bd1$  and  $bc1$ , we have the resources to express the following situations, besides nonconclusive evidence; no evidence at all:  $v(A) = v(\neg A) = 0$  and conflicting evidence:  $v(A) = v(\neg A) = 1$ . The system obtained by adding the axioms  $bd1$  and  $bc1$  to CPL+ is called  $mbCD$ , a minimal logic of inconsistency and

undeterminedness.  $mbCD$  is correct and complete with respect to a bivalued semantics defined by clauses (i) to (iii) of Def. 15.1 plus the clause (vi) above.

Although  $mbCD$  is able to express also the absence of evidence, the negation still may be improved to better represent the deductive behavior of the notion of *preservation of evidence*. The logic  $LET_K$  (the logic of evidence and truth based on CPL+) is thus obtained by adding to  $mbCD$  the axioms 11 to 14 below

$$\text{Ax. 11. } A \leftrightarrow \neg \neg A ,$$

$$\text{Ax. 12. } \neg(A \wedge B) \leftrightarrow (\neg A \vee \neg B) ,$$

$$\text{Ax. 13. } \neg(A \vee B) \leftrightarrow (\neg A \wedge \neg B) ,$$

$$\text{Ax. 14. } \neg(A \rightarrow B) \leftrightarrow (A \wedge \neg B) .$$

The axioms above fit the intuitive meaning of the simultaneous attribution of the value 0 or the value 1 to a pair of propositions  $A$  and  $\neg A$  as absence and presence of evidence respectively. Let us consider axiom 12. It is reasonable to conclude that if there is some evidence that a conjunction is false, that same evidence must be evidence that one of the conjuncts is false. On the other hand, if there is some evidence that  $A$  is false, that same evidence must be evidence that  $A \wedge B$  is false, for any  $B$ . Analogous reasoning applies for disjunction and implication.

A bivalued complete and correct semantics for  $LET_K$  is obtained by adding to the semantics of  $mbCD$  the following clauses

(vii)  $v(A) = 1$  iff  $v(\neg \neg A) = 1$ ,

(viii)  $v(\neg(A \wedge B)) = 1$  iff  $v(\neg A) = 1$  or  $v(\neg B) = 1$ ,

(ix)  $v(\neg(A \vee B)) = 1$  iff  $v(\neg A) = 1$  and  $v(\neg B) = 1$ ,

(x)  $v(\neg(A \rightarrow B)) = 1$  iff  $v(A) = 1$  and  $v(\neg B) = 1$ .

The logic  $LET_K$  can be proven without much trouble to be sound and complete with respect to the semantics above. The proof needs only to drop the clauses related to Ax. 10 and to extend the soundness and completeness proofs for  $mbC$  [15.7, pp. 38ff] to the new axioms and semantic clauses, which can be done without difficulties. In  $LET_K$ , a DAT holds as in  $mbC$  and a classical negation is definable in the same way as in  $mbC$ , thus  $LET_K$  may be also seen as an extension of propositional classical logic. It is worth noting that according to the intuitive interpretation proposed,  $LET_K$  like  $mbC$  does not tolerate true contradictions: indeed, a true contradiction yields triviality, as in classical logic. If  $A$  is simultaneously true and false, this is expressed by  $(\circ A \wedge A) \wedge (\circ A \wedge \neg A)$ , that, in its turn, is equivalent to  $\circ A \wedge A \wedge \neg A$ , but the latter is nothing but a *bottom particle*  $\perp$ , i. e., a formula that alone implies triviality: for any  $B$ ,  $\perp \vdash B$ .

## 15.3 Abduction

The problem of abduction has been formulated by *Peirce* as the process of forming hypotheses with explanatory purposes. It is, thus, a kind of a reversed explanation [15.10, CP 7.202]:

“Accepting the conclusion that an explanation is needed when facts contrary to what we should expect emerge, it follows that the explanation must be such a proposition as would lead to the prediction of the observed facts, either as necessary consequences or at least as very probable under the circumstances. A hypothesis then, has to be adopted, which is likely in itself, and renders the facts likely. This step of adopting a hypothesis as being suggested by the facts, is what I call *abduction*.”

The basic idea may be expressed as follows: When some fact is discovered that is not explained by the available theory (i. e., is not a consequence of the available theory), a set of new premises is added as a hypothetical solution to the problem. However, the act of adding something before using it as an explanation poses a second problem: how is it possible to generate an abductive *explanans*? First, we have to recognize that characterizing the concept of explanation is one of the greatest challenges in the philosophy of science. This problem is even harder in logic and mathematics, where explanations are sometimes confused with proofs [15.11].

Although we are not suggesting that *explaining* can be reduced to *deducing*, it is certainly acceptable that the idea of explanation in deductive sciences includes the query for missing hypotheses; it is in this context that the general abductive process can be formulated as the process of generating new hypotheses within arbitrary deductive systems, and afterwards using them in deductive terms. The former task (generating new hypotheses) is referred to here as *creative abduction*, while the latter (using such new hypotheses) as *explicative abduction*. The term *explicative* is here understood under the following proviso: A missing link in a deduction certainly does not exhaust the need for an explanation, but does constitute the first necessary step towards explaining a surprising (i. e., not yet deducible) fact.

Two natural assumptions about explanations that can be posed are the following: First, there can be various explanations for the same surprising fact, and second, there can be explanations of various *degrees* for the same surprising fact. For example, searching for the ultimate scientific explanation as to why the grass of your garden is wet in the morning and discovering that the sprinkler was left on all night may be two different things. Both explain the fact, but responding to different

needs. The question is analogous to the one in automatic theorem proving: finding any proof is one thing, while finding a *philosophically interesting* proof is another. In the same manner as automatic theorem proving is satisfied with the first level of proofs, so automatic abduction will be satisfied with a first-level explanation. We are mainly interested here in abductions with no *obvious* explanations, particularly those in which contradictions may be involved.

Let  $\vdash$  be a deductive relation; if  $\Gamma \not\vdash A$ , the creative abductive step consists of finding an appropriate  $\Delta$  so that  $\Gamma \cup \Delta \vdash A$ . In this case, the discovered  $\Delta$  performs the explicative abductive step. Obviously, there must be some constraints, otherwise  $\Delta = \{\perp\}$  would be a trivial solution for the abduction problem in most deduction relations. Usually, if the underlying logic is explosive (e.g., classical or intuitionistic), another constraint is that  $\Gamma \not\vdash \neg A$ , for this would imply that any explicative  $\Delta$  would be a trivial explanation. This restriction, however, will not be necessary in our case, as the following developments and the examples will make clear.

From the point of view of general argumentation (and not only deduction), abduction concerns the search for hypotheses or the search for explanatory instances that support reasoning. In this sense, it can be seen as a complement to argumentation, in the same manner that in the philosophy of science, the context of discovery is a complement to the context of justification. And moreover, further pursuing the analogy, the question of the logical possibility of creative abduction lies on the same side of the famous question of the logical possibility of scientific discovery.

A renewed interest in abduction acquired impetus due to the factual treatment of data and the question of virtual causality in the information age. The enormous amount of data stored on the World Wide Web and in complex systems, as well as the virtual relationship among such data, continuously demands new tools for automatic reasoning. These tools should incorporate general logical methods which are at the same time machine-understandable, and sufficiently close to human semantics as to perform sensible automated reasoning.

An example wherein abductive inference is highly relevant is the model-based diagnosis in engineering and AI (artificial intelligence). Suppose that a complex system, such as an aircraft, is being tested before a transatlantic flight. The electronic circuitry permits the testers to predict certain outputs based on specific input tests. If the instruments show something distinct from the expected, it is a task of model-based diagnosis to discover an explanation for the anomaly and use it to

separate the components responsible for the problem, instead of disassembling the whole aircraft.

Another example occurs in the process of updating in the so-called datalog databases. Suppose we have a logic program (see introductory chapter for a brief overview of abduction in logic programming) composed of the following clauses, where  $desc(x, y)$  means  $x$  is a descendent of  $y$ ,  $parent(y, x)$  means  $y$  is a parent of  $x$  and  $\beta \leftarrow \alpha$  means that the database contents plus  $\alpha$  produce (or answer)  $\beta$

$$\begin{aligned} desc(x, y) &\leftarrow parent(y, x), \\ desc(x, y) &\leftarrow parent(z, x), desc(z, y). \end{aligned}$$

There is a subtle difference between inserting information in the database in an explicit versus implicit manner: information of the form  $y$  is a parent of  $x$  is a basic fact, and can be inserted explicitly, while information of the form  $x$  is a descendent of  $y$  is either factual knowledge or is a consequence of the machine reasoning (as simple as it can be). If one wishes to insert a piece of implicit information, it is necessary to modify the set of facts stored in the database in such a way that this information can be deduced: this is an example of creative abduction and of explicative abduction at the same time. For instance, if we have stored  $desc(Zeus, Uranus)$  and  $parent(Uranus, Cronus)$ , for implicitly inserting  $desc(Aphrodite, Uranus)$  there are two different ways: we may either insert  $parent(Zeus, Aphrodite)$  or alternatively insert  $desc(Aphrodite, Cronus)$ . These two alternative additions are examples of abductive explanations for  $desc(Aphrodite, Uranus)$ . In fact, logic programming uses this abductive mechanism for answering queries, in the form: *Is the fact  $desc(Aphrodite, Uranus)$  compatible with the program clauses and data?* or *Is there any  $x$  such that  $desc(x, Uranus)$ ?* The whole procedure is creative as much as it can be automatized. Therefore it is evident that a useful abductive mechanism for databases should be based on first-order logic, and not merely on propositional logic.

Moreover, abductive approaches are also used to integrate different ontologies and database schemes, or for integrating distinct data sources under the same ontology, as for example [15.12], where an abductive-based application for database integration is developed. Suppose that, while a query is being processed by a user, another data source had inserted  $desc(Uranus, Aphrodite)$  in our database, plus a constraint of the form: *For no  $x$  and  $y$ , simultaneously  $desc(x, y)$  and  $desc(y, x)$  can be maintained in the database.* If  $parent(Zeus, Aphrodite)$  had been inserted for one data source, the insertion of  $desc(Uranus, Aphrodite)$  by the second data source would cause a collapse in view of the constraint. What

can be done? The alternative of deleting all data seems inconceivable, and the one of having all queries be answered positively (since a database established on classical logic grounds would deduce anything from a contradiction) is of course intolerable. Thus a legitimate logic to ground this process would have to be a first-order logic that sanctions useful reasoning in the presence of contradictions.

Proposals from this perspective have been investigated in [15.13]. A first-order LFI,  $QmbC$ , that is an extension of the logic  $mbC$ , has been presented and investigated in [15.14]. We will argue here that simple yet powerful techniques for automatic abduction can be usefully implemented by means of tableau proof-procedures for the logic  $mbC$ , which may be extended to  $QmbC$ .

Although a wide-scoped study of tableaux and abduction was offered by [15.15] in 1997, the quite natural idea of using the backward mechanism of tableaux for gaining automatic explanations occurred earlier: [15.16] in 1992 already proposed a fully detailed treatment for the question of *completing* a database in a way as to deduce (in classical propositional logic) a previously undeducible formula. In the same year a tableau proof system for da Costa's logic  $C_1$  was proposed in [15.17], and several examples of using such tableau systems for automatic solving dilemmatic situations were extensively discussed. Even though neither of these references explicitly mentions the concept of abduction, these papers undoubtedly proposed ways to solve the abductive problem, for classical propositional logic and for the propositional paraconsistent logic  $C_1$  respectively. In [15.18], tableau systems for LFIs were proposed, and this logical formalism was used as a method to devise database repairs in [15.13]. Such methods are based upon many-valued semantics, or upon bivalued semantics.

The question of abduction thus involves two independent, but complementary problems:

1. Finding a method to automatically perform abduction (and, if possible, to automatically generate abductive data), and
2. Doing this within a robust reasoning environment, in a such a way as to keep running and providing reasonable output even in the presence of the possible contradictions that this search would engender.

Any contradictions found in the process of producing lucid outputs are a condemnation of the whole process if the underlying logic is classical, so, the abductive experience can sometimes appear to be lethal. We argue here, however, that very simple and natural logical models can be designed for dealing with abduc-

tion, by means of defining them in terms of refutation procedures based on LFIs.

It is well accepted that abduction does not go in the forward direction of deduction. It is not difficult to accept, either, that abduction cannot coincide with any backward form of classical deduction, but it does not follow that another form of backward deduction would not work. In this sense, some LFIs are good candidates. Let us take as example *mbC*: it does not prove anything that classical logic would not prove; it tolerates contradictions, but, nonetheless, it can encode the whole of classical reasoning. Backwards proof procedures for LFIs indeed constitute a suitable approach for abduction, and we intend to show how this approach can be programmed and treated on a natural basis departing from a very simple formalism.

We have already seen here that it is typical that cognitive situations can enter into a situation of (presumably temporary) contradictory state. Of course, in a situation where we have serious theories competing around a contradiction, there is little sense in rejecting one of them a priori just to save the principle of explosion. It seems to be out of question that it is more convenient to tame the logic, rather than to sacrifice a precious (and possibly correct) theory.

This is not only the case for scientific theories. A single digit in a database can of course be extremely valuable than to be just thrown away, and it is already widely recognized that no automated reasoning is possible without means of controlling logical explosion. What is yet not clear is whether the act of guessing is involved in the discovery context of abduction, and furthermore under such conditions, can be the subject of logic. Although it seems that Peirce maintained the negative, we argue that in many interesting cases the process of guessing can be solved semi-automatically by means of careful manipulation of the concept of consistency, viewed as a primitive notion independent from the concept of contradiction, as shown in Sect. 15.2.1 above. In this way we can obtain a reasonably efficient and conceptually simple method for discovering new logical hypotheses that will serve as explanans for a given explanandum.

### 15.3.1 mbC-Tableaux

The beginnings of automatic heuristics by means of paraconsistent tableaux can be traced back to [15.17], although the logic used there is da Costa's  $C_1$ . As argued in the preceding sections, an important LFI is the logic *mbC*. A relevant feature of *mbC* is that it can be defined by means of refutative tableau-type proof procedures. Such backward proof procedures are very convenient for formalizing abductive routines. The ba-

sic idea is that the open branches may be seen as a heuristic device that helps indicate the formulas that would close the tableau, and these formulas are then taken as the explicative hypotheses.

We present below a definition of the notion of an abductive explanation:

#### Definition 15.2

Let  $\Gamma$ ,  $\Delta$  be finite sets of sentences and  $A$  be a sentence in the language of a given logic  $L$ .  $\Gamma$  and  $A$  form an abductive problem and  $\Delta$  is an abductive explanation for the abductive problem if:

1. (Abductive problem): The context  $\Gamma$  is not sufficient to entail  $A$ , that is,  $\Gamma \not\vdash A$
2. (Abductive solution): The enriched context  $\Gamma$  plus  $\Delta$  is sufficient to entail  $A$ , that is,  $\Gamma, \Delta \vdash A$
3. (Nontriviality of solution): The enriched context  $\Gamma$  plus  $\Delta$  is nontrivial, that is, there exists  $B$  such that  $\Gamma, \Delta \not\vdash B$
4. (Vocabulary restriction of solution):  $Var(\Delta) \subseteq Var(\Gamma) \cup Var(A)$
5. (Minimality of solution): by lack of any other criteria, a mathematically minimal  $\Delta$  is a good explanation (in the sense, for example, that it is composed of a set with minimal cardinality and with formulas of minimal length).

While conditions (1) and (2) just define what is an abductive problem and what is a solution, conditions (3), (4) and (5) impose restrictions for a solution to be considered relevant: condition (3) avoids, for instance, that  $\Delta$  be taken as the collection of all formulas, or as a single bottom particle (which would entail any other formulas). Since the compactness theorem holds for *mbC*,  $\Gamma$  and  $\Delta$  can always be taken as finite sets.

Below, we present a tableau system for *mbC*, based on the bivaluation semantics presented in Definition 15.1 [15.7, p. 48]. We use 0 and 1 as syntactic labels to represent the semantic values 0 and 1.

$$\begin{array}{l}
 R1 \frac{\mathbf{0}(\neg X)}{\mathbf{1}(X)} \\
 R2 \frac{\mathbf{1}(\circ X)}{\mathbf{0}(X) \mid \mathbf{0}(\neg X)} \\
 R3 \frac{}{\mathbf{1}(X) \mid \mathbf{0}(X)} \\
 R4 \frac{\mathbf{1}(X_1 \wedge X_2)}{\mathbf{1}(X_1), \mathbf{1}(X_2)} \\
 R5 \frac{\mathbf{0}(X_1 \wedge X_2)}{\mathbf{0}(X_1) \mid \mathbf{0}(X_2)}
 \end{array}$$

$$\begin{array}{l}
 R6 \quad \frac{\mathbf{1}(X_1 \vee X_2)}{\mathbf{1}(X_1) \mid \mathbf{1}(X_2)} \\
 R7 \quad \frac{\mathbf{0}(X_1 \vee X_2)}{\mathbf{0}(X_1), \mathbf{0}(X_2)} \\
 R8 \quad \frac{\mathbf{1}(X_1 \rightarrow X_2)}{\mathbf{0}(X_1) \mid \mathbf{1}(X_2)} \\
 R9 \quad \frac{\mathbf{0}(X_1 \rightarrow X_2)}{\mathbf{1}(X_1), \mathbf{0}(X_2)}
 \end{array}$$

A branch is closed when it contains a couple of labeled formulas  $\mathbf{1}(X)$  and  $\mathbf{0}(X)$ , or when it contains a triad of labeled formulas  $\mathbf{1}(X)$ ,  $\mathbf{1}(\neg X)$  and  $\mathbf{1}(\circ X)$ . The rule  $R3$  could in principle be eliminated, but it is convenient to keep it in the system. The results proven in [15.19] guarantee that the tableau system is sound and complete for  $mbC$ .

Now, making use of the tableau system above, we can illustrate how an abduction mechanism based on the logic  $mbC$  works. Let us consider, first, an example from the folklore; a theory  $\Gamma$  containing the following sentences:  $\Gamma = \{A \rightarrow C, B \rightarrow C\}$ , where  $A$  means *It rained last night*,  $B$  means *the sprinkler was left on*, and  $C$  means *the grass is wet*. If we observe that the grass is wet, and we want to explain why this is so, *It rained last night* is an explanation, but *the sprinkler was left on* is another competitive (though not incompatible) explanation. Tableaux allow for automatically computing nontrivial explanations. After we have such explanations, we may employ some criteria to discard some explanations or choose the best one among competitors. For instance, the hypothetical explanation that the sprinkler was left on may be true, but canceled by the fact that the main water register was known to be off. In any case, some choices may be necessary in order to implement a preference policy for ranking multiple explanations – facts may have precedence over hypothetical explanations, and likelihood may be used to classify explanations. Although this is an important part of the whole question that will affect the usefulness of the automatic explanations produced, it is not part of the abduction problem as originally posed. It is worth noting that the position we are holding here does not require a nonmonotonic logic. The logic used here to produce the abductive output,  $mbC$ , is monotonic. Nonmonotonic reasoning, if necessary, may be used in further steps.

#### Example 15.1

A case where  $mbC$ -tableaux and classical tableaux give the same result:

Let  $\Gamma = \{A \rightarrow C, B \rightarrow C\}$ ; of course  $\Gamma \not\vdash C$ . Running an  $mbC$ -tableau for  $\mathbf{1}(\Gamma) \cup \{\mathbf{0}(C)\}$  produces an open branch containing  $\mathbf{0}(A)$  and  $\mathbf{0}(B)$ . Clearly, this branch

would be closed by  $\mathbf{1}(A)$  or  $\mathbf{1}(B)$ , which indicates that there are three possible abductive solutions:  $\Delta_1 = \{A\}$ ,  $\Delta_2 = \{B\}$  and  $\Delta_3 = \{A, B\}$ .

In the example above, by principle, we consider that a  $\Delta$  minimal provides a better explanation. However, in real-life contexts of reasoning, the choice between these solutions is a problem that may depend on data and criteria to be established by the user of the system.

#### Example 15.2

Let  $\Gamma = \{A \rightarrow B, B \rightarrow C\}$ ; clearly,  $\Gamma \not\vdash C$ . Running an  $mbC$ -tableau for  $\mathbf{1}(\Gamma) \cup \{\mathbf{0}(C)\}$  produces an open branch containing  $\mathbf{0}(A)$  and  $\mathbf{0}(B)$ . Again, it indicates the same three possible abductive solutions:  $\Delta_1 = \{A\}$ ,  $\Delta_2 = \{B\}$  and  $\Delta_3 = \{A, B\}$ .

#### Example 15.3 Impossible Explanations Explained

Suppose that we know that, if it rained last night, then the grass is wet; we know that the grass is wet, but we also know (or have been informed, or have independent evidence for it) that it did not rain. How can we explain that the grass is wet? Let the situation be represented as  $\Gamma = \{A \rightarrow B, \neg A\}$ ; here,  $\Gamma \not\vdash B$ , but no classical tableau is able to find an explanation, since the only possible candidate,  $A$ , has to be ruled out by clause (3) of Definition 15.2 as it entails triviality. However,  $mbC$ -tableaux will be able to provide a solution. In situations like this, common sense suggests that rain may be accepted as an explanation, if the information suggesting that it did not rain is uncertain or dubious. Running an  $mbC$ -tableau yields an open branch containing  $\mathbf{1}(A)$ . Clearly,  $\Delta = \{A\}$  would close the branch, but classically it would not be a solution, since the set of premises contain a formula  $\neg A$ . But  $A$  is indeed a solution, that also indicates the proposition  $\neg A$  is not well established as true – that is, is not consistent. In fact, in  $mbC$ ,  $A, \neg A \vdash \neg \circ A$ . For this reason, this explanation does not violate Definition 15.2. Notice that this scenario cannot be represented by a classical tableau.

#### Example 15.4 Explanations that Avoid Hasty Conclusions

We know that taking certain drugs has beneficial consequences for health, but also the same drugs, under certain conditions, will produce undesirable effects on our health. Represent this situation as  $A \rightarrow B$  and  $A \rightarrow \neg B$ . Under classical reasoning (using classical tableaux, or any other classical inference mechanism) an immediate conclusion would be  $\neg A$ , that is, we should not take these drugs. However, the negative effects could be explained by inappropriate doses, or by different

health conditions in different people, and so on. Using *mbC*-tableaux, however, this case turns out to be an interesting abduction problem, since in *mbC*  $A \rightarrow B, A \rightarrow \neg B \not\vdash \neg A$ , as can be checked by the reader, by consulting the semantics given in Sect. 15.2.1, A Semantics for *mbC*. We are thus invited to look for an abductive explanation: this explanation, automatically produced by the *mbC*-tableau, is that the drug is to be banned only if the contradictory effects are undeniable, that is, if  $\circ B$ . Indeed, in *mbC*  $A \rightarrow B, A \rightarrow \neg B, \circ B \vdash \neg A$ . Hence,  $\Delta = \{\circ B\}$  is an explanation: the resulting *mbC*-tableau is closed.

### Example 15.5 Whodunit?

A diamond was stolen in a hotel room and only two people had entered the room on two different days, Bob and Alice. Since there is only nonconclusive evidence against them and the standard of a proof in a criminal trial must be so strong that there should be *no shadow of doubt*, the police initially consider that they are not guilty, but certainly one of them is guilty, that is, the evidence basis contains  $\Gamma = \{\neg A, \neg B, A \vee B\}$  where *A* and *B* stand, respectively, for *Alice is guilty* and *Bob is guilty*. At this point,  $\Gamma \not\vdash A$  and  $\Gamma \not\vdash B$ , so we have two abductive problems. Now, by running the respective *mbC*-tableaux, we easily see that either  $\circ A$  (meaning that the initial supposition about Alice's innocence was indeed consistent) or  $\circ B$  (meaning, alternatively, that the initial supposition about Bob's innocence was indeed consistent) would decide the question. Indeed, in *mbC*,

$$A \vee B, \neg A, \neg B, \circ A \vdash B \quad \text{and}$$

$$A \vee B, \neg A, \neg B, \circ B \vdash A$$

The presumed innocence of exactly one of them must be revised. Defending the innocence of one of them amounts to the culpability of the other. Notice that they cannot be both innocent – if this were the case, we get triviality.

These examples illustrate the fact that employing logics of formal inconsistency in the general problem of abduction has interesting consequences, automatically producing meaningful explanations that would be imperceptible within the classical environment. *mbC* is not the only choice, and other LFIs would play a similar role. It is worth noting that *mbC* is decidable, and the complexity of its satisfiability problem is no worse than that of the classical satisfiability problem.

## 15.3.2 Quantification

The extension of the ideas of obtaining abductive explanations by means of tableaux to the first-order case

is not only quite natural, but expected in real applications. Although there are some technical complications, from the tableau-proof-theoretical standpoint, all the grounding constructions are already at our disposal: the logic *QmbC*, first-order extension of the propositional *mbC*, has been studied in detail in [15.14]. We recall the main ideas about *QmbC* and show how the underlying tableau procedure can be used in abductive problems. Let  $\Sigma$  be the language of *mbC* enriched with  $\forall$  and  $\exists$ , and *Var* be a set of variables. The formulas of *QmbC* are defined as usual in first-order logics; all the familiar syntactic notions of free and bound variables, closed formulas (sentences), substitution etc., are defined as usual. From the semantic side, sentences of *QmbC* are interpreted by adding the following to the semantics of *mbC*:

- i.  $v(\exists xA) = 1$  iff  $v(A[x/t]) = 1$  for some term  $t$  in  $L$
- ii.  $v(\forall xA) = 1$  iff  $v(A[x/t]) = 1$  for all  $t$  in  $L$
- iii. If  $A$  is a variant of  $B$ , then  $v(A) = v(B)$

We say that  $A$  is a variant of  $B$  (and vice versa) if  $A$  can be obtained from  $B$  by means of addition or deletion of void quantifiers, or by renaming bound variables. It is a theorem of classical first-order logic that if  $A$  and  $B$  are variants of each other, then  $A$  and  $B$  are logically equivalent. However, in *QmbC* the clause (3) above has to be postulated to solve some technical problems that will not be considered in detail here, but the reader can find in [15.14]. From a syntactical perspective, what interests us here for the sake of abduction, a tableau system for *QmbC* is obtained by adding to the tableau rules of *mbC* the following rules for the quantifiers

$$R10 \frac{\mathbf{1}(\forall xA)}{\mathbf{1}(A(x/t))}$$

$$R11 \frac{\mathbf{1}(\exists xA)}{\mathbf{1}(A(x/s))}$$

$$R12 \frac{\mathbf{0}(\forall xA)}{\mathbf{0}(A(x/s))}$$

$$R13 \frac{\mathbf{0}(\exists xA)}{\mathbf{0}(A(x/t))}$$

R14 If  $B$  is variant of  $A$  :

$$\frac{\mathbf{1}(A)}{\mathbf{1}(B)} \quad \text{and} \quad \frac{\mathbf{0}(A)}{\mathbf{0}(B)}$$

The rules above are subjected to the following restriction:  $t$  is an arbitrary term and  $s$  is a new term with respect to  $\forall xA$ , i. e., it does not appear in any branch containing  $\forall xA$  (respectively for  $\exists xA$ ).

The method introduced here for obtaining automatic explanations can thus be extended to first-order theories. Of course, this involves some additional com-

plications, because *QmbC*-tableaux, as much as their classical counterparts, are not a decision procedure for *QmbC*-validity – indeed, *QmbC* is undecidable. Let us see an example below.

#### Example 15.6

Consider the following set of propositions:  $\Gamma = \{\forall x(Cx \rightarrow Bx), \forall x(Gx \rightarrow Bx), \neg Ca\}$ . Here,  $\Gamma \not\vdash Ba$ . Running an *mbC*-tableau for  $\mathbf{1}(\Gamma) \cup \{\mathbf{0}(Ba)\}$  produces an open branch containing  $\mathbf{0}(Ca)$ ,  $\mathbf{1}(\neg Ca)$  and  $\mathbf{0}(Ga)$ . Classically, the only candidate to be an abductive explanation is *Ga*. But from the point of view of *QmbC*, we obtained two possible explanations, since  $\mathbf{1}(Ca)$  also closes that branch. In the latter case, a further conclusion is that *Ca* is not *consistent*, i. e., is not well established as a true proposition. Thus, this explanation does not violate Definition 15.2.

## 15.4 Modality

Modal logics and paraconsistent logics are cousins. In 1948, while attempting to answer a question posed by J. Lukasiewicz, S. Jaśkowski presented the first formal system for a paraconsistent logic with his *discussive logic*. Interestingly enough, his logic was framed in terms of modalities, and later on it was proven to be a particular case of the family of LFIs [15.7]. However, it was only in 1986 that the first modal paraconsistent system was proposed in [15.20], with the aim of dealing with deontic paradoxes. That system was a modal extension of da Costa's paraconsistent logic  $C_1$ . This approach has been extended by means of deontic modalities combined with LFIs, as developed in [15.21, 22].

Paraconsistent negation can be regarded as a kind of modal operator, considering the fact that the classical negation for possibility (and, a fortiori, for necessity) has a paraconsistent behavior. Namely, the operator  $\neg$ , defined as

$$\neg A \stackrel{\text{def}}{=} \diamond \sim A,$$

is a paraconsistent negation where, as usual,  $\sim$  denotes the classical negation. This relationship has been studied in [15.23], both with respect to the standard modal logic *S5* and to four-valued modal logics [15.24]. It is worth noting that the fact that  $\diamond \sim A$  defines a paraconsistent negation was already observed in 1987 in [15.25], when a Kripke-style semantics was proposed for Sette's logic *PI* based on Kripke frames for modal logic *T*.

One of the interests in paraconsistent modal logics is the potential of dealing with, or even avoiding,

To the extent that LFIs permit fine control of reasoning in the presence of inconclusively established hypotheses, particularly under contradictions, the mechanism presented here is thus capable of proposing solutions for an extensive class of abductive problems. As we have seen, the *mbC*-tableaux increase the range of options provided by classical reasoning. The issues discussed here have much in common with belief revision, default reasoning, the closed-world assumption, and negation as failure of logic programming, as well as databases with evolutionary constraints, thus making our proposal valuable for several applications. Abduction, however, can also be regarded, from a much more abstract standpoint, as a companion for argumentation (see chapter by Barés and Fontaine, this section, for a proposal in this direction). From this perspective, any attempt to make abduction somewhat closer to deduction is welcome.

some modal paradoxes. Moral dilemmas are a typical situation in which paraconsistent modal logics provide a tool to handling contradictions without triviality. Let us take as an example the well-known dilemma, posed by [15.26], of the man in occupied France who, on the one hand, wants to fight the Nazis but, on the other, must take care of his mother. He believes that each alternative is a moral obligation, but doing one implies not doing the other. Let *A* and *B* be, respectively, *fight the Nazis* and *take care of his mother*. Let the symbols *O* and *P* mean, respectively *it is obligatory that* and *it is permitted that* (as usual  $\square$  means necessity and  $\diamond$  means possibility). From the premises

$$OA, OB, \sim \diamond(A \wedge B),$$

plus the following principles of deontic logic

$$\square(A \rightarrow B) \rightarrow (OA \rightarrow OB),$$

$$OA \rightarrow \sim O \sim A,$$

and given that in classical modal logic  $\sim \diamond(A \wedge B)$  is equivalent to  $\square(A \rightarrow \sim B)$ , a contradiction may be obtained in a few steps. On the other hand, a paraconsistent modal logic may handle the contradiction without triviality.

Another example is Urmson's paradox. In this case, the modal paradox is just avoided. Consider the following proposition

- (X) It is optional that you attend my talk or not, but your choice is not indifferent.

It is clear that the notions *optional* ( $Opt$ ) and *indifferent* ( $Ind$ ) must be distinct in (X). Again, let  $P$  and  $O$  mean *permitted* and *obligatory*. It is natural in modal logic to formalize  $Opt$  and  $Ind$  as

$$Opt(A) \stackrel{\text{def}}{=} PA \wedge P\sim A.$$

$$Ind(A) \stackrel{\text{def}}{=} \sim OA \wedge \sim O\sim A.$$

In classical modal logic a contradiction occurs because  $\sim$  is a classical negation and  $OA$  is equivalent to  $\sim P\sim A$ . Hence, it is easy to see that  $Opt$  and  $Ind$  are equivalent. So, attending the talk is simultaneously optional and not optional. On the other hand, if a nonexplosive negation  $\neg$  is available, it can be used to express the notions  $Opt$  and  $Ind$ . In this way, no paradox occurs because  $OA$  and  $\neg P\neg A$  are no longer equivalent.

Paraconsistent deontic logics have also been studied in the literature for quite a some time [15.20], and deontic counterparts of LFIs, the *logics of deontic (in)consistency* (LDIs), have been introduced in [15.21]. These logics are shown to be able to handle deontic paradoxes, as the well-known Chisholm's paradox. Since contradictory obligations do not trivialize such LDIs, several paradoxes involving conflicting obligations are dissolved [15.22].

It is important to note, however, that the potential of combining paraconsistency and modalities extends far beyond deontic issues. Not only can some problems, described in [15.27], be thought in paraconsistent terms, but also certain problems and paradoxes in epistemic and doxastic logics gain new insight when regarded from paraconsistent perspective.

A detailed investigation of the relationship between LFIs and their modal versions is carried out in [15.28], where the so-called *anodic systems* (purely positive modal systems) introduced in [15.29] are extended by adding certain paraconsistent axioms based on LFIs, defining a class of modal systems called *cathodic systems* (modal systems involving degrees of negations). For an explanation of the terms *anodic* and *cathodic* see [15.29]. A semantic interpretation of cathodic systems is given in [15.28], where it is shown that the cathodic systems can be semantically characterized in two different ways: by means of *Kripke-style semantics* and by means of *modal possible-translations semantics*.

In the following sections we start by presenting a positive (i. e., *anodic*) modal system, that can be enhanced with degrees of negation, as shown in [15.7], so as to obtain a family of *cathodic* systems. We start with the anodic modal system  $K^\diamond$ , a negationless fragment of the well-known modal system  $K$ .

The first paraconsistent modal system we shall consider is  $mbC^\square$ , which will be obtained as an extension

of the anodic modal system  $K^\diamond$ . Then, we show how paraconsistent modal logics that are fragments of the familiar systems  $T$ ,  $S4$  and  $S5$  may be obtained, as extensions of  $mbC^\square$ . Correct and complete semantics are presented for all of these systems.

### 15.4.1 The Anodic System $K^\diamond$

In this section, a purely positive bimodal system  $K^\diamond$  will be defined in a negationless language that is both an extension of CPL+ and a fragment of  $K$ . The only modal axioms are positive versions of the distribution axiom ( $K$ ) (namely, ( $K$ ), ( $K1$ ), ( $K2$ ) and ( $K3$ )) together with the usual necessitation rule ( $Nec$ ).

The language  $L_2$  of  $K^\diamond$  has the following set of connectives:  $\{\vee, \wedge, \rightarrow, \square, \diamond\}$ . Notice that both modal operators are needed as primitive because one cannot be defined in terms of the other, given that no negation is available. The set of *formulas* of  $K^\diamond$  is obtained as typically done in modal logic. The formulas of  $K^\diamond$  are represented by Roman capital letters, and sets of formulas are represented by uppercase Greek letters  $\Gamma, \Delta$  etc. The definition of a derivation of  $A$  from a set of premises  $\Gamma$  ( $\Gamma \vdash_{K^\diamond} A$ ) is the usual one: a finite sequence of formulas  $B_1 \dots B_n$  such that  $A$  is  $B_n$  and each  $B_i$ ,  $1 \leq i \leq n$  is an axiom, a formula that belongs to  $\Gamma$ , or a result of an inference rule. A theorem is a formula derived from the empty set of premises. When there is no risk of ambiguity, we write just  $\vdash$  instead of  $\vdash_{K^\diamond}$ .

#### Definition 15.3

The anodic modal system  $K^\diamond$  is defined by adding to CPL+ the following modal axiom-schemas and modal rule:

- |       |  |
|-------|--|
| (K)   | $\square(A \rightarrow B) \rightarrow (\square A \rightarrow \square B)$   |
| (K1)  | $\square(A \rightarrow B) \rightarrow (\diamond A \rightarrow \diamond B)$ |
| (K2)  | $\diamond(A \vee B) \rightarrow \diamond A \vee \diamond B$                |
| (K3)  | $(\diamond A \rightarrow \square B) \rightarrow \square(A \rightarrow B)$  |
| (Nec) | $\vdash A$ implies $\vdash \square A$                                      |

A modal system is called *normal* if it contains the distribution axiom ( $K$ ) and the necessitation rule ( $Nec$ ) among its axioms and rules, and *minimal* if it has only ( $K$ ) as a modal axiom and ( $Nec$ ) as a modal rule.  $K^\diamond$  is minimal and normal. In addition, it is not difficult to see that  $K^\diamond$  is a fragment of the system  $K$ , since the axioms ( $K1$ )-( $K3$ ) can be derived in the system  $K$ , as the reader can verify as an exercise (remember that  $K$  is obtained by adding to CPL+ the axiom  $K$  and the necessitation rule). As well as  $mbC$ ,  $K^\diamond$  satisfies the properties of reflexivity, monotonicity, cut and compactness. Besides, the deduction theorem is also valid.

### A Semantics for $K^\diamond$

Now a Kripke-style semantics for  $K^\diamond$  will be presented, or in other words, a possible world semantics. Such a semantics has two basic and primitive notions: (i) the notion of possible world, usually understood as a way things in the world might have been, and (ii) the notion of accessibility, or relative possibility, between worlds. The basic idea of (ii) is that it may be the case that some alternative worlds are not possible with respect to a given world. These intuitions are expressed as follows:

#### Definition 15.4

An *anodic frame* is a birelational structure  $\mathfrak{F} = \langle W, R_\square, R_\diamond \rangle$ .  $W$  is a nonempty set (a set of possible worlds), and  $R_\square$  and  $R_\diamond$  are any binary relations on  $W$  (accessibility relations between worlds).

Notice that the definition above needs two binary relations because  $\square$  and  $\diamond$  are not interdefinable. Frames play a central role in modal logic because the conditions imposed on the accessibility relation are placed on frames. In  $K^\diamond$ , as well in  $K$ , there is no condition on the relations  $R_\square$  and  $R_\diamond$ .  $\mathfrak{F}$  is said to be a *frame* for a modal system  $S$  if every theorem of  $S$  is valid on  $\mathfrak{F}$ . It will become clear throughout this section.

A *model* for a modal system  $S$  is defined by specifying what formulas receive the semantic value 1 in which worlds. The following definition specifies what a model for the anodic system  $K^\diamond$  is:

#### Definition 15.5

A model for  $K^\diamond$  is a pair  $\mathfrak{M} = \langle \mathfrak{F}, v \rangle$  where  $\mathfrak{F}$  is a frame for  $K^\diamond$  and  $v : \text{Var} \times W \rightarrow \{0, 1\}$  is a function satisfying:

- (i)  $v(p, w) = 1$  or  $v(p, w) = 0$
- (ii)  $v(A \rightarrow B, w) = 1$  iff  $v(A, w) = 0$  or  $v(B, w) = 1$
- (iii)  $v(A \wedge B, w) = 1$  iff  $v(A, w) = 1$  and  $v(B, w) = 1$
- (iv)  $v(A \vee B, w) = 1$  iff  $v(A, w) = 1$  or  $v(B, w) = 1$
- (v)  $v(\square A, w) = 1$  iff  $v(A, w') = 1$ , for all  $w' \in W$  such that  $wR_\square w'$
- (vi)  $v(\diamond A, w) = 1$  iff  $v(A, w') = 1$ , for some  $w' \in W$  such that  $wR_\diamond w'$ .

A sentence  $A$  is said to be *satisfied in a model*  $\mathfrak{M}$ , if there is a  $w \in W$  such that  $v(A, w) = 1$  (notation:  $\mathfrak{M}, w \models A$ ). A sentence  $A$  is said to be *valid in a model*  $\mathfrak{M}$ , if  $v(A, w) = 1$  for all  $w \in W$  (notation:  $\mathfrak{M} \models A$ ). A sentence  $A$  is said to be *valid in a frame*  $\mathfrak{F}$ , if  $A$  is valid in all models  $\mathfrak{M}$  based on  $\mathfrak{F}$  (notation:  $\mathfrak{F} \models A$ ).

A special class of frames  $\mathcal{F}$  is the collection of frames that satisfy some condition imposed on the relation  $R$ . Examples are the special class of reflexive

frames, where  $R$  is reflexive, and the class of general frames, where there is no condition imposed on  $R$ . Remember that there is no condition on the accessibility relations in  $K^\diamond$ .

A sentence  $A$  is a *semantic consequence* of  $\Gamma$  with respect to the class  $\mathcal{F}$  of frames if  $\mathfrak{F} \models \Gamma$  then  $\mathfrak{F} \models A$ , for each  $\mathfrak{F} \in \mathcal{F}$ , where  $\mathfrak{F} \models \Gamma$  means that  $\mathfrak{F} \models B$  for all  $B \in \Gamma$ .

Notice that the semantics in the clauses above, (i) to (iv) are classical in the sense that, in each world  $w$ , the propositional connectives behave classically. This is expected, since  $K^\diamond$  is an extension of CPL+. The system  $K^\diamond$  can be proven sound and complete with respect to the semantics given above. The proof is a bit complicated, and requires some technical details [15.30].

### 15.4.2 The Logic $mbC^\square$

Catholic systems can be obtained by extending  $K^\diamond$ , adding to its language a paraconsistent negation  $\neg$  and the consistency operator  $\circ$  plus specific paraconsistent axioms. The modal paraconsistent logic  $mbC^\square$  is defined by adding to  $K^\diamond$  the following axioms

$$\text{Ax. bc1. } \circ A \rightarrow (A \rightarrow (\neg A \rightarrow B)),$$

$$\text{Ax. 10. } A \vee \neg A.$$

It is clear that  $mbC^\square$  is both an extension of  $mbC$  and of  $K^\diamond$ . Notice that the properties of reflexivity, monotonicity, cut and compactness hold for  $mbC^\square$ , as well as the deduction theorem. Given that it is possible to define a classical negation  $\sim$  in  $mbC$ , then the possibility operator  $\diamond$  can be defined from the necessity operator  $\square$  as usual in modal logic.

$$\diamond A \stackrel{\text{Def}}{=} \sim \square \sim A \tag{15.5}$$

Hence, the axioms (K1)–(K3) are innocuous in  $mbC^\square$ , since they can be easily proven as theorems, as the reader can verify.

#### A Semantics for $mbC^\square$

##### Definition 15.6

A *frame* is a relational structure  $\mathfrak{F} = \langle W, R \rangle$ , where  $W \neq \emptyset$  is a universe and  $R$  is a binary relation on  $W$  (notice that now we need only one relation that covers both  $\diamond$  and  $\square$ ).

A bivalued relational model for the catholic system  $mbC^\square$  is defined as follows:

##### Definition 15.7

A *bivalued relational model*  $\mathfrak{M}$  for  $mbC^\square$  is a pair

$\langle \mathfrak{F}, v \rangle$  where  $\mathfrak{F}$  is a frame and  $v : Var \times W \longrightarrow \{0, 1\}$  is a bivalued modal assignment satisfying the conditions:

- (i)  $v(p, w) = 1$  or  $v(p, w) = 0$ ;
- (ii)  $v(A \rightarrow B, w) = 1$  iff  $v(A, w) = 0$   
or  $v(B, w) = 1$
- (iii)  $v(A \wedge B, w) = 1$  iff  $v(A, w) = 1$   
and  $v(B, w) = 1$
- (iv)  $v(A \vee B, w) = 1$  iff  $v(A, w) = 1$  or  $v(B, w) = 1$
- (v)  $v(A, w) = 0$  implies  $v(\neg A, w) = 1$
- (vi)  $v(\Box A, w) = 1$  iff  $\forall w'(wRw'), v(A, w') = 1$
- (vii)  $v(\Diamond A, w) = 1$  iff  $\exists w'(wRw'), v(A, w') = 1$
- (viii)  $v(\circ A, w) = 1$  implies  $v(A, w) = 0$   
or  $v(\neg A, w) = 0$ .

The notion of validity in a frame is defined as usual.

### 15.4.3 Extensions of $mbC^\Box$

From  $mbC^\Box$ , stronger systems may be defined. The well-known modal systems  $D$ ,  $T$ ,  $S4$ ,  $B$  and  $S5$  are obtained by adding one or more of the following axioms to system  $K$

- (D)  $\Box A \rightarrow \Diamond A$  ;
- (T)  $\Box A \rightarrow A$  ;
- (4)  $\Box A \rightarrow \Box \Box A$  ;
- (B)  $A \rightarrow \Box \Diamond A$  ;
- (5)  $\Diamond A \rightarrow \Box \Diamond A$  .

Now, axiomatic systems for the modal logics listed below are obtained as follows

$$\begin{aligned} D &\stackrel{\text{def}}{=} K + (D) \\ T &\stackrel{\text{def}}{=} K + (T) \\ S4 &\stackrel{\text{def}}{=} K + (T) + (4) \\ B &\stackrel{\text{def}}{=} K + (T) + (B) \\ S5 &\stackrel{\text{def}}{=} K + (T) + (5) \end{aligned}$$

Sound and complete semantics can be obtained for the systems above by imposing appropriate conditions on frames. A *frame*  $\mathfrak{F}$  is

Reflexive iff for every  $w \in W$ ,  $wRw$  ;

Symmetric iff for every  $w, w' \in W$ ,

$wRw'$  implies  $w'Rw$  ;

Transitive iff for every  $w, w', w'' \in W$ ,

$wRw'$  and  $w'Rw''$  implies  $wRw''$  ;

Serial iff for every  $w \in W$  there is some  $w' \in W$  .  
such that  $wRw'$

The modal logics  $K$ ,  $K^\Diamond$  and  $mbC^\Box$  have no condition on frames – that is, they have no condition on the relation  $R$  of accessibility between worlds. Starting from  $K$ , the systems  $D$ ,  $T$ ,  $S4$ ,  $B$  and  $S5$  are obtained imposing the following condition on frames

$D$  : serial;

$T$  : reflexive;

$B$  : reflexive and symmetric;

$S4$  : reflexive, transitive;

$S5$  : reflexive, symmetric, transitive.

Now,  $mbC^\Box$  may be extended, obtaining paraconsistent modal systems that are both extensions and fragments of each of the systems above.

$$\begin{aligned} mbC^D &\stackrel{\text{def}}{=} mbC^\Box + (D) , \\ mbC^T &\stackrel{\text{def}}{=} mbC^\Box + (T) , \\ mbC^B &\stackrel{\text{def}}{=} mbC^\Box + (T) + (B) , \\ mbC^{S4} &\stackrel{\text{def}}{=} mbC^\Box + (T) + (4) , \\ mbC^{S5} &\stackrel{\text{def}}{=} mbC^\Box + (T) + (5) . \end{aligned}$$

Kripke-style semantics for the above paraconsistent modal systems may be obtained by just adding clauses corresponding to the respective restrictions on frames to the semantics for  $mbC^\Box$ .

The modal logic  $S5$ , where the relation is reflexive, symmetric and transitive, or in other words every possible world may access every possible world, is usually accepted as the system that better expresses the intuitive idea of Leibniz according to which possibility amounts to truth in some possible world and necessity amounts to truth in every possible world. Kripke has refined the basic intuition of Leibniz, ingeniously providing complete and sound semantics for the axiomatic systems that were already available.  $S5$  is also taken as the strongest propositional modal system among those presented here. Besides, it is claimed, although not without dispute, that  $S5$  is the system that better expresses the notion of logical necessity. It is worth noting that the system  $mbC^{S5}$  may be seen an extension of  $S5$ , since a classical negation is definable in it. Hence,  $mbC^{S5}$  presents itself as a very powerful paraconsistent modal system, capable of expressing everything that is expressed by  $S5$  plus the resources of the paraconsistent logic  $mbC$ . Applications of  $mbC^{S5}$

in philosophical issues in modal logic, as well as the possibility of enhancing it in order to fit some contexts of reasoning or philosophical problems related to modalities in general are topics that deserve further attention.

Although a large class of anodic and cathodic multimodal logics can be shown to be complete with respect to Kripke frames, an interesting point about anodic and cathodic modal logics is that some incomplete systems can be found in both families. *Bueno-Soler* in [15.31] shows that some classes of cathodic multimodal paraconsistent logics (that is, logics endowed with weak forms of negation) are incomplete with

respect to Kripke semantics. The meaning of this kind of incompleteness is also discussed in [15.31], but, surprisingly, the phenomenon of modal incompleteness is also found among purely positive (multi)modal logics: *Bueno-Soler* in [15.30] obtains some examples of Kripke-incompletable purely positive modal logics, demonstrating that modal incompleteness is a result of the interaction of modalities, independent of negation. The incompleteness in the case of cathodic modal logics, however, does not obtain with respect to possible-translations semantics, marking a distinction between this kind of semantics and Kripke semantics for modalities.

## 15.5 On Alternative Semantics for mbC

The semantic characterization of nonclassical logics in general is not an easy task. As it was proven in [15.7], *mbC*, as well as the majority of LFIs, cannot be characterized by a finite logical matrix. Moreover, *mbC* cannot be algebraizable, even in the wide sense of *Blok* and *Pigozzi* [15.32]. These restricting results also hold for several LFIs extending *mbC*, and for the logics of the  $C_n$  hierarchy. Being so, these systems lie outside standard semantic analysis such as categorical or algebraic semantics. Because of this, the development of alternative semantic techniques for these kinds of LFIs is an important and challenging task.

This section briefly describes some alternative semantic approaches to *mbC* and many other LFIs. All these semantics have an intrinsic nondeterministic character, suggesting that nondeterminism is the correct perspective for this kind of logics.

Let us begin by recalling the valuation semantics for *mbC* introduced above (Definition 15.1). The clauses for the binary connectives  $\rightarrow$ ,  $\vee$  and  $\wedge$  are the same as for classical logic. However, as we have seen, the clauses for the paraconsistent negation  $\neg$  and the consistency operator  $\circ$  give the following (nondeterministic) quasi-matrices

$A$	$\neg A$	$\circ A$	
1	1	0	$v_1$
	0	1	$v_2$
		0	$v_3$
0	1	1	$v_4$
		0	$v_5$

Accordingly, there are five possible valuations for *mbC* concerning propositions  $A$ ,  $\neg A$  and  $\circ A$ , namely  $v_1$  to  $v_5$ , such that  $v_1(A) = v_1(\neg A) = 1$  and  $v_1(\circ A) = 0$ ;  $v_2(A) = v_2(\circ A) = 1$  and  $v_2(\neg A) = 0$ , and so on. Ob-

serve that, if  $v(A) = v(\neg A) = 1$ , then  $v(\circ A)$  is forced to be 0, by the gentle explosion law (*bc1*). Otherwise, when  $v(A) \neq v(\neg A)$  the value of  $v(\circ A)$  is arbitrary. As *Avron* observed in [15.33], simultaneously taking into account the semantic values of  $A$ ,  $\neg A$  and  $\circ A$  instead of taking these values separately, five semantic values derived from the five valuations  $v_1$ – $v_5$  can be obtained, namely  $B_5 = \{t, T, t_0, F, f_0\}$ , where  $t = (1, 1, 0)$ ,  $T = (1, 0, 1)$ ,  $t_0 = (1, 0, 0)$ ,  $F = (0, 1, 1)$  and  $f_0 = (0, 1, 0)$ . This allows a semantic characterization of *mbC* in terms of nondeterministic matrices (see below).

This approach, however, can be traced back to *Fidel's* ideas, already presented in his definition of the notion of twist structures in [15.34] (independently of *Vakarelov* in [15.35]). Indeed, in his PhD thesis [15.36], *Fidel* claims that, by considering  $n$ -tuples of a given class of algebras (for some  $n \geq 2$ ), it is possible to analyze the structure of the algebraic models of other nonclassical logics. Besides twist structures for Nelson's logic (where  $n = 2$ ), he introduces in [15.36, Chap. 4] a new semantics for the logic of Ockham algebras  $P_{3,1}$  by considering triples of elements of distributive lattices. Any triple  $(a, b, c)$  is such that  $a$  represents the value of a formula  $A$ , while  $b$  and  $c$  represent the values of  $\neg A$  and  $\neg\neg A$ , respectively.

These ideas from *Fidel* inspired [15.37], wherein the notions of *snapshots* and *swap structures* for *mbC* (and some LFIs extending it) were introduced.

### Definition 15.8

Let  $\mathcal{A} = \langle A, \wedge, \vee, \rightarrow, 0, 1 \rangle$  be a Boolean algebra, and let  $\mathbb{B}_{\mathcal{A}} = \{(a, b, c) \in A \times A \times A : a \vee b = 1 \text{ and } a \wedge b \wedge c = 0\}$ . A *swap structure* for *mbC* over  $\mathcal{A}$  is any multialgebra  $\mathcal{B} = \langle B, \wedge, \vee, \rightarrow, \neg, \circ \rangle$  such that  $B \subseteq \mathbb{B}_{\mathcal{A}}$  and where the multivalued operations satisfy the following

conditions, for every  $(a, b, c)$  and  $(a', b', c')$  in  $B$ , and for each  $\# \in \{\wedge, \vee, \rightarrow\}$ :

- (i)  $(a, b, c)\#(a', b', c')$   
 $\stackrel{\text{def}}{=} \{(a'', b'', c'') \in B : a'' = a\#a'\};$
- (ii)  $\neg(a, b, c) \stackrel{\text{def}}{=} \{(a'', b'', c'') \in B : a'' = b\};$
- (iii)  $\circ(a, b, c) \stackrel{\text{def}}{=} \{(a'', b'', c'') \in B : a'' = c\}.$

The elements of a given swap structure are called *snapshots*. Intuitively, a snapshot  $x = (a, b, c)$  simultaneously keeps track of the value  $a$  of a given formula  $A$ , the value  $b$  of  $\neg A$ , and the value  $c$  of  $\circ A$ . Because of this,  $a \vee b = 1$  by the principle of excluded middle, and  $a \wedge b \wedge c = 0$  by the gentle explosion law, which are both valid in  $mbC$ .

The binary operations (cf. clause (i)) kept fix the first coordinate of the given snapshots: the second and third coordinates of the output do not depend on the given data. It reflects the fact that the binary connectives are classical, but the truth value of  $\neg(A\#B)$  and  $\circ(A\#B)$  are unrelated to the truth values of  $A, B, \neg A, \neg B, \circ A$  and  $\circ B$ . With respect to the unary connectives (cf. clauses (ii) and (iii)), the negation  $\neg x$  of a snapshot  $x$  is the set of snapshots with the second coordinate of  $x$  on the first place. Accordingly, the consistency  $\circ x$  of  $x$  has the third coordinate of  $x$  in the first place. This reflects the intuitive meaning of the components of a snapshot, as mentioned above. As in the case of (i), the second and third coordinates of  $\neg x$  are independent from  $x$ , since  $\neg\neg A$  and  $\circ\neg A$  are independent from  $A, \neg A$  and  $\circ A$ . The same observation holds for  $\circ x$ .

Swap structures are multialgebras defined over suitable subsets of  $A^3$ , for any Boolean algebra  $A$ . Hence they naturally determine a family of nondeterministic matrices in the sense of Avron and Lev (see below) which semantically characterize  $mbC$  and other LFIs.

Any swap structure  $\mathcal{B}$  for  $mbC$  determines a nondeterministic matrix  $\mathcal{M}(\mathcal{B}) \stackrel{\text{def}}{=} \langle \mathcal{B}, D_{\mathcal{B}} \rangle$  such that  $D_{\mathcal{B}} = \{x \in \mathcal{B} : x_1 = 1\}$  is the set of designated truth values (here,  $x_1$  denotes the first coordinate of the snapshot  $x$ ). Let  $\mathbb{K}$  be the class of such nondeterministic matrices, and define the semantic consequence with respect to swap structures for  $mbC$  as follows:  $\Gamma \models_{\mathbb{K}} A$  iff  $\Gamma \models_{\mathcal{M}(\mathcal{B})} A$ , for every swap structure  $\mathcal{B}$  for  $mbC$  (the consequence relation on each nondeterministic matrix is defined by means of valuations in the sense of Avron and Lev, see below). Then, the following result can be proven [15.37]:

#### **Theorem 15.1 Soundness and Completeness**

Let  $\Gamma \cup \{A\}$  be a set of formulas in  $mbC$ . Then,  $\Gamma \vdash_{mbC} A$  if and only if  $\Gamma \models_{\mathbb{K}} A$ .

The last result can be strongly improved: Let  $\mathcal{A}_2$  be the two-elements Boolean algebra, and let  $\mathbb{K}_2$  be the nondeterministic matrix  $\mathcal{M}(\mathcal{B})$  induced by the unique swap structure  $\mathcal{B}$  for  $mbC$  over  $\mathcal{A}_2$  with domain  $\mathbb{B}_{\mathcal{A}_2}$ . Observe that  $\mathbb{B}_{\mathcal{A}_2}$  coincides with the set  $B_5 = \{t, T, t_0, F, f_0\}$  mentioned at the beginning of this section (with the notation introduced therein). Then, the following result can be proven [15.37]:

#### **Theorem 15.2 Soundness and Completeness with Respect to $\mathcal{A}_2$**

Let  $\Gamma \cup \{A\}$  be a set of formulas in  $mbC$ . Then,  $\Gamma \vdash_{mbC} A$  if and only if  $\Gamma \models_{\mathbb{K}_2} A$ .

Theorem 15.2 is nothing more than the semantic characterization of  $mbC$  by means of Nmatrices obtained in [15.33]. The notion of *nondeterministic matrices* (or *Nmatrices*) was proposed by Avron and Lev in [15.38], and afterwards studied by Avron and his collaborators. Basically, an Nmatrix is a logical matrix  $\mathcal{M} = \langle \mathcal{A}, D \rangle$  such that each operation in the algebra  $\mathcal{A}$  is multivalued, that is, if  $c^{\mathcal{M}}$  is an  $n$ -ary operator of  $\mathcal{A}$  (interpreting a connective  $c$ ) and  $(a_1, \dots, a_n) \in A^n$  (where  $A$  is the domain of the multialgebra) then  $c^{\mathcal{M}}(a_1, \dots, a_n)$  is a finite, nonempty subset of  $A$ . The valuations are mappings  $v$  assigning to each formula of the logic being interpreted by  $\mathcal{M}$  an element of  $A$  in a coherent way, as follows:  $v(c(A_1, \dots, A_n)) \in c^{\mathcal{M}}(v(A_1), \dots, v(A_n))$ . The semantic consequence is defined as in the case of standard logical matrices, namely:  $A$  follows from a set  $\Gamma$  of formulas if, for every valuation  $v$ ,  $v(A) \in D$  (the set of designated truth values) whenever  $v(\gamma) \in D$  for every  $\gamma$  in  $\Gamma$ .

As observed above, the Nmatrices for  $mbC$  considered by Avron were defined by means of a notion equivalent to snapshots in  $B_5$ , with the same motivations described here. Swap structures propose a generalization of this approach to arbitrary Boolean algebras (instead of taking the two-valued Boolean algebra). From this, some interesting perspectives to study LFIs from the point of view of multialgebras arise, by adapting appropriate techniques from algebraic logic.

Finally, the *possible-translations semantics* paradigm will be briefly surveyed here. The *possible-translations semantics* (PTS) were introduced by Carnielli in 1990 [15.39] as an attempt to offer a more palatable interpretation, from the philosophical point of view, for some nonclassical logics, and especially for paraconsistent logics. PTSs are based on the notion of translations between logics (that is, mappings that preserve consequence relations). Using an analogy with natural languages, translations can be thought of as different *world views*, and the concept of PTSs is a way

of interpreting a given logic  $L$  as the combination of all possible *world views*, represented by an appropriate set of translations of the formulas of  $L$  into a class of logics with known consequence relation. By choosing an adequate collection of such translations, the object logic  $L$  acquires a semantic meaning throughout the logics into which it is translated (the so-called *traducts*). When the translations and traducts are decidable, PTSs offer a decision procedure.

In formal terms, a possible-translations semantics for a logic  $L$  is a pair of families  $\{\{L_i\}_{i \in I}, \{f_i\}_{i \in I}\}$  such that each  $L_i$  is a logic and each  $f_i$  is a mapping from  $L$  to  $L_i$  such that  $\Gamma \vdash_L A$  if and only if  $f_i[\Gamma] \vdash_{L_i} f_i(A)$ , for every  $i \in I$ .

In [15.40] it was shown that possible-translations semantics are able to express Nmatrices, which implies that the latter is a particular case of the former. On the

other hand, from the viewpoint of the consequence relation, and leaving aside algebraic aspects, swap-structure semantics is nothing more than a semantics defined by a family of nondeterministic matrices. Therefore, it can be seen as a particular case of possible-translations semantics, as pointed out above.

From the previous considerations, it can be seen that possible-translations semantics is a semantic tool having a wide scope of applications and a high degree of generality. On the other hand, Nmatrices and swap structures offer semantic interpretations with a more algebraic-oriented perspective, thus being more intuitive. In particular, swap structures offer not only a promising way to study *mbC* and other LFIs from the point of view of algebraic logic, but also a new angle for understanding why such logics matter for the analysis of reasoning.

## 15.6 Conclusions

Classical logic is a very powerful tool for modeling both informal and scientific reasoning. However, the fact that it is not able to handle contradictions is an important constraint. Although paraconsistent logics have been gaining an increasingly relevant place in contemporary philosophical debate, there is still some resistance against recognizing their philosophical significance, and it is likely that this reluctance is primarily related to the awkwardness of the claim that there are meaningful contradictory propositions about reality which are true. An epistemological interpretation of the acceptance of contradictions by paraconsistent logics has been presented and defended here. It has also been argued that the logics of formal inconsistency are capable of expressing contradictions as *conflicting evidence*, a notion weaker than truth that occurs in several contexts of informal reasoning and scientific research. The unary operator  $\circ$  initially had the purpose of representing the metatheoretical notion of consistency within the object language. But the idea has been further developed in such a way that it may receive alternative meanings. Actually, any *logical property* may have its validity restricted to a group of propositions, depending on the context of reasoning one wants to represent. This has been done in the logics *mbCD* and its extension *LET<sub>k</sub>*, which restrict not only explosion but also excluded middle.

In Sect. 15.3 we have argued that the logic *mbC*, and its first-order extension *QmbC*, are naturally connected to the general question of finding solutions for (respectively, sentential and quantified) problems of abduction. Although the use of tableaux in abductive contexts is not a novelty, paraconsistent tableaux do represent an ad-

vance, due to the problem of contradictory character of certain abductive solutions. The subject of abduction is currently investigated, and employed, in several fields such as artificial intelligence research, formal systems of law and norms, diagnostic expert systems and databases. In such cases, theory and practice rely more and more on the paraconsistency paradigm. In this way, logic-based abduction, regarded from a paraconsistent perspective, acquires special interest. Taking into account, for instance, that probabilistic abductive reasoning as a form of taking decisions is already extensively used in areas of higher degree of uncertainty such as medical diagnoses and pharmaceutical tests, further investigation on paraconsistent probabilistic methods combined with tableau would open a new research window, adding interest to the type of approach here expounded.

With respect to the paraconsistent modal logics surveyed in the Sect. 15.4, it is worth noting that the epistemological interpretation of contradictions in reasoning scenarios can be naturally combined with modal logics. The informal interpretation here suggested, according to which a pair of contradictory propositions  $A$  and  $\neg A$  means that there is conflicting evidence about  $A$ , and that  $\circ A$  means that the truth value of  $A$  has been conclusively established, can be combined with modalities with interesting new aspects. For example,  $\circ \Box A$  may be understood as meaning that the question about whether or not  $A$  is necessary has been conclusively established, and  $\Box \circ A$  may be understood as meaning that necessarily the truth value of  $A$  will be conclusively established, assigning thus a realistic determinism on the proposition  $A$ . The mere possibility of performing this

separation by means of cathodic and anodic modalities already seems to offer new logical perspectives to some modal dilemmas, although this is not the appropriate place to develop such analysis. In all cases, the ideas here surveyed certainly offer new tools for philosophers and logicians.

Finally, in Sect. 15.5, some alternative semantics were discussed for *mbC* (and for nonclassical logics in general). The fact that *mbC* lies outside the scope of the traditional algebraic methods has furthered the development of new kinds of semantics. Three paradigms were briefly surveyed, and their interrelations were dis-

cussed: swap structures, nondeterministic matrices and possible-translations semantics. These paradigms are bounded nondeterministic in nature, in the sense that the result of an input by the semantic procedure can produce more than one single output, but within a previously determined set of values. This strongly suggests that bounded nondeterminism is a suitable approach when studying *mbC* as well as other logics of the same kind. Besides characterizing *mbC*, the formal properties of such semantics deserve future studies. In particular, the algebraic properties of swap structures constitute an instigating topic of research.

The chapters contained in Part D, *Model-Based Reasoning in Science and the History of Science*, provide conceptual tools that allow us to understand model-based-reasoning in current science and the history of science and akin notions such as similar system-based inferences. On the one hand, they give analytic frames – cognitive, historical, and methodological ones – (Chaps. 16–19) to help us understand that kind of scientific reasoning in any domain or across the social sciences. On the other hand, they address specific forms of model-based reasoning: a paradigm of model-based diagnostic reasoning, supported by a formal theory of diagnostic reasoning (Chap. 20) and a review of the debate on thought experiment (Chap. 21).

Chapter 16 proposes an interpretative frame based on cognitive science to understand the effects mathematical representations may have on scientists' model-based reasoning, specifically on that of physicists. This frame is constituted by the concept of *model-based reasoning*, the concept of *metaphorical processes* founded on embodied cognition and on more basic conceptual spaces, and the concept of *long-term working memory*. Ryan Tweney defends this proposal on the basis of three claims: (i) that mathematical representations used in physics exemplify model-based-reasoning, (b) that the working of such models depends on acquired metaphors and conceptual blend, and (c) that the acquisition of these metaphorical grounds can be explained by developing long-term working memory. He illustrates the argument that the above-mentioned cognitive schemes can be understood as the basis of mathematical representations in physics, developing the analysis of one part of J.C. Maxwell's field theory of electromagnetism.

Chapter 17 seeks to clarify and underline the merits of the cognitive-historical approach elaborated by Nancy Nersessian, an environmental perspective within cognitive studies of science, with which a central aspect of model-based reasoning in science is treated: a process to solve representational problems generating historically creative ideas. In order to achieve this goal, Nora A. Schwartz introduces the main problems and solutions provided using the cognitive-historical method. Accordingly, the chapter consists of three parts: questions about the creation of the scientific concepts, epistemic virtues of the cognitive-historical analysis, and a hypothesis about the creation of scientific concepts. The first one is focused on the nature of cognitive processes implied in the creation of ideas and the search of an account for their effectiveness in achieving successful results. The second one exhibits the epistemic virtues of the historical and cognitive dimensions of the method. The last one introduces the dynamic hypothesis of cog-

nitive processes implicated in scientific change and also develops the argument that model-based reasoning is effective to create new candidate representations because it facilitates the changes of *constraints*.

Chapter 18 helps to improve the understanding and appreciation of the notion of physically similar systems in the philosophy of science. Susan Sterrett characterizes this concept as it is understood currently, based on the article by Edgar Buckingham *On Physically Similar Systems: Illustrations of the Use of Dimensional Equations*. Then she draws a path from the earliest precursors of the concept in the Renaissance to its plain articulation in the twentieth century, bringing out, on the one hand, the key ideas of function, which was developed in the eighteenth century, and, on the other hand, the idea of a coherent system of units, which was developed in the late nineteenth century. Also, Sterrett discusses the role that the notion has in reasoning and drawing inferences: The concept of similar systems has been useful in developing methods to draw inferences about values of specific quantities in a system, based on observations in other systems. Sterrett emphasizes that the success of this approach in physical chemistry promoted the extension of a similar system approach to electromagnetic theory and gas kinetic theory.

Chapter 19 focuses on the distinctive features of the method of hypothetical modeling in social sciences by treating it as one style of reasoning: abstract or theoretical model-based reasoning. With this goal, Caterina Marchionni, Alessandra Basso, and Chiara Lisciandra compare this method with other styles of reasoning employed in social science: experiments and computer simulations. Differences between hypothetical modeling and experiments are found, and the consequences they have for making inferences about the world are explored. Considered closely, computer simulations are also viewed as a different style of reasoning from that of analytical models, in that they are particularly apt for dealing with complex systems. Also, the legitimacy of hypothetical modeling as a way of learning about social scientific phenomena is examined. From recognizing the little philosophical agreement on the issue, the discussion is rebuilt by organizing the different perspectives around the function of models that is taken as primary.

Chapter 20 presents *model-based-diagnostic reasoning*, understood as a paradigm of diagnostic inference aimed to give rational explanations of some faulty behavior of the system under discussion. The main idea of this paradigm is the comparison between the behavior of the observed system and the one which can be predicted using knowledge about the system model.

---

The model-based diagnostic approach is placed within knowledge engineering methods from the artificial intelligence domain and is based on the formal theory of diagnostic reasoning by *R. Reiter*. *Antoni Ligeza* and *Bartłomiej Górny* illustrate the method in detail with applications; particularly they mention the dynamic system of three tanks.

**Chapter 21** is structured in five parts. In the first one, *Margherita Archangeli* introduces in a historical context a sample of examples of thought experimentation with the purpose of giving a precise idea of the issues under discussion. In the second part, she refers to the more relevant steps in the history of thought experiments: the beginning, when the term was coined, and the two phases into which the debate can be divided, the *classic* one and the *contemporary* one. In the last three

sections, *Archangeli* tackles the following questions: what is a thought experiment? What is the function of thought experiments? How do they achieve their function? She reviews what has been said about thought experiment definitions placed within an experimental domain and within a theoretical domain and, finally, she refers to the main features that should help us to identify thought experiments. Further, she deals with the central epistemological questions treated in the literature on thought experiments: what kind of knowledge do thought experiments produce? To what extent are thought experiments a reliable source of information? What role do thought experiments play in the processes of rational choice? Finally, she reviews what has been said about the cognitive underpinnings of thought experimentation and focuses on the role of imagination in thought experiments.

# 16. Metaphor and Model-Based Reasoning in Mathematical Physics

Ryan D. Tweney

The role of model-based reasoning in experimental and theoretical scientific thinking has been extensively studied. However, little work has been done on the role of mathematical representations in such thinking. This chapter will describe how the nature of mathematical expressions in physics can be analyzed using an extension of the metaphoric analysis of mathematics. In *Where Mathematics Comes From*, Lakoff and Núñez argued that embodied metaphors underlie basic mathematical ideas (e.g., the concept of *number* is based on the embodied operations of *collecting objects*), with more complex expressions developed via conceptual blends from simpler expressions (e.g., *addition as combining collections*). In physics, however, the need to represent physical processes and observed entities (including measurements) places different demands on the blending processes. In model-based reasoning, conceptual blends must often be based on immediately available embodiments as well as highly developed mathematical expressions that draw upon expert use of long term working memory. Thus, Faraday's representations of magnetic fields as *lines of force* were modeled by Maxwell as vectors. In this chapter, we compare Faraday's experimental investigation of the magnetic field within a magnet to Maxwell's mathematical treatment of the same problem. Both can be understood by unpacking the metaphoric underpinnings as physical representations. The implications for analogical and model-based reasoning accounts of scientific thinking are discussed.

Mathematics is central in science; it is frequently used as the basis for calculation, as a means of derivation of new expressions, and – the focus of this chapter – as a means of *representation*. Oddly, however, there are few attempts to deal with the power of mathematics as a representational medium in science, in spite of

extensive work on the psychological and cognitive underpinnings of scientific thought in general [16.1].

To clarify what is meant by representation, consider the following. *Isaac Newton*, in his *Principia Mathematica* [16.2] formulated a law of universal gravitation which is usually today expressed with the following

equation

$$F = G \frac{m_1 m_2}{r^2}. \quad (16.1)$$

The equation gives the force  $F$  between two bodies of mass  $m_1$  and  $m_2$ , separated by the distance  $r$ ;  $G$  is the universal gravitational constant. About a century after Newton, *Lagrange* [16.3] showed that there was an alternate way to represent the dynamics among a system of bodies

$$L = T - U. \quad (16.2)$$

Here  $L$ , now known as the Lagrangian, is given as the difference between the kinetic energy  $T$  and the potential energy  $U$ , quantities which can be defined for every point in the space between two (or more) objects. Lagrange showed that his formulation could solve all the same problems as Newton's equations and in many cases was easier to use; it possessed calculation advantages and led to new derivational possibilities.

In fact, however, the two expressions, Newton's and Lagrange's, are fundamentally different in the way they represent the same physical reality. Newton's equation is based on an *action at a distance* view; it tells the relation between the masses in terms of the distance between them, but says nothing about the intervening space; the gravitational attraction just *happens* across empty space. Lagrange's equation, however, is defined at every location *between* the masses. Thus, where Newton's equation is nonlocal in character, Lagrange's equation is local. In this sense, it is more compatible with a field-like conception of the gravitational forces. As representations, therefore, the two expressions convey something entirely different about the dynamics of gravitational attractions. Furthermore, given this difference, it is appropriate to ask what effects the differing representations might have on the way in which physicists reason about gravitation. In particular, how might such representational differences affect the model-based reasoning of a physicist?

It is a commonplace to say that different kinds of mathematics are needed to deal with different kinds of physics. Thus, an Aristotelian world view, which is focused upon a world of objects, is associated with Euclidean geometry, an extremely powerful way of dealing with object shape and size. During the seventeenth century, and the emergence of analytic geometry, it became easier to talk about the relations among objects. For example, one could readily determine the intersection between two curved lines or surfaces. The physics that emerged as the result of the Galilean/Newtonian

world view, in turn, drove the development of calculus as a means of determining and describing the motion of objects, and, more generally, of changing quantities in general. The eighteenth century saw extensive development of the tools of calculus (Lagrange's work being just one example), a development that continued in the nineteenth century [16.4].

But the nineteenth century brought a new kind of physics on the scene, one based on field theory, as exemplified by the work of Michael Faraday and James Clerk Maxwell. New ways of thinking required new kinds of mathematics, the mathematics of space filling, vectorial, expressions. Field theories require attention to the entire space surrounding objects (and even, as we shall see, inside the objects) and gave new meaning to Lagrange's approach. For field theories, Euclidean formulations are inadequate, and even analytic geometric methods can be tedious and unilluminating. Developments in the calculus during the eighteenth century overcame these limitations to a larger extent; in particular, as partial differential equations became available, it became easier to represent phenomena that were not tied to the object-centered world of objects and motion [16.5].

Note that in speaking of the representational power of mathematical expressions, the use of mathematics in science is really being talked about, rather than of mathematics as such. Both Newton and Maxwell, for example, were powerful mathematical thinkers, but they were also finely tuned to the representational use of mathematical expressions. For *Newton*, this centered on a geometric mathematics; for modern readers, his *Principia Mathematica* [16.2] is difficult to read (in part) because we have lost the feel for how his physics can be represented in this way. Translated into the (today) more familiar Leibnizean notation for the calculus; however, the underlying representations become more transparent. For Maxwell, the notation is more familiar (to those who have had a physics course in electricity and magnetism). While some translation is still needed [16.6], Maxwell's field-like use of integral and differential vector expressions, as exemplified in his *Treatise on Electricity and Magnetism* of 1873 [16.7] is still important.

Newton's mechanics, especially as it was understood after Newton, assumed that the fundamental principle of motion depended upon forces that acted at a distance. Two masses attract each other because the gravitational force centered on each produces the motion. Throughout the eighteenth and most of the nineteenth centuries, similar action at a distance forces were presumed to be responsible for electric and magnetic actions. Just as gravitational force obeys an *inverse square law* (as in (16.1)), so also did the attractive or

repulsive force between two magnets or two electric charges. The action at a distance account was challenged by Michael Faraday, who instead argued that electric and magnetic forces depended upon *lines of force*; the first true field theory in physics. By the end of his life, Faraday believed he had demonstrated the physical reality of the lines as immaterial but real centers of *power* [16.8].

Faraday was mainly well-known for his many experimental researches and discoveries, but his theoretical account had almost no adherents – except the young Maxwell. For Maxwell, Faraday’s account was a seminal one, and he set about to translate it into mathematical expressions. Eventually, he was able to show that the prevalent action at a distance theories of electromagnetic effects were less tenable than a true field theory (although this account also was slow to gain acceptance, as *Hunt* has shown [16.9]).

In this chapter, using a part of Maxwell’s account, it will be shown how cognitive science can provide an analytic framework for an understanding of the role of mathematics in physics. Maxwell’s reformulation of classical physical ideas can thus be understood in cognitive terms, using recent formulations of model-based reasoning in science, and recent analyses of the under-

lying metaphoric bases of mathematics. The argument is based on three claims:

1. That mathematical representations can serve in model-based reasoning, and
2. That an understanding of how they are used requires attention to the embodied metaphoric understandings of the expressions. The metaphoric bases are in turn
3. Dependent upon automated cognitive processes related to the employment of long term working memory (LTWM).

In this way, the external representation in the form of a mathematical expression is coordinated with an internal representation.

One terminological point is needed. In distinguishing between metaphors and analogies, an unconventional division between two terms often seen as interchangeable is used. In the present usage (following [16.10]), *Metaphor* is used to signal a taken-for-granted, tacit, comparison. I use *analogy* to signal a comparison between a source and a target that must be explicitly argued. In the particular case of Maxwell’s physics, there have been many studies of his use of analogy in this sense, but little about his use of metaphor.

## 16.1 Cognitive Tools for Interpretive Understanding

Each of the three cognitive claims has a somewhat different epistemic grounding. Here the first claim has been taken to be given. That is, abundant research and scholarship, some reflected in the other chapters of this volume, have shown that model-based reasoning is ubiquitous in science – this will not be argued as such in this chapter. On the other hand, the embodied metaphoric claim is an extension of a current approach, one which is not without controversy. While we will not review the pros and cons, nor claim sides, we do hope to convince the reader that the use of a metaphoric analysis of the tacit, taken-for-granted, aspects of mathematical physics can illuminate the representational power of mathematics. The embodiment of metaphor will be assumed here, and is important to the notion of model-based reasoning as a species of abduction [16.10–14]. Note also that *Simpson* [16.15, 16], while emphasizing the rhetoric of Maxwell’s *Treatise*, is advancing a similar argument. Finally, we use recent research on expertise and long term working memory as an explanatory tool, a way of justifying the metaphoric analysis and of suggesting ways in which such model-based reasoning can be learned and acquired as a working tool.

### 16.1.1 Model-Based Reasoning

Model-based reasoning rests on the claim that scientific thinking is largely a matter of the development of mental models of a richly varied sort; models that are involved in constructive and manipulative activities and that draw upon information in various formats, including linguistic and imagistic simulations, as well as external representations [16.14]. The traditional cognitive views of mental models [16.17], which centered on linguistic and propositional reasoning, have been extended in their application to scientific thinking. Thus, *Nersessian* [16.14], drawing partly on Maxwell’s use of analogy, described a model-based reasoning process which included the mental simulation of complex physical systems (see also [16.18]). *Clement* [16.19] emphasized the recursive character of model-based reasoning, arguing for a *Generate-Evaluate-Modify* cycle. As with *Nersessian*’s approach, *Clement* emphasized the way in which scientific models are successively modified and tested. By studying both scientists and advanced college students in real time, *Clement* was able to track these processes from their initial formulations to the final, tested and justified, model.

### 16.1.2 Metaphoric Processes

In recent years, linguists and cognitive scientists have explored the metaphoric underpinnings of language. The claim is that common expressions like *falling in love*, or *building an argument* are actually based on the specific metaphors of physical falling or of building construction. This has been argued as a way to connect the abstractness of language with sensori-motor cognition, and of *embodied* cognition in general [16.20].

Lakoff and Núñez [16.21] argued that even the most abstract of mathematical formulations are also grounded in basic cognitive embodiments via the use of metaphor. For example, the arithmetical operation of addition is related to the elementary cognitive operations of collecting objects. Thus, *Object collection* as source is mapped onto *Arithmetic* as target. *Collections of objects of the same size* are mapped onto *Numbers*, *Putting collections together* onto *Addition*, and *Taking a smaller collection from a larger one* onto *Subtraction* [16.21, p. 55]. Arithmetic itself can then become the source for further extensions to new target domains. *Grounding metaphors* according to Lakoff and Núñez are linked directly to sensori-motor experience (as in the examples), and these are then the source for further conceptual metaphors.

Turner [16.22] has argued that *conceptual integration*, the *blending* of disparate conceptual spaces is a basic cognitive operation that underlies the emergence of new meaning. Thus, in the metaphor, *The surgeon is a butcher*, the spaces corresponding to the source and target of the metaphor each contribute some meanings to the blend, but the emergent meaning of the whole is something not characteristic of either of the parent spaces. Turner has shown how non-Euclidean geometry can be interpreted as a conceptual blending from Euclidean geometry [16.22, Appendix C, pp. 163–168]. In this fashion, as Lakoff and Núñez also argue, the seemingly abstract spaces of mathematics can be unwrapped by showing their origins in successively more basic conceptual spaces. The approach is general; for example, Núñez [16.23] has used it to interpret the historical case of the development of transfinite cardinal numbers by Georg Cantor.

The conceptual theory of metaphor and its role in science has been the subject of some controversy (see, e.g., the critiques by Murphy [16.24, 25] and Weiskopf [16.26] and the reply by Gibbs Jr. [16.27]). Still, for present purposes, in which the approach is used to structure an interpretive framework, the outcome of the controversy is not directly relevant. For the present analysis, what counts is the ability of the approach to provide a tool for the untangling of what is usually implicit in mathematical physics. Note also

that my approach differs from accounts that regard metaphor as a somewhat loose use of similarity, while analogy has been regarded as founded on more severe constraints; thus Gentner and Jeziorski [16.28] adopt such a view. By contrast, we are using the two terms in unconventional fashion, with metaphor referring to implicit comparisons and analogy to those drawn explicitly.

### 16.1.3 Long Term Working Memory

Cognitive scientists have long distinguished between (1) short term memory (STM), which holds a limited amount of new information for a brief time, (2) long term memory (LTM), a larger, more permanent, store, and (3) WM which holds material recently retrieved from LTM as needed in a specific task. Ericsson and Kintsch [16.29] extended the concept of WM by noting that, among experts, specific kinds of processes seemed to be taking place when domain-specific material was retrieved. Referring to this as (4) LTWM, Ericsson and Kintsch suggested that many of the results of expertise can be explained by the emergence of LTWM. In particular, rather than relying upon specific retrieval cues, experts have acquired *structured* retrieval mechanisms to bring domain-relevant material and skills into WM. In the case of mathematical reasoning in science, a differential equation, say, can be thought of as entraining a series of other components of the knowledge of calculus into LTWM.

Ericsson and Kintsch showed that expert readers (but not inexperienced readers) can keep the thread of a book's argument in mind long after the contents of ordinary (short term) WM have been replaced by new information. In effect, LTM remains immediately accessible. Experts thus have a specific set of retrieval structures that make this possible. The relevant skill is more than simply possession of a set of retrieval cues. The expert retrieval structures also imply an anticipatory element that flags what might be relevant in the near or far distant future. Such structures are domain specific and develop only after extensive deliberate practice. In the case of expert reading, the larger gist of text remains available across long stretches of text. The same is true for differential equations in physics [16.30]; in addition to a specific cue, the skills required to use and interpret such equations become automatic.

For Ericsson and Kintsch, LTWM is acquired as an aspect of the acquisition of expertise and comes about via the extended deliberate practice characteristic of the highest levels of expertise. Thus, physics professors perform differently than physics graduate students on problems where both have the same specific con-

tent knowledge, as *Chi et al.* [16.31] have shown (see also [16.32]). The professor subjects have developed such LTWM retrieval structures centered around the ba-

sic principles of physics, while the graduate students are still acquiring them and are more dependent upon surface-level cues.

## 16.2 Maxwell's Use of Mathematical Representation

In the previous section, three cognitive concepts have been outlined; these will serve as the interpretive framework for the following discussion. We will argue

1. That the mathematical representations used in physics exemplify model-based reasoning
2. That the functioning of such models depends upon acquired metaphors and conceptual blends, and
3. That the acquisition of such metaphoric foundations can be explained by the development of LTWM.

To illustrate the argument, we will develop an analysis of one part of Maxwell's field theory of electromagnetism, a *mini* case study. To provide context, we will give a brief account of experimental work by Faraday which is directly relevant.

### 16.2.1 From Faraday to Maxwell

In a conventional view that finds its way into many textbooks, Michael Faraday (1791–1867) was one of the greatest experimental scientists of the nineteenth century, responsible for a long string of discoveries, most famously in electricity and magnetism. Still, his theoretical ideas were couched in a nonmathematical language that did not, by and large, appeal to his contemporaries. By contrast, as the conventional view has it, James Clerk Maxwell (1831–1879), was one of the greatest of the mathematical physicists of the century. His *translation* of Faraday's theory into mathematical expressions and his subsequent extension of those theories was the ultimate triumph of classical physics. A good brief introduction to Faraday's work is [16.33]. For Maxwell, a good beginning is [16.34].

The conventional view, while broadly correct, misses the nuances of the relation between Faraday's and Maxwell's theory. In particular, Maxwell saw in Faraday an intuitive mathematician of the highest order [16.7, Vol. 1, p. ix]:

“As I proceeded with the study of Faraday, I perceived that his method of conceiving the phenomena was also a mathematical one, though not exhibited in the conventional form of mathematical symbols.”

In the case described below, this will become more clear.

Across thousands of experiments, Faraday developed by 1850 a coherent theory of electric and magnetic fields and the relation between the two [16.8, 35, 36]. Centering on the notion of *lines of force*, which he conceptualized as space-filling immaterial entities possessing dynamic properties, he argued that these were physically real and that his experiments had proved their existence and determined many of their properties. Faraday acknowledged the incompleteness of the theory, in part because it was not possible to determine the velocity with which such fields moved. And, while he had shown by experiment [16.37] a possible relation between electromagnetic fields and light (in the form of a rotation of the direction of polarization of light when traversing a dense transparent glass subjected to a strong magnetic field), he could only speculate on the physical nature of the relationship.

*Thomson* (later Lord Kelvin) [16.38, 39] was the first to attempt a mathematical treatment of Faraday's lines of force. Thomson showed that there was an analogy between the equations describing the distribution of electric and magnetic force and the equations describing the distribution of heat within a solid. In developing the analogy, *Thomson* took no position on the reality of the lines of force, although he later claimed that the equations constituted “a full theory of the characteristics of the lines of force” [16.38, p. 1, footnote added in 1854].

*Maxwell* began his account of Faraday's theory in a series of three papers in 1855–1856, 1861–1862, and 1864, and summarized the final state of his theory in the 1873 *Treatise on Electricity and Magnetism* [16.7]. The development across the three early papers has been extensively analyzed (see especially [16.40, 41]). In the course of the three papers, Maxwell did in fact *translate* Faraday's theory into mathematical form (as the conventional view has it), but there were significant changes along the way. Beginning, like Thomson, with an analogy, Maxwell considered the lines of force in Faraday's theory as if they were tubes carrying an incompressible fluid, then developed a mechanical model (based on vortex wheels in a mechanical ether, again, as an analogy), and finally re-expressed Faraday's notion of *force* into a new form, one based on a dynamical theory with *energy* as the focus; this last view was then fully developed in the *Treatise*. Maxwell's famous

derivation, suggesting that light was an electromagnetic manifestation, appeared initially in the second paper, was re-expressed in the third paper, and finalized at the end of the *Treatise*.

Maxwell's *Treatise* is a complex work with multiple goals. Conceived as a textbook, it includes much material on the fundamental empirical facts of electricity and magnetism, accounts of experiments and measuring devices, and a *dialectical* development of the final theory [16.6, 15, 16]. In its modern form, Maxwell's final account is summarized as *Maxwell's equations*, four vector equations that represent the electric and magnetic fields and the relation between the two. I have outlined how the four equations can be tied metaphorically to primitive embodied notions of stress and strain [16.10]. Here, I compare one aspect of Maxwell's treatment of magnetism to a parallel case examined experimentally by Faraday. This, in turn, will allow an account of how the three cognitive schemas outlined in the previous section can be understood as the bases of mathematical representations in physics.

### 16.2.2 Faraday: Magnetic Lines Within a Magnet

The year 1846 was a crucial one for the development of Faraday's theory of magnetism. In that year, he published three papers on the nature of magnetic interactions, first with light [16.37], then with matter (a brief account is in [16.36] and a more thorough account in [16.8]). Confirming his belief that magnetic lines of force extended through all of space, even penetrating into material bodies, he argued that lines of force were *conducted* within the substance of material bodies, thus establishing that diamagnetic substances (such as bismuth or glass), as well as paramagnetic substances (such as iron) were subject to magnetic influence. Further, by showing the rotation of a polarized light beam in a magnetic field, he was able to argue that magnetic lines of force were perhaps implicated in the nature of light.

Still, he needed to show that the lines of magnetic force could be observed even within the substance of a magnet and that they were closed curves [16.42]. To do this, he conducted an interesting series of experiments in which two long bar magnets of equal strength were placed side by side, with a small gap between (thus acting as a single, thicker, magnet). These were mounted on a shaft within an apparatus that allowed their rotation (Fig. 16.1). With commutators on the shaft of the rotating apparatus, he could then run a wire alongside or within the slot between the magnets, and the wire could be rotated together with or independent

**Fig. 16.1a-c** Faraday's experiments on the lines of force within a magnet. (a) The apparatus used; F and G are two identical magnets mounted on a shaft with a small gap between. Commutators are shown at H, I, and O. (b) The wire separated from and entirely outside the magnet. (c) The wire run through the inside of the magnet. Segments a-d and b-d can be rotated independently, or together with b-c. No current is produced by the entire loop, or by a-d alone, but current is produced by b-d alone or by c-b alone (in the opposite direction) (after [16.42, pp. 333, 338])

of the magnets (which were equivalent to a single magnet with a slot down the middle). Connecting the ends of the wire to a galvanometer, he was able to detect any induced currents in the wire.

Faraday tried a variety of configurations (I simplify his many arrangements in this description), first rotating the wire and magnet together (no current was produced), then the wire alone or the magnet alone (as in Fig. 16.1b, again no current was produced). He then separated the wire at the point b (Fig. 16.1c), which permitted the segments to be rotated separately while maintaining electrical contact. He found that rotating the magnet with the segment b-d and without the segment b-c *did* produce a current, and rotating the wire segment b-c without the segment b-d *also* produced a current, but in the opposite direction. He argued that the segment of the wire from b to d was cutting all the lines of force when revolved, as did segment b to c. Further, the size of the current produced was the same in both cases. Because the currents were in opposite directions, when the whole wire (a-d-b-c) was revolved and the magnet kept stationary, no current was

observed: Each wire was cutting *all* the lines of force but the generated currents were in opposite directions, thus cancelling each other. This was the result he was after: the lines of magnetic force ran through the magnet, out at one end, curved around through space, and re-entered at the other end of the magnet. Magnetic lines of force are closed curves.

### 16.2.3 Maxwell: Magnetic Lines Within a Magnet

Maxwell's *Treatise* is divided into four parts, with the fourth part developing the final form of his theory of electromagnetism and the third presenting his account of magnetism. The first chapter of the third part considered the magnetic potential at any point outside of a nearby magnet, showing that the force on a *unit magnetic pole* is equal to the gradient of the potential ( $\nabla V$ , where  $V$  is a scalar function), that is, to the rate of change of the potential in the direction of greatest change. In Chapter II, Maxwell considered the forces *within* a magnet. In contrast to Faraday, however, he did not here conduct experiments, nor replicate Faraday's (although they are cited). Instead, he conducted a series of thought experiments.

He began by imagining a cylindrical hollow cavity within a bar magnet (Fig. 16.2). Taking its length as  $2b$  and its radius as  $a$ , he then imagined a unit magnetic pole centered within the cavity. Such a pole is an imaginary object, since magnetic monopoles do not exist (that is, if you break a magnet into two pieces, each piece will have a North and South pole, breaking them again, each piece will have two poles, and so on). Still, *were such a thing to exist*, it is possible to represent the forces it would experience. There are two sources; first the forces due to magnetic induction from the ends of the cavity. Since the field lines are parallel to the walls of the cylinder, the walls play no role, only the circular ends are involved. Second, there are forces due to

**Fig. 16.2** Maxwell's thought experiment: a bar magnet with a cavity inside. The cavity is cylindrical, of length  $2b$  and with faces of radius  $a$ . Note that the polarity of the faces is the reverse of the polarity of the nearest end of the magnet

the potential field within the cavity. That is, there is an overall field because the cavity is within a magnet and a specific field due to the surface distribution of magnetism on the ends of the cylindrical cavity. Note that the forces due to the circular surfaces are of opposite polarity to the ends of the magnet.

Maxwell first considered the field due to the surface distribution on the cylinder ends, claiming that the forces on the monopole are equal and in the same direction (because the monopole will be attracted by one surface and repelled by the other). This force will be

$$R = 4\pi I \left( 1 - \frac{b}{\sqrt{a^2 + b^2}} \right), \quad (16.3)$$

where  $R$  is the force and  $I$  is the intensity of magnetization. Because the dimensions of the cavity are involved, the force is dependent upon the shape of the cavity. Interestingly, Maxwell does not show how this equation is obtained, taking for granted that the reader will know how to do this (while not lengthy, I will not carry this out – see [16.6, the comment on 396.2] and the discussion that follows).

With this in hand, Maxwell now asked the reader to consider two cases. In the first, imagine that  $a$  is very small, that is, shrink the diameter of the cylinder cavity. From (16.3), note that  $R$  will approach 0 as  $a$  approaches 0. In the second case, let the cylinder shrink in length. As  $b$  approaches 0, then  $R$  approaches  $4\pi I$ . This means that, in the first case, a long and thin cylinder, the force will simply be that due to the overall field; it will be the gradient of the potential. Maxwell calls this *magnetic force within the magnet* and symbolized it as a vector,  $\mathbf{H}$  (here using bold-face, to indicate a vector). In the second case, which becomes a flat disk as the cylinder length shrinks, the force is dependent on  $R$  and is compounded of  $4\pi I$  and  $\mathbf{H}$ . He symbolizes this new quantity as  $\mathbf{B}$  and calls it the *magnetic induction*. The two terms are related by a simple equation, via the overall intensity of magnetization,  $I$ , which, written as a vector, is

$$\mathbf{B} = \mathbf{H} + 4\pi \mathbf{I}. \quad (16.4)$$

Note from (16.4) that the distinction between  $\mathbf{B}$  and  $\mathbf{H}$  will hold only within a magnet; in the absence of a surrounding magnet, that is, when  $\mathbf{I} = 0$ , the two are identical (Fig. 16.3).

Maxwell used the relation between  $\mathbf{B}$  and  $\mathbf{H}$  to clarify a paradox in Faraday's notion of lines of force. The paradox arose because the directions of  $\mathbf{B}$  and of  $\mathbf{H}$  differ. That is, the magnetic force due to  $\mathbf{H}$  always goes from the North Pole of the magnet to the South Pole – both inside and outside the magnet! As a result, they

**Fig. 16.3** Showing the lines of force within and without a bar magnet; the North Pole is to the left. Solid lines are lines of induction,  $\mathbf{B}$ ; dashed lines are lines of  $\mathbf{H}$ . On the outside of the magnet, the two fields are identical

meedst head on, as it were, at the South Pole, which then constitutes a termination. But Faraday’s lines of force are continuous closed curves and do not meet; they run from the North Pole to the South Pole when outside the magnet and continue from the South Pole to the North Pole inside the magnet, thus constituting closed curves. The magnetic lines due to  $\mathbf{B}$  have the needed property – they run from north to south outside and from south to north inside. For this reason [16.7, Vol. 2, p. 28]:

“All that Faraday says about lines of force [...] is mathematically true, if understood of the lines [...] of magnetic induction.”

## 16.3 Unpacking the Model-Based Reasoning

How do we use the cognitive framework sketched in the first part of this chapter to understand the case study? Maxwell, like Faraday, used model-based reasoning in the example, as should be clear. Like Faraday, Maxwell described for the reader a series of actively used constructions to make the argument for forces within a magnet. Faraday described actual experiments, inviting the reader to construct a mental model of the apparatus, procedures, and results. Maxwell used a thought experiment in the same way; that is, his reader was asked to construct a mental model of an experiment that could be done only in the mind’s eye and

Thomson [16.43] had considered a problem similar to Maxwell’s, in determining the force on a unit pole placed within a small cavity in a magnet. However, he did not resolve the directional paradox between the directions of what were later called  $\mathbf{B}$  and  $\mathbf{H}$  by Maxwell. Smith and Wise [16.44] describe Thomson’s approach and indicate that he did not fully publish his results.

Maxwell’s clarification of the difference between  $\mathbf{B}$  and  $\mathbf{H}$  was highly consequential. In particular, it allowed him to distinguish between magnetic effects which were mechanical in nature and those which were involved in the production of currents in a nearby conductor. In the case of  $\mathbf{H}$ , one is speaking of the *magnetic force*, and this is purely mechanical and can be manifested by the effect on a compass needle or an iron filing. In the case of  $\mathbf{B}$ , the *magnetic induction*, the force can be manifested as an *electromotive force*, that is, as one producing a current in a conductor. For Maxwell (mathematically), as for Faraday (experimentally), these corresponded to two different ways to detect the presence of magnetic field.

Faraday initially mapped magnetic fields by using a small magnetized needle suspended from a thread; such a needle will orient itself along lines of force. He later used a small loop of wire attached to a sensitive galvanometer. When moved in a field, a current would be generated in the loop, a current detectable by a sensitive galvanometer at a distance. This *moving wire* became his favored method, mapping, in Maxwell’s terms, the lines of induction. In subsequent chapters of the *Treatise*, Maxwell developed the mathematical representation of such mappings in great detail, arguing that the magnetic induction and not the magnetic force is the physically significant quantity.

not in reality. That is not to say that actual experiments were entirely absent in Maxwell’s account, rather, they were presumed to be present in the reader’s knowledge, based, in part, on the previous chapters of the book and in the references to Faraday’s experiments.

Still, it is not the case that we can make a one-to-one mapping between the kinds of knowledge that underlies Faraday’s reasoning and that of Maxwell. This is because Maxwell also had to rely upon a kind of knowledge base not used by Faraday. In particular, Maxwell relied upon the *metaphoric* understandings embedded within the mathematical expressions used. For exam-

ple, consider (16.3) from the previous section

$$R = 4\pi I \left( 1 - \frac{b}{\sqrt{a^2 + b^2}} \right),$$

As noted earlier, Maxwell did not provide a derivation of this result, instead assuming that his readers would be able to recognize it. To show its metaphoric nature, first consider the term  $a^2 + b^2$ . From Fig. 16.2, it is apparent that this is related, via the Pythagorean theorem, to the length of the hypotenuse of the triangle with sides  $a$  and  $b$ . If we take the square root and call this  $r$ , then we can simplify (16.3)

$$R = 4\pi I \left( 1 - \frac{b}{r} \right), \quad (16.5a)$$

This, in turn, becomes

$$R = 4\pi I - 4\pi I \frac{b}{r}. \quad (16.5b)$$

Now suppose that  $a$  shrinks (Maxwell's first case). Then  $b/r$  goes to 1 and  $R$  goes to 0. And if  $b$  shrinks (Maxwell's second case), then  $R$  goes to  $4\pi I$ .

The attentive reader can now see how the metaphoric underpinnings worked in the discussion of this equation. For, in fact, what has been asked of *you* to do is what Maxwell (with, to be sure, more extensive metaphors assumed) asked of his readers! That is, we drew upon your knowledge of the Pythagorean theorem and upon your metaphoric sense of what happens when geometric terms like  $a$  and  $b$  change. Further, how the sense of algebraic equations can be modified, as in going from (16.3) to (16.5a) and (16.5b), was also involved. These did not need to be specifically argued because, as Lakoff and Núñez [16.21] argued, these have been acquired on the basis of long practice – they are conceptual blends with metaphoric groundings. On my account, they are not analogies, because the links between source and target are implicit and assumed to be known among his readers. This is why Maxwell does not explicate (16.3).

However, (16.3) is not yet fully explicated for our purposes. Where does the  $4\pi I$  come from? In the previous section, Maxwell had considered the force on a small magnet due to the distribution of a surface of magnetic *matter* (like the imagined cavity and the magnetic monopole, this is another convenient fiction). That discussion, in turn, relied upon results achieved in the first volume of the *Treatise*, in which he showed that the surface distribution of an electric charge on a conductor exerted a force near to the conductor equal to  $4\pi\sigma$ , where  $\sigma$  is the surface distribution of charge. In the present case,  $I$  is equivalent to the charge in the

earlier case. In particular, both charge and magnetic entities exert force according to an inverse square law, that is, inversely as the square of the distance. Thus,  $4\pi I$ , unlike the other part of (16.3) is an analogy, albeit itself grounded in the mathematics of earlier parts of the book [16.7, Vol. 2, p. 5]:

“Since the expression of the law of force between given quantities of *Magnetism* has exactly the same mathematical form as the law of force between quantities of *Electricity* of equal numerical value, much of the mathematical treatment of magnetism must be similar to that of electricity.”

Maxwell is able to carry over the expression for the magnetic surface density from the equivalent expression for electric surface density: he does not need to repeat the derivation (which is also built on metaphoric grounds and hence can be taken as given), he only needs to have shown the analogy.

We can again obtain an informal understanding by asking where the multiplier  $4\pi$  comes from. Note first that the monopole at point P is subjected to an attractive force from one face of the cylindrical cavity and a repelling force from the other face. Both forces are in the same direction, so any one face is contributing  $2\pi$  to the result. But  $2\pi$  is the circumference of a circle of radius 1. Here, it appears as if Maxwell is relying upon a previous result from the first volume of the *Treatise*, namely Stokes's theorem, which states that the surface integral of a function describing a surface is equal to the line integral of the curve bounding that surface. Explaining this would go beyond the scope of this chapter, but it implies in the case of the circular face of the cavity that the force due to the face can be construed as either based on the density of magnetization of the surface or, equivalently, as based on a circulation around the closed curve (the circle) that bounds it. Thus,  $2\pi$  emerges!

Note that for Maxwell's readers Stokes's theorem would have been assumed knowledge (it is explained in a *preliminary* chapter [16.7, Vol. 1, p. 29]). For the present purpose, however, it is enough to catch some glimpse of how the factor emerges; in the following chapter, Maxwell uses Stokes's theorem to make a more explicitly physical representation. There, he shows that a magnetic *shell* (a surface bounded by a closed curve) can be represented equivalently by an electric current in a conductor that follows the same closed curve.

One final point: Maxwell's *Treatise* is notable in part for its use of vectors as representational entities. In the selection here, these appear as  $\mathbf{H}$ ,  $\mathbf{B}$ , and  $\mathbf{I}$ . We have previously discussed the metaphoric basis of vector representations [16.10]. For the present case, it needs only to be noted that vectors are quantities that represent both magnitude *and* direction. They can be grounded on el-

elementary notions of muscular force and direction, and can then be conceptually blended with other mathematical concepts. Throughout the *Treatise*, Maxwell uses them (and the vector calculus) as part of his overall rep-

resentation of fields (as in Fig. 16.3). The introduction of such vector analysis was an important milestone in mathematical physics generally, one that continues to be used today [16.5, 45].

## 16.4 Cognition and Metaphor in Mathematical Physics

This chapter has presented a sketch of a mode of analysis that has important implications for understanding how mathematical representations have gained such great importance in science. There have been many analyses of the role of analogy in model-based reasoning, even extending to accounts of Maxwell's physics. However, the metaphoric aspect of mathematical representations holds the key to understanding how the tacit knowledge embedded within mathematical expressions can become an active part of model-based reasoning.

Three points were discussed in the introduction of this chapter: That mathematical physics does involve model-based reasoning, that metaphor underlies the representational use of mathematics, and that such metaphoric grounding is tacit and acquired (via LTWM) through the acquisition of expertise. We will discuss each in the reverse order.

Since the role of LTWM in Maxwell's case [16.46] has already been discussed, only brief comment is needed here. Maxwell wrote the *Treatise* partly intending it as a text for the new Tripos exam in Natural Philosophy at Cambridge University (he had been appointed to the newly established professorship of natural philosophy in 1871 [16.47, 48]). Maxwell's own education in science and mathematics (primarily at Edinburgh and Cambridge, but beginning even in his childhood) provided him with an extensive knowledge of the mathematics and physics that he took for granted in the book, and it is likely that he expected his students would have similar knowledge. He was writing the *Treatise* for those with the kind of retrieval structures that are fundamental to expertise. In recasting the case study for my readers, we have also made some assumptions; for example, that the reader would know the formula for the circumference of a circle, have algebraic skills, and know at least something about electricity and magnetism. Access to all of these relies upon a similar LTWM capacity; the cognitive underpinnings for Maxwell's students and my readers were not different in principle.

We have also previously spelled out the role of metaphors in the understanding of mathematical physics, using the modern form of Maxwell's equations [16.10]. For the present case study, we have in-

stead relied more closely on the actual text written by Maxwell. Although closer to Maxwell's argument, much has been left out. Further, the analysis is informal and adapted to my readership, not Maxwell's. In this sense, what we have provided is not an analysis of the actual historical materials, but rather a reconstruction of a *possible world*. It is interesting to note the similarity of this maneuver to that used by Lakatos in *Proofs and refutations*, which used a similar ploy to discuss the nature of discovery in mathematical proof [16.49]. Even so, it should be possible to see the way in which metaphors and conceptual blends play a role in the arguments made by Maxwell. The analytic task here is to work backward from the argument as presented by Maxwell to the underlying structure of the mathematical representations.

While a great deal has been written about Maxwell's use of analogy (especially [16.14, 41]), we believe our analyses are the first attempts to use metaphor and conceptual blends to describe the *tacit* knowledge which Maxwell brought to bear on his arguments (see, for a similar attempt, not rooted in metaphor in the same fashion, [16.50]). It has been argued that, from a cognitive point of view, there is no inherent difference between analogy and metaphor. Indeed, the terms, analogy and metaphor, have had a flexible boundary in much of the writing about their use in science. Thus, for example, much of what Bradie [16.51] has written about metaphor applies equally to analogy. The best-known such argument is due to Gentner [16.52]. Her *structure mapping theory* of analogy and metaphor is based on the processes involved in mapping relations from a source to a target, and there is much evidence to suggest that this correctly captures many of the phenomena. Nersessian has extended this, describing (using Maxwell, in part) how analogies can participate in the creation of new conceptual content in science. In turn, this chapter supplements and extends all of these accounts.

Model-based reasoning is an integral part of all naturalistic accounts of science, and this chapter is no exception. That Maxwell used it in presenting his analysis of the magnetic field within a magnet should be clear, even from the brief segment considered. The

thought experiment he presents is fundamentally anchored in the reader's ability to follow the claims made via the construction of a model and via the implementation of the mathematical representations involved. Note that they lead up to the expression of an *identity*, not an *equation* in the usual sense. That is, (16.4),  $\mathbf{B} = \mathbf{H} + 4\pi\mathbf{I}$ , is presented, not because it has calculational uses but because it shows the reader the relationships among key terms and because, by using vector notation for the first time in the section, it reiterates the directional character of the lines of induction, of force, and of magnetic intensity. It is important because of its representational character.

As noted earlier Faraday represented magnetic *lines of force* experimentally, by constructing apparatus that

enabled the detection of the lines within a magnet. Maxwell achieved the same thing using a thought experiment, a move that allowed him to distinguish between  $\mathbf{H}$  and  $\mathbf{B}$ , thus identifying  $\mathbf{B}$  as the physically significant quantity. The two approaches complement each other in an interesting fashion. Thus, Faraday's science is replete with *hand-eye-mind* representations [16.13]; for him, the lines of force were physically real to the extent that he could observe their effects and manipulate their character. For Maxwell, the observation and manipulation were based, not on experiment directly, but on the expression of a mental model and its extension via the metaphoric underpinnings of the mathematical representations. It, too, had a *hand-eye-mind* character.

## 16.5 Conclusions

Ultimately, then, this is the true fashion in which Faraday and Maxwell can be seen as similar: both were doing science in a style dependent upon a fundamental *embodiment* of the conceptual representations they created. For both, this was, in fact, a conscious goal. When Faraday is seeking the physical reality of his lines of force, he is doing just what Maxwell was doing in identifying the vector  $\mathbf{B}$  as the *physically significant* quantity. That they followed different pathways, that Faraday's was experimental and Maxwell's mathematical, is not, in the end, the most important aspect for an understanding of their creative achievements.

Beyond these two cases, however, there is a more general point to be made. That model-based reasoning is ubiquitous in science should be clear to the reader of this volume. What case studies of the type offered here can provide is a method of discovery of the finer points with which such reasoning is carried out. While not every scientist will resemble either Faraday or Maxwell in the way in which they employ such reasoning, still, the nuances may be quite general across cases. In particular, the importance of distinguishing between those aspects of model-based reasoning that are tacit (and hence unargued – what we have referred to as metaphorical in nature) versus those that are explicit (i. e., analogical in nature) is central to any understanding of scientific thinking. That is why determining the role of expertise and of long-term WM is so helpful in understanding the particularities of a case – any case.

The case studies also reflect a challenge to the common view that science deals with increasingly

*abstract* entities, particularly in situations in which mathematical representation is involved. In fact, however, the presence of arcane symbols and equations do not mean that, *for the scientist*, these are necessarily abstract, however they appear to the uninitiated. In the present chapter, we have tried to show how both Faraday and Maxwell were anchored in quite concrete representations of their respective models of the electromagnetic field within a magnet. Those representations depended for their utility on the highly skilled and easily accessible expertise that each investigator possessed. The presence of such expertise is the necessary cognitive grounding of creative achievement in science.

**Acknowledgments.** Thanks are due especially to Howard Fisher, who has saved me from many errors and is not responsible for remaining ones! I have benefitted greatly from discussions of Maxwell with John Clement, Howard Fisher, Frank James, Nancy Nersessian, and Thomas Simpson. The chapter's ultimate origin stems from discussions with the late David Gooding and with Elke Kurz-Milcke. The proximate origin is a paper given at MBR012 in Sestri Levante, Italy, in June, 2012; I am grateful for the questions and comments of the other participants and to Lorenzo Magnani for his support. Matt Lira and Frank James provided helpful comments on an early draft, for which I am grateful. An earlier version was published in L. Magnani (Ed.): *Model Based Reasoning in Science and Technology* (Springer, Berlin 2014) pp. 395–414.

## 17. Nancy Nersessian's Cognitive–Historical Approach

Nora Alejandrina Schwartz

Nancy Nersessian raises questions about the creation of scientific concepts and proposes answers to them based on the cognitive–historical approach. These problems are mainly about the nature of the cognitive processes involved in the generation of ideas fundamentally new in human history and the efficacy of those mechanisms in achieving successful results. In this chapter, I intend to show the epistemic virtues that make this method a useful tool for establishing the *dynamic hypothesis* about the creation of knowledge in science. I also point out that, compared to other methods of cognitive studies on the creation of scientific knowledge – ethnography, in vivo observation, and laboratory experiments – the cognitive–historical approach turns out to be primary. I analyze Nersessian's idea that scientists often employ model-based reasoning, in an iterative way, in order to solve representational problems in the target domain. Additionally, I examine her claim that model-based reasoning facilitates the conceptual change. This hypothesis involves a representation of concepts illustrated by the *dynamic frames* theory about concepts.

Nancy Nersessian has studied the creation of scientific concepts from a naturalized perspective in the philosophy of science: the cognitive historical approach. Why did she do this? What properties does this method possess that justify such employment? The main purpose of this chapter is to clarify the way in which she understands this method and to underline its merits. In order to achieve this goal, I will introduce the main problems about the issue she deals with by this method, and, on the other hand, I will mention the solutions to these questions that she has been able to provide using the cognitive-historical method.

This chapter consists of three parts. The first, Sect. 17.1 *Questions About the Creation of the Scientific Concepts*, highlights that, within Nersessian's recasting of the problem of conceptual change, there lies a fundamental question related to the creation of

scientific concepts, and that yet another question arises from this one. The basic question is about the nature of cognitive processes implied in the generation of ideas fundamentally new in human history, which leads to the assessment of their effectiveness in achieving successful results. First, I will introduce Nersessian's review of the way in which logical positivism and the historicist philosophy of science have framed the problem of conceptual change, as well as her critical evaluation of this matter.

The second part, Sect. 17.2 *Epistemic Virtues of the Cognitive-Historical Analysis*, deals with Nersessian's conception of the cognitive-historical method, emphasizing those qualities that make it a useful tool for answering the open questions about the creation of scientific concepts. In addition, it is pointed out here that, compared to other approaches to the creation of scien-

tific knowledge, the cognitive-historical method can be considered primary for it is the one that establishes the generative mechanisms of creative concepts in a historical sense.

The last part, Sect. 17.3 *Hypothesis About the Creation of Scientific Concepts*, has two sections. The first one introduces the dynamic hypothesis proposed by Nersessian to give a solution to the problem of the nature of practices that generate new scientific concepts. Mainly, it will be observed that, through her cogni-

tive-historical investigations, Nersessian confirms that scientists often employ model-based reasoning in an iterative way until they solve representational problems in the target domain. The second section presents the general conception of the meaning or the representation of concepts that Nersessian proposed in the first place so as to understand the change of conceptual structures, and the one that she has more recently suggested, in order to explain the effectiveness of model-based reasoning for creating new concepts.

## 17.1 Questions About the Creation of Scientific Concepts

This section will elucidate the questions about the creation of scientific concepts that have motivated Nersessian's investigation. For this I will show that, to a large extent, they arise from the need to find a suitable answer to the *problem of conceptual change*, and, in turn, from the assumption that such an answer depends on a recasting of the problem itself. Nersessian suggests posing this question from the naturalistic point of view in the philosophy of science, that is, the historical-cognitive method. We will see that her questions regarding concept formation are a core part of this new way of understanding the problem of conceptual change, or else, that they are further questions derived from the given answers to this problem.

In Sect. 17.1.1, I will deal with the way in which the problem of conceptual change has been presented by logical positivism and by the *historicist* philosophy of science, and I will also treat the evaluation of this formulation by some naturalistic scholars of science. In Sect. 17.1.2, I will examine the proposal of tackling the problem of conceptual change from a naturalistic point of view. In Sect. 17.1.3, I will present the new naturalistic casting of this problem, particularly its historical-cognitive version. I mention here that it is a core part of this casting to try to determine the nature of the cognitive processes that generate new concepts.

### 17.1.1 The Problem of Conceptual Change

The problem of conceptual change in science has been interpreted and faced in several ways. Although a crucial issue can be identified in it – “How, if in any manner at all, are successive scientific conceptualizations of a domain related to one another?” [17.1] – Nersessian revises the specific manner in which it has been posed and faced by logical positivism and by the *historicist* philosophy of science, and she refers to how some naturalistic researchers, including herself, have viewed this. Regarding the first, she considers that they understood

the problem by focusing on the terms of the change, that is, on the concepts, and that they analyzed those terms as linguistic structures. The neo-positivists faced the problem with the idea that the new conceptual structures are logical extensions of the previous ones; that is why they thought of conceptual change as continuous and cumulative; Kuhn, on the other hand, tackled it by introducing the idea that conceptual change is abrupt and discontinuous, which he developed in his thesis on incommensurability.

Nersessian, like other scholars of science, considers that both positions – the logical positivism's and Kuhn's – are unsatisfactory. Particularly, the thesis of the incommensurability seems to them anti-intuitive and contrary to historical evidence. In fact, they pointed out that, according to the results of individual studies on scientific creativity made by historians of science, conceptual change is continuous and noncumulative [17.2]. Nersessian highlighted that the answers of these two great philosophical movements of the twentieth century are based on an unsuitable treatment of the question, and that this was due to two main reasons:

1. That most of the philosophers of logical positivism assumed that the analysis of science is done in two contexts, the context of justification and the context of discovery; and that they were convinced that the context concerning philosophy of science is the justification one, and not the discovery one.
2. That the group of science philosophers and historians of which Kuhn was part, together with Hanson and Feyerabend, in spite of having taken the initiative to study the context of discovery, did not have the analytical tools necessary to investigate in depth the scientific activities that it seeks to comprehend.

I will give a further explanation of these two points. Regarding the first reason mentioned, Nersessian recounts that the neo-positivists worked within what they

called *the justification context*. This means that they tended to make *rational reconstructions* of science, in particular artificial maps of the logical relationships between concepts [17.3, p. x]. They analyzed scientific concepts as linguistic structures and considered that logical and conceptual studies were enough to understand the meaning of the scientific theories, not studying the real scientific activity [17.4, p. 4]. With respect to the second reason why she thinks that the treatment of scientific change has been unsatisfactory, *Nersessian* highlights the fact that, though *Kuhn* and *Feyerabend* resorted to scientific knowledge in order to understand conceptual change, the Gestalt psychology available then did not give them the suitable tools for that [17.1, p. 6]. She points out that the perceptive metaphor of *change of Gestalt*, which *Kuhn* took from the Gestalt psychology, had an adverse effect [17.1, p. 6].

“[...] By emphasizing the endpoints of a conceptual change (e.g., Newtonian mechanics and relativistic mechanics) [...], the change of Gestalt was made to appear artificially abrupt and discontinuous.”

Moreover, *Nersessian* wrote that, as a philosopher of science, *Kuhn* neglected the processual aspect of conceptual change [17.1, p. 7].

“Significantly, although *Kuhn* does talk about discovery as an *extended process* [17.5, pp. 45ff] and, in his role as historian of science, has provided detailed examinations of such processes, in his role as philosopher of science he identifies conceptual change with *the last act when the pieces fall together* [17.6].”

Regarding the discussion of the problem of conceptual change in the second half of the twentieth century, *Arabatzis* and *Kindi* [17.4], *Andersen* and *Nersessian* [17.7], and *Thagard* [17.8] can be consulted.

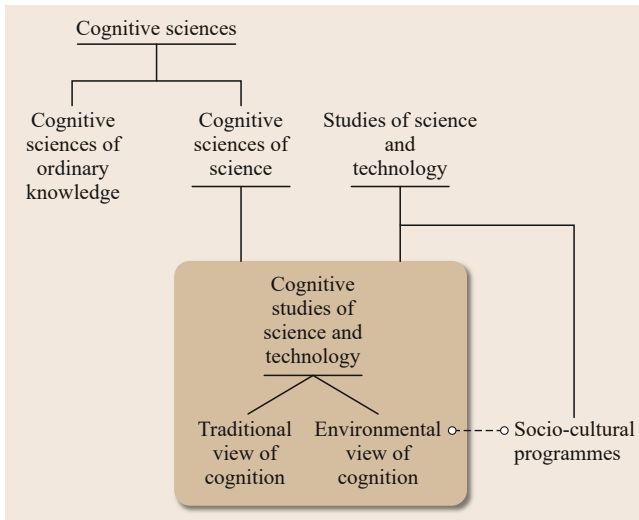

### 17.1.2 The Naturalistic Approach to Science: Revision of the Problem

During the 1980s and 1990s, *Nersessian*, *Paul Thagard* and *Hanne Andersen*, and *Peter Barker* and *Xiang Chen* concurred in revising the *Kuhnian* idea of a radical and sudden conceptual change in science, and they realized that something like that would be, at the most, exceptional. Thus, *Thagard* proposed that to think of changes as gestaltic ones “[...] makes it hard to see how conceptual change can take place” [17.8, p. 49]; see also [17.9]. The conviction that a naturalist scientific approach would enable facing the problem in a suitable way began to impose itself. That is why several scholars

of science further developed such an approach which had been started by the *historicist* philosophers. From this developed a methodological form of naturalism, which defends the need to appeal to science in order to understand science [17.10, Introduction]. Methodological naturalism is one of the various kinds of naturalistic philosophy that have been proposed. *Nersessian's* approach, like *Ronald Giere's*, belong to this position. Usually this one is attributed to *Kuhn* in *The Structure of Scientific Revolutions* [17.5], but was pioneered by *Ludwick Fleck* in *Genesis and Development of a Scientific Fact* [17.11]. Within the domain of philosophy of science, *Fleck* insisted on studying the practice of science instead of propounding rational reconstructions of the logics of the investigation. Therefore, the real subject of the science is an issue of methodological naturalism concern [17.10, p. 3]. *Ronald Giere* characterized the stance as “[...] the vision that all human activities should be understood entirely as natural phenomena, as are activities of chemicals or animals” [17.12, p. 8]. As for the naturalistic studies of science, he describes them as the perspective of “[...] using science in the attempt to understand science itself” [17.13, p. 145]. *Nersessian* bases her own research of science on a naturalistic approach that, to understand scientific knowledge, philosophical theories need to have the best scientific information available on the human subject and about the practices for constructing knowledge used by scientists; she also holds the view that empirical methods are admissible in developing and testing philosophical hypothesis [17.14, pp. 4–5].

### 17.1.3 The Naturalistic Recasting

With the adoption of the naturalistic approach to science, the presentation of the problem of conceptual change is modified. The contrived logical reconstructions of science are replaced by the study of effective scientific practices aiming at explaining the continuous and noncumulative character of conceptual change. *Kuhn* conceived normal scientific cognition in terms of *practices* of solving puzzles guided by solutions to *exemplar* problems [17.15, Chap. 6]. The post-*Kuhnian* group of cognitive orientation holds that interest in scientific activity, focusing, specifically, on the practices of formation and changing of scientific concepts. In general, scientific practices can be understood as procedures carried out by scientific agents. For example, *David Gooding* characterizes the notion of *procedure* implied in such practices as “[...] a sequence of acts or operations whose inferential structure is undecided” [17.16, p. 8]. An overview of the philosophical discussions related to scientific practices can be found in the work of *Joseph Rouse* [17.17]. Although

**Fig. 17.1** Participation of the environmental cognitive studies of science within the cognitive sciences of science and within the studies of science and technology

a scientific procedure is a singular process, two complementary aspects can be distinguished within it:

1. The experimental practice, that is, the manipulation of objects, tools, and experience
2. The intellectual or theoretical practice, that is, the manipulation of concepts, models, propositions, and formalisms.

*Nersessian* presents the problem of conceptual change in the following way: “[...] *how it is that scientists build on existing structures while creating genuine novelty*” [17.1, p. 9]. Unlike the logical positivists, the naturalistic researchers of science understand the question in a way focused on the practices developed by scientists. Thus, they incorporate the *context of discovery* in epistemology. *Nersessian* even came to appreciate the need to demarcate a new domain of investigation, different than both the justification context and the discovery one, which she called *context of development* [17.1, p. 6].

“The context of development is the domain for inquiry into the processes through which a vague speculation gets articulated into a new scientific theory, gets communicated to other scientists, and comes to replace existing representations of a domain.”

I interpret that her goal in doing this was to emphasize that her investigative interest did not focus on

sudden acts of innovation and conceptual change, but on long-lasting processes.

In particular, *Nersessian* develops a naturalistic approach with which she recasts the problem and tries to explain it: the cognitive-historical approach. She says that [17.1, p. 8]:

“In cognitive-historical analysis the problem of conceptual change appears as follows. It is the problem of understanding how scientists combine their human cognitive abilities with the conceptual resources available to them as members of scientific communities and wider social contexts to create and communicate new scientific representations of a domain.”

So her presentation aims at understanding how the cognitive abilities that scientists have as human beings within an environment – and which they share with people who have ordinary knowledge – enable them to construct new concepts. These underlying abilities behind scientific practices are integrated within the cultural, material, and social context, and this environment provides them with conceptual resources [17.14, p. 5]. Although I will analyze the cognitive-historical method in the next section, here I will place it within the cognitive studies of science and technology, one of the naturalistic perspectives of science (Fig. 17.1).

Cognitive science – a confederation of disciplines that includes philosophy, cognitive psychology, artificial intelligence, neurology, cognitive anthropology, and many other areas of study – does research on the cognitive processes and structures implied in ordinary knowledge. It also examines the cognitive mechanisms and the representations involved in scientific knowledge. The *contemporary cognitive science of science* is a naturalist perspective that began to be elaborated in the 1980s and which *Nersessian*, together with Ronald Giere, Lindley Darden, and other philosophers, promoted within the field of philosophy [17.18, p. 2]. One of their main objectives is to explain how scientists construct science naturally. Giere describes this purpose as the aim to reveal how scientists manage to interact with the world when they make science. He points out that scientists, as human beings, have several cognitive abilities, biologically founded, to make that possible [17.12, p. 5].

Within the cognitive science of science, there is a variety of approaches. Some of them, denominated *cognitive studies of science* or *cognitive studies*, consider it relevant to take into account the cultural and social dimensions of scientific practice. These approaches, besides being part of the cognitive science of

science, also participate in the studies of science and technology (STS), together with the social–cultural programs. Some of the methods of the cognitive studies of science use the traditional view of cognitive science. This means that they assume that cognition is a processing of symbols that occurs within the individual minds of humans. Therefore, the cultural and social dimensions of scientific practice are not an integral part of their analysis. On the other hand, other approaches of cognitive studies, the environmental ones, recognize that material, cultural, and social environments in which science is practiced, are crucial to understand scientific cognition. Nersessian argues that, in order to give accounts which capture the fusion of the cultural-cognitive-social dimensions in the practices producing scientific and engineering knowledge, it is convenient to use the view of environmental perspectives in cognitive science. *Nersessian* [17.19] provides an overview of the environmental analysis lines of research that have been delineated between the 1980s and the year 2000. The environmental paradigm emphasizes that sociocultural and body factors have a substantial role in cognitive processes [17.19, 20]. Although it should be pointed out that researchers in cognitive science that study science based on the environmental perspective resist the view of those who think that

all the aspects relevant to science can be explained in terms of sociocultural factors. Nersessian considers that this view is a form of reductionism which is manifested, for example, in the declaration of a 10 year moratorium on cognitive science studies, which was initiated by *Bruno Latour* and *Stephen Woolgar* in 1986 [17.21].

In short, the cognitive-historical method is an environmental approach inscribed within the cognitive studies of science with which Nersessian interprets the problem of conceptual change. The new version of the problem of conceptual change contains a basic question related to the creation of scientific concepts: Which situated cognitive processes, that is, integrated within their environment, do scientists develop in order to come to articulate new concepts from vague notions? As will be treated in Sect. 17.2, this issue has led to investigations that indicate the sought-after processes are *model-based reasoning*. This conclusion, in turn, impelled the posing of new questions, and one among them that stands out for its relevance and potential to determine why this kind of reasoning affords an appropriate medium to generate new scientific concepts is: “*What features of model-based-reasoning make it a particularly effective means of conceptual innovation?*” [17.14, p. 186].

## 17.2 The Epistemic Virtues of Cognitive Historical Analysis

Nersessian studies scientific practices from the perspective of the cognitive-historical approach, aiming at providing suitable answers to the questions related to the creation of scientific concepts mentioned in Sect. 17.1. Here, I will analyze the way in which she conceives of this method, highlighting the advantages it offers to carry out such investigations about science.

In Sect. 17.2.1, I will characterize the cognitive-historical approach in a general way, and will present a brief overview of its expressions and of the conception Nersessian has about it. In Sect. 17.2.2, the dimensions that constitute the cognitive-historical method highlighting the virtues that enable it to provide knowledge about the creation of scientific concepts will be analyzed. In Sect 17.2.3, the cognitive-historical analysis with other approaches used to study the creation of scientific knowledge, for example, ethnography, in vivo observation, and laboratory experiments will be compared. These contrasts will highlight a distinctive property that deserves to be considered a *primary* approach to the study of the creation of scientific concepts with a historical impact.

### 17.2.1 The Cognitive–Historical Approach

Nersessian mentions several approaches to cognitive studies of science provided by the various disciplinary fields within them – in particular philosophy of science, history, cognitive psychology, and cognitive anthropology – from which perspectives creative scientific practices are investigated. She states that ([17.22, p. 127]; [17.18, Chap. 1])

“In contemporary cognitive studies of science, the methodologies employed in investigating the practices scientists use in creating knowledge are ethnography, in vivo observation, laboratory experiments, and cognitive-historical analysis.”

Among these methodologies, she evaluates one of them as particularly advantageous in order to undertake the investigation of those creative practices: cognitive historical analysis. What characteristics does it have? A broad way of describing it is that it is the result of the combination of cognitive and historical methods [17.23, p. 42]. It was *Nersessian* who coined the

term *cognitive history*: “Recently a research frontier I call *cognitive history* has emerged within the history of science and is finding its place in this confederation (Cognitive science)” [17.24, p. 194]. However, this kind of mixed approach was used by other authors, at least since the 1970s. *Tweney* [17.25] presented an overview of its versions that includes the contributions published principally since the 1980s. He restricts his attention to

“those studies that are truly *cognitive-historical*, that is, to those studies that have used cognitive frameworks for the understanding of historical episodes *in such a way* that the methodological niceties of both history and cognitive science are respected.”

They comprise:

1. The application of the solving-problem approach to scientific discoveries by Herbert Simon and his colleagues, understanding the solving of problems as the search within a space of problems which follows heuristic principles, for example, *Kulkarni* and *Simon* [17.26, 27]
2. Kuhn’s appeal to cognitive psychology in order to understand the change in paradigms in *The Structure of Scientific Revolutions* and the work on Kuhnian psychology of science by *De Mey* regarding conceptual change in *The Cognitive Paradigm* [17.28]
3. The use of the Piagetian theory in the cognitive biography of Charles Darwin by *Howard Gruber* [17.29] and the use of some Piagetian ideas to explore the development of concepts in modern physics by *Miller* [17.30]
4. The cognitive formalization of some aspects of Kuhn’s theory about scientific change with the purpose of understanding cases in the history of science by *Andersen et al.* [17.9]
5. The research by *Nersessian* on the psychological nature of change of meaning in science, particularly of the notion of electromagnetic fields in theoretical physics [17.3], and its subsequent elaborations
6. The use of tools provided by cognitive sciences in order to interpret scientific work by Faraday by *Tweney* [17.31]
7. The reconstruction of experiments made by Michael Faraday and the design of conceptual maps of the process by which his vague interpretations became concrete, conveyable scientific concepts by David Gooding; as well as his conception of the emergence of scientific concepts as a process where “hand, eye, and brain” interact [17.16]
8. The cognitive-historical replications by *Tweney* [17.32] and by *Cavicchi* [17.33, 34].

The way in which *Nersessian* understands the cognitive-historical method constitutes a kind of philosophical analysis that integrates several contributions from philosophy, history, and psychology. This is not a purely formal analysis like the ones exalted by logical positivism and questioned by the philosophy of science of the mid-twentieth century. It is, by contrast, an interpretation of historical scientific practices in terms of contemporary cognitive science with the purpose of elaborating a philosophical conception of specific conceptual developments ([17.35, p. 3] and [17.36, p. 163]). A particularity of this approach, as underlined by *Nersessian*, is its reflexiveness [17.1, p. 7]. This means that, from this perspective, the methods, theories, and cognitive categories are used to interpret historical cases and that they are also objects of examination themselves. In fact, these tools may be inadequate to understand the complexity of science, and it is necessary to pay attention to this, in order to identify which changes need to be done on them. Such changes do not only affect the cognitive science of science, but also the cognitive science of ordinary cognition. Consequently, through cognitive-historical analysis, the studies on scientific cognition feedback to the field of cognitive science, thus forming the base for additional cognitive research [17.14, p. 7].

### 17.2.2 Epistemic Virtues and Dimensions of this Approach

References to the dimensions of the cognitive-historical method can be found in multiple articles and books by *Nersessian* [17.1, 14, 22, 24]. I will analyze these dimensions with the purpose of deriving the characteristics that make this perspective an advantageous one to answer the questions related to the creation of scientific concepts. It will be seen that, on the historical side of the method, they are: to enable the epistemic access to conceptual change, and therefore, to the practices of the creation of scientific concepts with historical impact; to enable a deep, detailed study of scientific cognition; to satisfy the requirement of ecological validity, that is, of not altering the studied phenomenon by placing it in an artificial situation; and to retrieve data from the scientific practices in a way that exceeds the verbal accounts. On the cognitive side, one attribute stands out: Making possible interpretations of historical practices in a manner that general conclusions about their nature and function can be drawn.

The *historical dimension* of this method is understood in a wide sense. On the one hand, it is a temporal perspective, that is, it seeks to recover the way in which representational, methodological, and reasoning scientific practices are developed during a long period of

time. Some examples of practices approached in this way are [17.24, p. 194]:

“[...] devising and executing real-world and thought experiments, constructing arguments, inventing and using mathematical tools, creating conceptual innovations, devising means of communicating ideas and practices, and training practitioners.”

This temporal feature of the method is valuable because it makes it possible to obtain knowledge on conceptual change, a scientific phenomenon that is difficult to capture because it is exceptional and it usually implies long lapses. The historical component of the analysis does not constitute a historical narrative, but a detailed investigation of microstructures and micro-processes, more specifically, of representational practices and practices of problem solving [17.1, 14, 24]. On the other hand, the historical dimension of the method is a contextual perspective, that is, it takes into account the community where the scientific practices have been carried out and the cultural resources implied therein. This point of view has the virtue of satisfying the objective of preserving the essence of the phenomenon under investigation pursued by the ecological approach in the psychological investigation. One of the ways to access long-term scientific activities is through historical records. Among the sources are: diaries, laboratory notebooks, publications, correspondence, experimental equipment, drawings, diagrams, lecture notes, and texts. In the case that the investigated procedures are long term and extend into the present, data about them can be obtained in other ways, for example, using field observation and other ethnographic methods (see the next section). Here the main sources of information are the cognitive tools employed in scientific activities and the artifacts produced by them. Consequently, another benefit of the cognitive-historical method is that the information about the practices embedded in the conceptual change is not restricted to scientists' verbal accounts.

The cognitive *dimension* of the method is inscribed in the tradition of psychological epistemology, including works by Locke, Hume, and Quine [17.1, p. 5]. It refers to the employment of cognitive sciences for understanding the scientific practices involved in the creation and change of concepts. It postulates that results, interpretations, and relevant debates on cognitive science would help to understand such scientific practices [17.14, p. 6]. As has been previously mentioned, the cognitive approach adopted by *Nersessian* is the *environmental* one, and this implies considering scientific and engineering thought as a complex *system* that com-

prises material, cultural, and social aspects [17.19]. The *continuum hypothesis* justifies that the achievements of cognitive sciences can be employed to understand scientific practices. This hypothesis refers to the human cognitive capacities and mechanisms of those who make science. It maintains that they are *basically* the same as those of ordinary humans. Therefore, to a great extent, what scientists do, and the constraints they experience, derive from their human cognitive condition [17.1]:

“The underlying presupposition is that the problem-solving strategies scientists have invented and the representational practices they have developed over the course of the history of science are very sophisticated and refined outgrowths of ordinary reasoning and representational processes.”

The *continuum hypothesis* does not negate the fact that there are great differences between scientific and the ordinary cognition. Indeed, scientists have a vast knowledge of a specific domain, have a methodological training, and have learned to metacognitively reflect on and refine the use of cognitive capacities that give them the ability to reason scientifically in carrying out the necessary cognitive functions [17.37, p. 2]. *Nersessian* defends this hypothesis by pointing out that it is not speculative, it is not an *a priori* conjecture, but that it is, on the contrary, a claim based on psychological facts. She also suggests that the understanding of the investigated scientific practices consists in attributing to them a sense which transcends the specific characteristics of the case. This appears to derive from the fact that this sense would be similar to, if not the same as, the one that makes ordinary cognitive practices generalizable. Therefore, the possibility to make *general* descriptions about the nature and processes of scientific activities is opened. In fact, *Nersessian* affirms that such regularities can be abstracted from the *thick descriptions* of the particular case ([17.38, Chap. 1]; [17.14, p. 9]). *Thick description* is a concept from qualitative investigation. It is thought to have been introduced for the first time by Gilbert Ryle. For Ryle [17.39], the *thick* description implied assigning intentionality to one's behavior. The *thick* description interprets behavior within the context and assigns thought and intentionality to the observed behavior. So, for Ryle the *thick* description implies understanding and absorbing the context of the situation or the behavior. Also it signifies assigning current and future intentionality to behavior. Geertz borrows this philosophical term from Ryle in order to describe the ethnography work [17.40]. In this way, abstracting regularities about scientific activities, the problem that historicist philoso-

phers have to face is solved: the one of *how to go from a case study to a more general conclusion*, avoiding the risks of making a hasty generalization [17.1, p. 35]. The cognitive-historical approach, therefore, is satisfactory for understanding the nature of scientific practices and surmounting conclusions established for particular cases.

### 17.2.3 Cognitive Methods to Investigate Conceptual Innovation

Nersessian asserts that the *primary* method to investigate practices of conceptual innovation in science is cognitive-historical analysis (Fig. 17.2). She agrees with other cognitive researchers of science that none of the approaches in use is sufficient by itself to understand those practices and considers, like them, that those methods must be complemented in order to understand the complexity of scientific cognition. For example, *Simon* and *Klahr* assert that [17.41, p. 531]:

“[...] the fundamental thesis in this article is that the findings from these diverse approaches, when considered in combination, can advance our understanding of the discovery process more than any single approach;”

a similar position is taken by *Thagard* [17.18, Chap. 1]. However, at the same time, she considers that not all the employed methodologies are necessarily equal. There is a central feature in cognitive-historical analysis that makes Nersessian consider it fundamental and that distinguishes it from the other methodologies: It enables acquisition of knowledge about the mechanisms that have had a historical impact in science. This quality will be properly understood after examining the other approaches and highlighting in them a characteristic they all share, and which contrasts with the one just mentioned as distinct from cognitive-historical analysis.

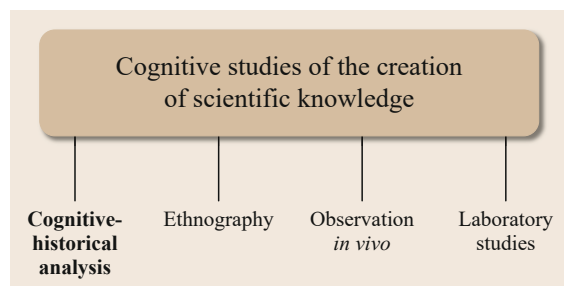

*Ethnographic studies* are based on field work and, in particular, studies about science are usually based

on research made in scientific laboratories [17.42]. Ethnography of science started at the beginning of the 1980s with the sociology of scientific knowledge (SSK) considered as part of social studies of science and technology (STS) – with the work of *Latour* and *Woolgar* [17.21] and *Knorr-Cetina* [17.43], among others. But ethnography of science also is deemed as among the cognitive studies pursued to investigate cognition and its context in mutual relation ([17.44–46]; [17.19, p. 38]). Thus, Nersessian points out that both the way in which scientists understand the problems and the tools they use to solve them depend on a sociocultural context [17.14, p. 7,9]. Specific ethnographic methods are qualitative: They include field observation, collection of artifacts, and field interviews. Each of them is useful to investigate the heuristic of discovery that scientists follow in their daily scientific practice, as they carry it out, that is, in real time and, therefore, to study scientists’ cognitive mechanisms when creating new concepts.

*In vivo* observation is a method suggested by *Dunbar* [17.47, 48]. It arises from the premise that scientists forget many of the important thought processes they use, and that, consequently, there is no record of them in their notes or laboratory notebooks. So he argues that it is necessary to investigate living scientists in order to have information about these processes, that is, by observing them while they perform their work. During observational studies, important activities at the laboratory are recorded, and then the data are codified and interpreted within the frame of psychological constructs.

*Laboratory experiments* are studies of the processes for solving problems of people in artificial situations with the purpose of isolating one or more relevant aspects of science from the real world. In general, they are performed in a psychology laboratory. The experimentation on discovery processes is carried out employing nonscientists as experimental subjects. The principal roles for this experimentation are two: being tools for testing the hypothesis already posed, and being exploratory tools. In this latter case, the experiments are conducted to make certain phenomena appear [17.41, pp. 526–527]. *Klahr* maintains that the experimentation on the discovery processes enables a detailed analysis of the processes of solving problems and that they can be entirely identified and recorded [17.49].

Ethnography, *in vivo* observation, and laboratory experiments have in common that they all provide information about the activities performed at the scientists’ own laboratories, or at laboratories of cognitive sciences during normally brief sessions: hours or days. However, the ethnographic studies mixed with the cognitive-historical method can be extended for years, each of them providing relevant information. An example

**Fig. 17.2** Cognitive approaches of the creation of scientific knowledge

of this is Nersessian's and her collaborators' own research in biomedical engineering laboratories. In this case [17.44, p. 2],

“Ethnographic studies tell us what BME practitioners do in the context of their research and cognitive-historical studies provide insight into how and why these cognitive practices have evolved.”

What is more important is that these approaches are characterized by revealing the creative mechanisms that underlie the practices performed when learning, taking ownership of, and employing *existing concepts*. In other words, they inform about the scientists' cognitive mechanisms that are psychologically creative, that is, mechanisms that produce a conceptual novelty *for them*.

Unlike these approaches, the cognitive-historical method is the only one that can provide information about cognitive practices that are extended in time, thus revealing the mechanisms generating creative concepts in a historical sense, that is, of those concepts previously nonexistent and that have, consequently, historical impact [17.50]. Nersessian adopts Margaret Boden's distinction between psychologically creative ideas and, on the other hand, historically creative ideas. While the first ones “[...] are surprising, or even fundamentally novel, with respect to *the individual mind* which had the idea [...],” the historically creative ideas have not been previously thought by anyone [17.50, p. 43]. This is the reason why Nersessian considers the cognitive-historical method necessary to understand conceptual innovation. Besides, she has in mind that historically creative mechanisms are also psychologically creative, for they generate not only novelties for humanity, but also novelties for the scientists themselves. For this, she considers that ethnography, in vivo observation, and laboratory experimentation are necessary, although in a secondary way, for studying conceptual change. In fact, as these three approaches provide knowledge about scientists' psychologically creative mechanisms, they

can improve the cognitive interpretations of historical episodes in scientific change provided by the cognitive-historical analysis [17.22].

An objection that might be made to the employment of the cognitive-historical method to investigate scientific practices of the creation of concepts is related to a question that any proposal to naturalize the philosophy of science should answer: whether it is legitimate to use scientific knowledge in order to develop a theory of scientific knowledge. A general argument contrary to such a proposal comes from traditional philosophy of science. It states that the use of scientific methods to investigate science is necessarily circular, that it supposes a *petitio principii*, or leads to a regression [17.51, p. 333]. Nersessian defends the use of the cognitive-historical method to develop a theory of the production of scientific knowledge from the argument of circularity. She adopts a point of view similar to the one of the philosophers who practice a naturalized antifundamentalist epistemology, such as *Ronald Giere*, who maintains that [17.12, p. 11]

“The [Cartesian] program of trying to justify science without appeal to any even minimally scientific premises has been going on without conspicuous success for 300 years. One begins to suspect the lack of success is due to the impossibility of the task.”

The circularity implied in the naturalized conception of science, therefore, seems to be inherent to humans and insurmountable for them. But this does not mean that such circularity is vicious. Nersessian supports a virtuous circularity, which could be obtained by putting cognitive and historical interpretations in a state of reflective equilibrium. As has been pointed out earlier, she considers that this reflexivity is a particularity of the cognitive-historical analysis [17.1, p. 7]. Therefore, the studies on scientific cognition provide feedback for the field of cognitive science, thus forming the basis for additional cognitive investigation [17.14, p. 7].

### 17.3 Hypothesis About the Creation of Scientific Concepts

With the cognitive-historical approach, *Nersessian* investigates the cognitive processes that create scientific concepts and succeeds in posing a hypothesis that integrates the dynamic area of a cognitive theory of conceptual change [17.1, p. 5]. This part of the theory *explains* the phenomenon of conceptual change in terms of mechanisms, in a similar way to how dynamics explains movement in physics. This dynamic investiga-

tion requires some representation of scientific concepts, and more broadly, of concepts in general, and, all the more, if one expects to understand why certain mechanisms are very effective in generating them. This is a meta-theoretical question considered as a central one in another of the areas of a cognitive theory of conceptual change, namely, kinematics. This one deals with *describing* the conceptual changes that have occurred

throughout the history of science, in a way similar to that in which in kinematics describes movement in physics.

In Sect. 17.3.1, I will expatiate the dynamic hypothesis proposed by Nersessian to solve the problem of the nature of the practices that create new scientific concepts from the cognitive-historical perspective. In Sect. 17.3.2, I will cite how she understands the power of modeling to generate scientific concepts and refer to her proposal on how to consider the representation of concepts in elaborating this position.

### 17.3.1 Dynamic Hypothesis

The cognitive-historical analysis proceeds by bootstrapping, that is, enables the establishment of hypotheses about conceptual structures and cognitive processes implied in historical cases of scientific investigation, which in turn, serve as support to make new historical studies and cognitive interpretations that provide additional knowledge. Let us see how Nersessian employs it when she poses the *dynamic hypothesis* to solve the problem regarding the nature of the cognitive processes that scientists elaborate in order to articulate new concepts.

The historical studies of several episodes that have led to a conceptual change in science provide information which, according to *Nersessian*, supports the following conclusion: Conceptual innovation does not occur suddenly, but results from *extended problem-solving processes* [17.52, pp. 13–14]:

“[...] If one examines their deeds [of scientists] – their papers, diaries, letters, notebooks – these records support a quite different interpretation in most cases. As I have been arguing for some years, conceptual change results from extended problem-solving processes.”

This way of interpreting historical information fits with the reality that Nersessian includes herself within an epistemological tradition constituted by Dewey, Mead, and Popper, by which science is seen precisely as a problem-solving process. However, in spite of her closeness to these authors, she assumes some distance from them, for their view has a limited range, that is, it does not include the scientific phenomenon of conceptual change [17.1, p. 12]. Nersessian articulates the basic interpretative scheme of the cases of conceptual change as problem-solving processes in psychological terms and, in its elaboration, she uses some concepts that come from Gestalt theory and also from cognitive psychology. A brief reference to them will help to clarify her interpretation.

R. E. Mayer reminds us that, in the psychological literature, a problem consists of a given state, a state of destination, and a set of operators. The problem occurs, according to Gestalt theory, when a situation is in one state, the solver wants it to be in another state, and there are obstacles that prevent a fluid transition from one state to the other. In addition, Mayer asserts that, from a cognitive perspective, the solution of problems is “[...] directed, cognitive processing aimed at finding a way to achieve a goal” and that two phases can often be distinguished in it: the representation of the problem and the solution of the problem. The represented problem may be of various kinds, one of them – of particular relevance for our explanation – is the one of representational problems. There are usually two different ways of finding and carrying out the solution of problems:

1. The sudden appearance of the solution (insight leap), which occurs immediately after a sudden and more suitable restructuring of the representation of the problem – this kind of solution often comes along with the aha! or *Eureka* experience, a subjective feeling of surprise.
2. The process of step-by-step solution – also called the *analytic method* – which consists of finding a strategy and executing a sequence of actions in order to generate a solution to the problem [17.53, pp. 112–113].

*Weisberg* categorizes step-by-step problem solving as an analytic method: “[...] we can categorize the various modes of solving problems that are based on degrees of specificity of knowledge about a problem as *analytic methods*” [17.54, p. 282].

By means of these psychological conceptual tools, Nersessian interprets that, basically, the kind of problem that occurs in conceptual change is a *representational* one, and that the solution implied is a step-by-step one. This means that, on the one hand, this problem consists of a given situation in which a certain phenomenon escapes understanding and the solver does not know how to obtain the new conceptual resources to understand it [17.14, p. xii]; and that, on the other hand, the solution to the representational problem of conceptual change is reached through an heuristic strategy that, as will be immediately apparent, consists of a bootstrapping cycle of modeling, understood as a kind of creative reasoning [17.14, p. 184].

Let us go back to the bootstrapping employment Nersessian’s cognitive-historical method. She realizes that the historical studies of specific cases of conceptual change show, in a ubiquitous way, that scientists use analogy, visual representation, and thought experiments to solve representational problems. She points

out that these three practices have in common that they are ways of modeling, that is, of the construction and manipulation of models. For example, when examining the development of the current concept of the electromagnetic field, she indicates that Faraday articulated the notion of “continuous, progressive transmission of the action” with the help of the concrete visual image of induction “cutting” the strength lines, and with the help of vague analogies between the electric and magnetic actions and *known* progressive phenomena [17.3, pp. 144–145]. Again, Nersessian interprets historical data with cognitive tools and considers that the modeling practices, with which new concepts are constructed, are kinds of reasoning. In doing this, she uses a broad reasoning notion that comes from cognitive psychology, particularly from Johnson-Laird’s semantic conception of reasoning.

Unlike the philosophical traditional notion of reasoning, which only comprises deductive and inductive arguments, Johnson-Laird’s conception enables including kinds of creative reasoning. According to this, much of human reasoning is done through *mental modeling*. When referring to deductive reasoning, *Johnson-Laird et al.* assert that [17.55, p. 3]:

“On the other side, there are those, such as ourselves (see also *Johnson-Laird* and *Byrne* [17.56]) who claim that it is a semantic process that depends on mental models akin to the models that logicians invoke in formulating the semantics of their calculi.”

Following Johnson-Laird, Nersessian maintains that humans retrieve or construct models through which they make inferences about a target problem. The represented structure is supposed to contain parts that can possess an analogous model that also is made of parts. The nature of mental models is, in Peirce’s words, iconic.

The idea that modeling is a kind of reasoning may be applied both to scientific contexts and to ordinary contexts. As she focused on scientific reasoning tasks, Nersessian finds that she needs to extend Johnson-Laird’s conception by widening the domain of mental models. She understands that models are interpretations intended to satisfy the salient constraints of a physical system, process, phenomenon, or situation. This implies that mental models not only comprehend the structural analogues of what is modelled, that is, models which embody representations of spatial, temporal relations, and causal structures, but that they also include functional analogues which are also dynamic in nature. Through her conception of mental modeling, she does not intend to participate in the numerous debates that have been sparked by this notion. That is the reason

why she calls her own hypothesis *minimalist* [17.52, p. 12]:

“To carry out an analysis of model-based reasoning in conceptual change requires only that we adopt a *minimalist* version of a mental modeling hypothesis: that in certain problem solving tasks humans reason by constructing an internal model of the situations, events and processes that in dynamic cases provide the basis for simulative reasoning.”

A property of scientific model-based reasoning is that it does not guarantee the production of a solution, that is, it is not an algorithmic procedure and, because of this, *Nersessian* understands it as heuristic [17.57, pp. 325–326]. The difficulty to produce solutions would be that the models used for reasoning may be unsatisfactory, that is, they may not embody the relevant constraints of the target situation, and not so much that the reasoning may be incorrect [17.52, p. 14].

“In the case of science where the situations are more removed from experience and the assumptions more imbued with theoretical assumptions, there is less assurance that a reasoning process, even if correct, will yield *success*. In the evaluating process, a major criterion for success remains the goodness of fit to the phenomena, but success can also include such factors as enabling the construction of a viable mathematical representation.”

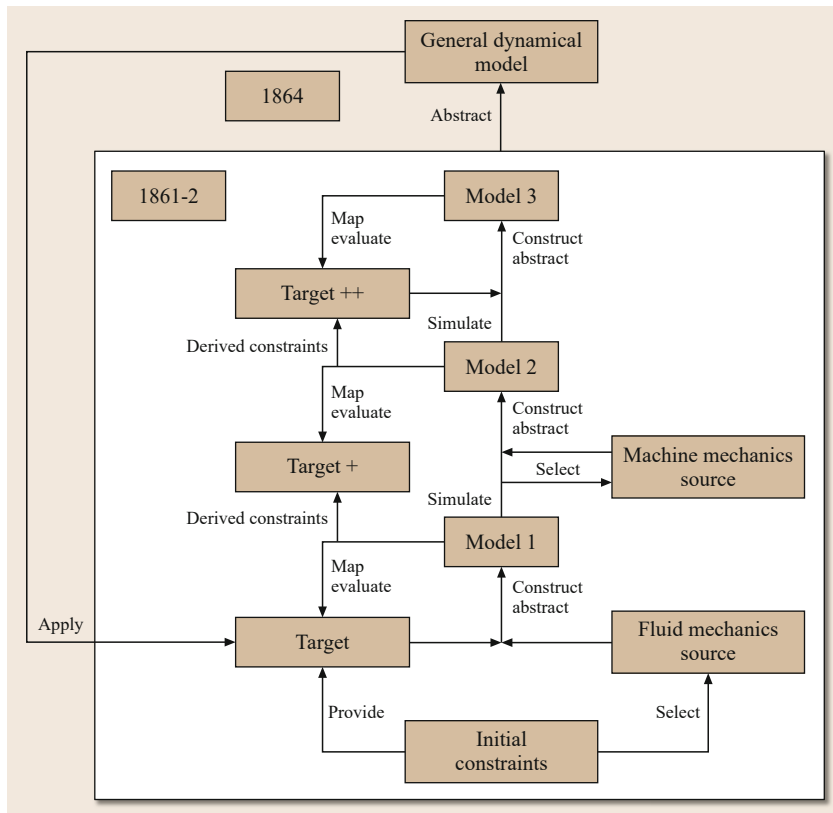

Let us continue with the iterative application of the cognitive-historical method. According to the historical studies of scientific practices, being able to have a model that satisfies the constraints of the target problem frequently involves a cycle of construction, manipulation, evaluation, and adaptation of intermediate models. This is a bootstrapping process. This means that each intermediate model that is constructed achieves a higher satisfaction of the constraints of the target domain, and contributes to constructing the subsequent model. Intermediate models are hybrid, that is, they embody not only the constraints of the target domain, but also those of the respective source domains [17.52, p. 21]. Through the process of construction of satisfactory models, the solution to the representational problems implied in conceptual change cases is achieved. *Nersessian* compares this kind of extended-in-time process with organic phenomena wherein a perfect innovation emerges [17.14, p. ix]:

“Rather, such conceptual innovation, like perfect orchids and flavorful grapes, emerges from lengthy,

organic processes, and requires a combination of inherited and environmental conditions to bud and bloom and reach full development.”

An important feature of the bootstrapping process of creating a model with such reasoning is that it implies selectivity. By means of abstraction and evaluation processes, the irrelevant features are left aside, and attention is focused on the relevant ones according to the problem-solving context. These historical findings differ from those established by the current cognitive theories of analogy. According to them, the models to reason with are already provided by the target source [17.1, p. 20]. Therefore, in order to understand the iterative character of the construction of analogue models in science, it is necessary to modify those cognitive theories. In this way, the reflexive nature of the cognitive-historical method becomes evident. Nersessian deeply analyzes a case that exemplifies the idea that there are modeling processes that generate conceptual innovation. Those are the modeling processes that led Maxwell to make the first derivation of field equations for electromagnetic phenomena. Figure 17.3 shows the contribution of the target, source, and model constraints to these processes of reasoning [17.14, Chap. 2].

The thesis of scientific cognition as model-based reasoning has been developing over more than the last thirty years, due not only to Nersessian’s work, but also to the contribution of authors such as Ronald Giere, Lorenzo Magnani, and Paul Thagard. *L. Magnani* enriched Nersessian’s analysis of model-based reasoning with the reference to the problem of abduction in creative reasoning, also taking advantage of the recent cognitive research on distributed cognition [17.58]. It is fitting to point out the fact that N. Nersessian, since 1998, in collaboration with L. Magnani and P. Thagard, created and promoted the MBR Conferences on Model-Based Reasoning, realizing its seventh convocation in 2015. One of the problems that the thesis of scientific cognition as model-based reasoning presents is that the notion of mental modeling implies that of representation, and the latter has been questioned within the cognitive sciences by the dissenters of the dogma of cognitivism. This *doctrine* of cognitivism is integrated within the representational and the computational theories of the mind [17.59]. As I have mentioned before, Nersessian adopts a moderate environmental perspective that places her on those dissenters’ side. From this environmental approach, she defends the idea of mental modeling, but conceives of it as a procedure carried out

**Fig. 17.3** Maxwell’s modeling process (after [17.14, p. 57])

by a cognitive system constituted by internal representations, frequently coupled with resources from the real world [17.60]. Moreover, together with Lisa Osbeck, she suggests a conception of representations organized in models as practices. These representational practices may be interpreted as distributed, that is, they can be expanded through internal–external traditional domains. These representations are [17.61, Introduction]:

“[...] created and used in the cooperative practices of persons as they engage with natural objects, manufactured devices, and traditions, as they seek to understand and solve new problems.”

In their description of the distribution of representation in scientific cultures, Nersessian and Osbeck employ a language with which they try to convey the co-constitutive nature of culture and cognition, that is, the relation between these two domains in a unique system. In it, the concepts of *cognitive partnering*, *internal–external representational coupling*, and *enactment* are central [17.59, 61].

### 17.3.2 The Power of Model-Based Reasoning

Summing up what was written in the previous part about the hypothesis that Nersessian managed to establish in relation to the creation of scientific concepts, let us say they explain that this scientific practice is based on mechanisms consisting of a modeling iteration. The modeling series ends with the construction of a satisfactory model from which to draw inferences about a target problem. Once she has reached this conclusion about the process of the creation of scientific concepts, Nersessian poses another question. She tries to explain the efficiency of model-based reasoning for creating scientific concepts and, with this in mind, she decided to stipulate a particular concept of concept.

During the 1980s, Nersessian dedicated her studies primarily to the issue related to how to represent concepts in order to understand that conceptual change in science is continuous, gradual, and noncumulative. In this way, she came to describe the representation of a type of concepts as “a set of family resemblances exhibited in its ‘meaning schema’.” But more recently, in [17.14], mentioning the state of the art of the concept representation issue, she stated that there is no agreement either in cognitive science or in philosophy of science about how to conceive of a *concept*. As it is necessary to have some conception about it in order to explain the power of model-based reasoning in the creation of scientific concepts, she propounds one that does not require answer to other problems in debate. In

what follows, I will review the way in which Nersessian treated this issue in order to show the relation it has with her conception of the role of models in creative reasoning.

Nersessian considers the meta-theoretical problem of the representation of concepts as a central theme of the kinematics of conceptual change. This area of the theory of conceptual change aims at determining the *form* of conceptual change, that is, the differences existing between conceptual structures as time goes by, both between conceptual systems and between individual concepts. This task presupposes that a particular representation of concepts is available. On the one hand, the kinds of change that took place between different conceptualizations, the first conceptual structures just mentioned, refer to changes in the form of the organization of the concepts that integrate them. A conceptual system can be analyzed as a network of nodes, where each node corresponds to a concept and each line within the network corresponds to a link between concepts. Within conceptual networks, concepts are organized through links such as kind, property, and relation. These links can be characterized as connections, which indicate that a concept is a kind of another concept, that an object has a property and which express relations, respectively [17.8, pp. 30–31]. Accordingly, the restructuring of the conceptual systems supposes changes related to the concepts that integrate them, and these changes have impact on the other concepts. For instance, changes of hierarchy, changes from properties to relations, and the addition and suppression of concepts. These changes are coordinated, that is, since concepts are interlinked, changes related to a concept have an impact on other concepts.

Nersessian recounts a relevant case of change of conception in the history of science, the one that refers to the representation of movement. She analyzes various phases of this change – the medieval philosophers’, Galileo’s, and Newton’s conceptions of movement – pointing out how some concepts attained a new organization, for instance, the concepts of *movement*, *vacuum*, and *space*, and how the new concept of the *force of gravity* was built. Let us consider a representative sample of the way in which she carries out her examination. She indicates that: *movement* changes in hierarchy within the medieval conceptual structure it is a kind of process, while, within the Galilean conception, it is a state; *gravitas* changes from a property to a relationship – within the medieval mechanics *heaviness* is a property of bodies, while, on the other hand, within Newtonian physics it is a force which acts on the bodies and, as such, a relationship between them; within the Galilean conception, the medieval conception of the distinction of natural/violent movement is abandoned;

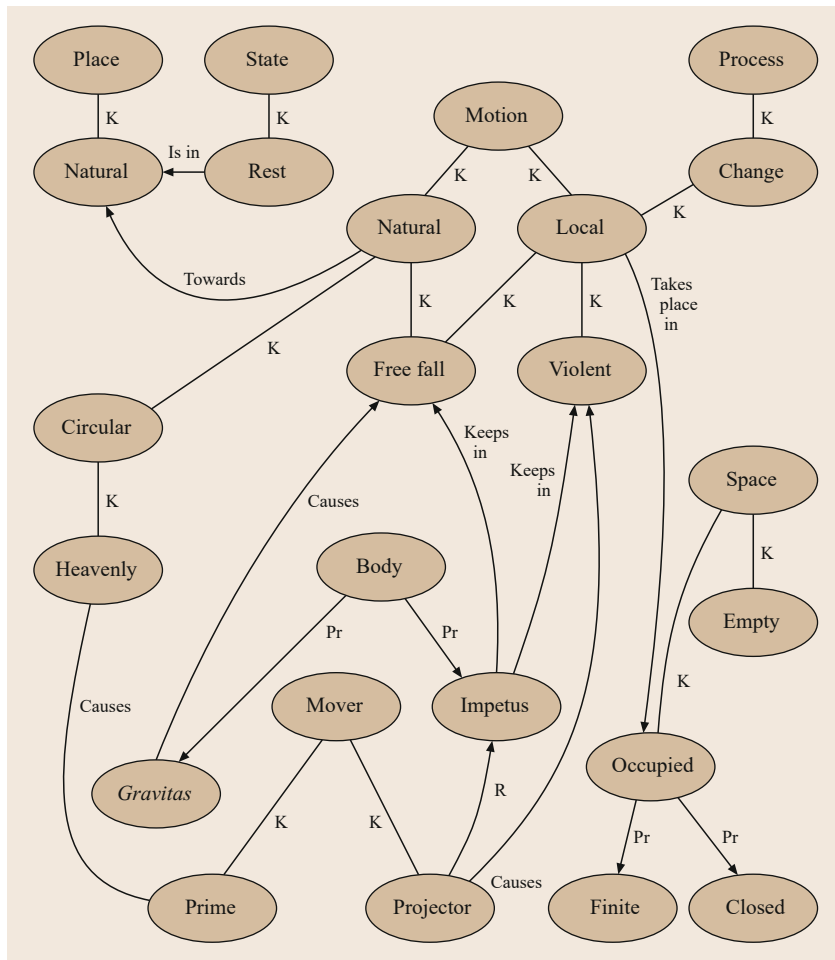

and, finally, within the Newtonian conceptual structure, the *principle of inertia* is added to the theory of mechanics.

Nersessian adopted a system of representation of knowledge, conceptual maps, in order to facilitate the analysis of the changes happening in the various phases. These maps contain conceptual nodes and links between them. For instance, in [17.62, pp. 171–173], she drew three conceptual maps, reproduced in Figs. 17.4–17.6, which represent salient parts of the conceptual structures of the medieval, Galilean, and Newtonian theories of movement. It should be mentioned that Nersessian has made valuable contributions regarding the applicability of knowledge about the way in which conceptual systems in science change to teaching and learning in the field of science [17.62, p. 166].

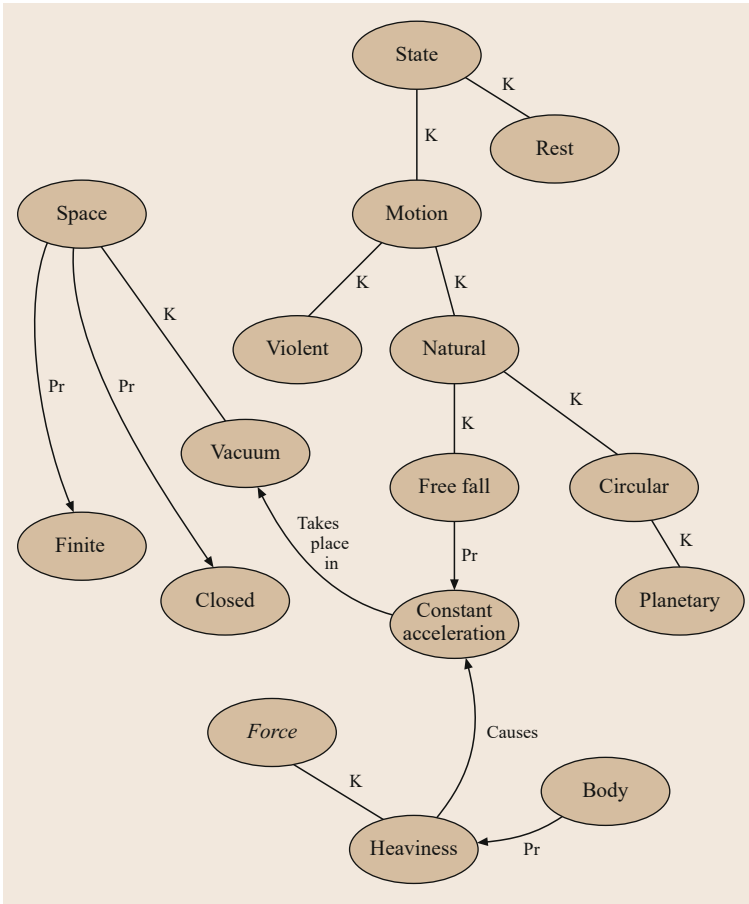

On the other hand, the difference in form that occurs throughout time (in this case not related to complete conceptions, but to an individual concept) refers to the change in meaning between its instances. This kind of

change can be exemplified with the concept of an *electromagnetic field*. Nersessian derived that this concept has undergone three phases. The first one, which she calls *heuristic guide*, encompasses the contributions of Faraday and the first two papers by Maxwell: *On Faraday's Lines of Force* and *On Physical Lines of Force*; the second one, which she calls *elaborative*, comprises the subsequent contributions of Maxwell and those of Lorentz; and the third one, which she calls *philosophical*, that is, a critical reflection on its foundations, encompasses the contributions of Einstein.

To determine the change of an individual concept supposes that a general conception of meaning is available that justifies the existence of an identifiable line of descent among the instances of a concept. In this way, the meta-theoretical problem of establishing the representation or meaning of a concept emerges. Nersessian's early proposal for a general conception of meaning [17.3, Chap. 7] is the following: All the instances of an individual concept fulfill an explana-

**Fig. 17.4** Partial conceptual structure of the medieval theory of motion (after [17.62, p. 171])

**Fig. 17.5** Partial conceptual structure of the Galilean theory of motion (after [17.62, p. 172])

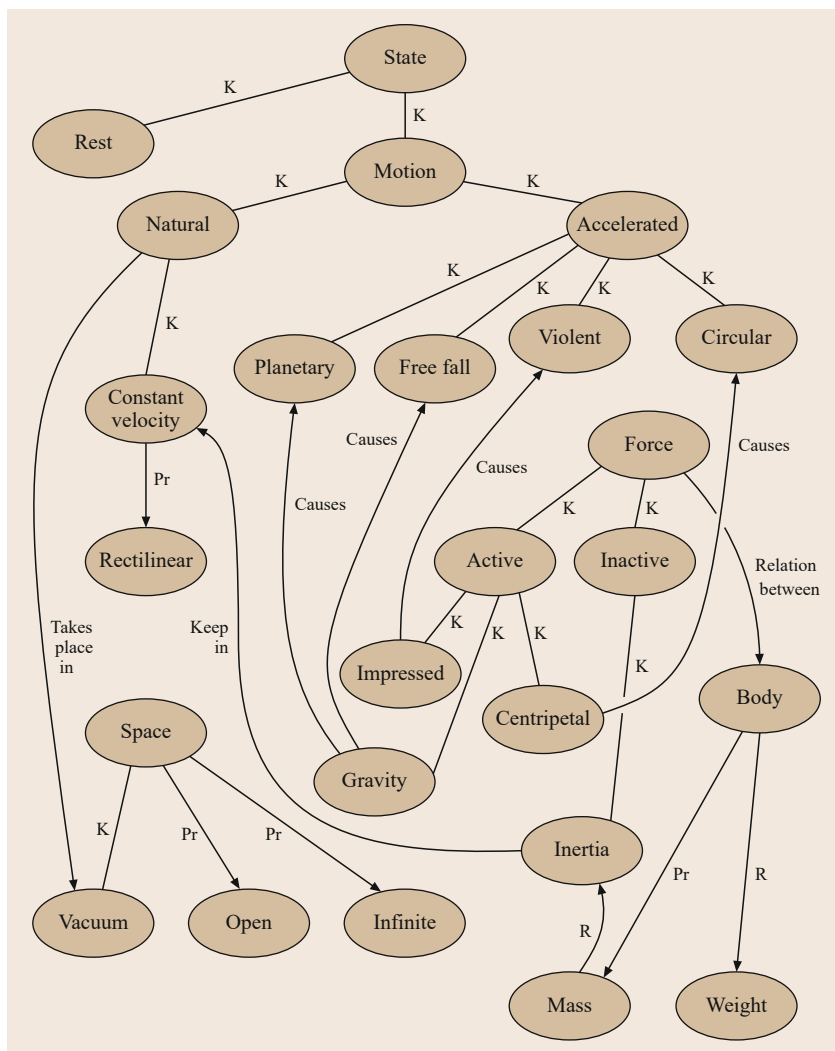

tory/descriptive role in scientific theories. The meaning of a concept or *scheme of meaning* can be understood as a two-dimensional array based on those roles: the dimension that contains a summary of the features of each instance, which can be subsumed under the following factors: *thing, function, structure, and causal power*; and the dimension that contains the development of these features of each instance with the passage of time, which enables one to identify a line of descent between those instances.

In other words, the *instances* of a concept can be represented in both a *synchronic* and a *diachronic* way. Nersessian refers to the synchronic representation of the instances of a concept as a *vector* composed of their salient features. On the other hand, she describes the diachronic representation of the cases of an individual concept as a *vector* expanded to an *array*. Within the array, it is shown how each of the components of the concept's meaning changes over time [17.36, p. 166]. From the representation of the *instances* can arise the representation of a type of concept, which, as I anticipated, is "a set of family resemblances exhibited in

its 'meaning schema'." The representation of a type of concept is an adaptation of the notion of the *prototype* of a concept. Nersessian writes [17.63, p. 161]:

"I have adapted a *prototype* notion of a concept, associated with the work of Eleanor Rosch, to develop a *schema* representation of a scientific concept as an overlapping set of features."

The notion of prototype was elaborated on the basis of the empirical research about concepts carried out by Rosch and her collaborators beginning in 1970. Nersessian found this cognitive view appealing because it enables one to represent the development, the continuity, and the change of concepts in general and of scientific ones in particular [17.36, p. 168]. In fact, the notion of prototype makes it possible to establish a familiarity relationship between the earlier and the later forms of a concept. The probabilistic or prototypes theories about concepts propose that human beings represent a concept by a prototypical example, which is the typical representation of a concept. A prototype in-

**Fig. 17.6** Partial conceptual structure of the Newtonian theory of motion (after [17.62, p. 173])

cludes a list of the features that most probably describe the exemplars of the concept. Some instances of a given concept are better examples than others, depending on the degree in similarity of the object in question to other instances of the concepts or to the prototypical instance. That is why there is a reference to the *graduated structures* of the concepts. Rosch follows Wittgenstein, as, in her conception, a concept is represented by a set of *family resemblances* among the instances placed in the category [17.64]; [17.65, pp. 151–166]. Continuing with the analysis of the example of the concept of *electromagnetic field*, in the three phases of its development, the concept fulfills the role of describing the transmission of electric and magnetic forces and the role of explaining how such continuous and progressive action is possible. On this basis, Nersessian managed to reconstruct the scheme of meaning of the

concept, as summarized in Table 17.1. Here it can be observed that each instance of the concept is linked to the next through *chains of reasoning connections* (COR) (Nersessian borrows this notion from *Dudley Shapere* [17.66]).

In later analyses dealing with the creation of scientific concepts in [17.14], Nersessian discussed briefly the state of the art with respect to the representation of concepts. She wrote that there is no agreement about that, thus [17.14, p. 187]:

“For the present analysis, the format issue can be bypassed by *stipulating* only that whatever the format of a concept, concepts specify constraints for generating members of a class of models.”

Nersessian’s stipulation that concepts specify constraints seems to come from the frame theory about con-

**Table 17.1** Concept of electromagnetic field (after [17.3, p. 158])

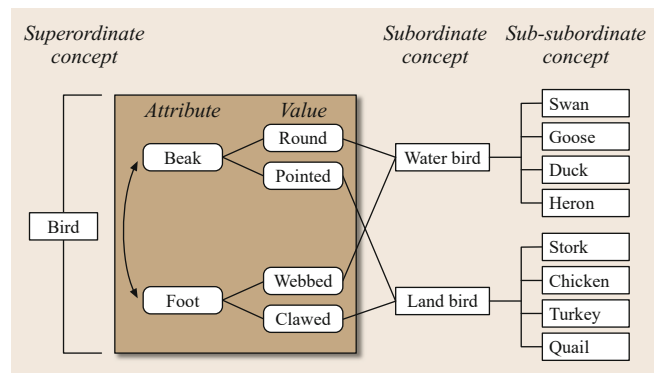

Stuff	Function	Structure	Casual power
Force in region of space (lines are substances? states of <i>aether</i> ?)	Transmits electric and magnetic actions (light? gravity?)	Unknown	Certain electric and magnetic effects
C	C	C	C

cepts. According to this, the *frame of a concept* is a theoretical representation that organizes all the possible information related to a given concept within a speech community. There are various versions of this conception and one of them is Lawrence Barsalou's *dynamic frames* approach. *Nersessian* judges that this frame perspective has been used successfully in many analysis of the change of taxonomic concepts, but she points out that "[...] the case of science is complicated by the existence of many nontaxonomic concepts, such as 'force' and 'mass'" [17.67, p. 183]. The distinction of taxonomic and nontaxonomic concepts corresponds to the Kuhnian classification between *basic* and *theoretical* concepts [17.68] and, later, to the classification between *normic* and *nomc* concepts [17.69]. While taxonomic, basic or normic concepts are learned by pointing out many of their instances, theoretical or nomic concepts are learned by pointing out complex problem situations to which a law is applied [17.70]. *Nersessian* considers that Barsalou's approach helps to illustrate precisely the idea that concepts specify constraints [17.70]. According to Barsalou, a *frame* is a set of attributes with a multiplicity of values, integrated by structural connections. In general, these attributes hold relationships with each other that are given through the majority of the exemplars of a concept. Barsalou calls these *structural invariants* to these relationships. Furthermore, the values of frame attributes are linked with each other through relationships of dependency. These relations are *constraints*. "Instead, values constrain each other in powerful and complex manners" [17.71, p. 37]; [17.72].

*Nersessian* uses the case expounded by *Hanne Andersen* et al. [17.9, Chap. 4] where, precisely, they employ the notion of dynamic frame – in order to illustrate the idea that concepts specify constraints. The case refers to the representation of the concept of *bird*. This one appears in various ways in the successive taxonomies of Ray, Sundevall, and Gadow. In each one, the corresponding frame of the concept of bird reflects a different set of attributes and different constraints between their values. Figures 17.7–17.9 illustrate the difference of conceptual representation in those three ornithological taxonomies.

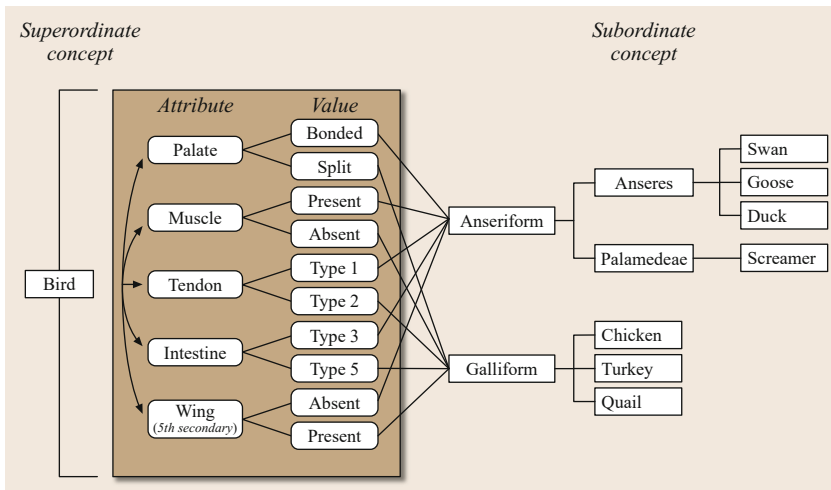

Based on her idea that concepts specify constraints, *Nersessian* describes the concept formation and change as a process of generating new constraints or modify-

**Fig. 17.7** Partial dynamic frame of Ray's concept of bird (1678) (after [17.9, p. 73])

**Fig. 17.8** Partial dynamic frame of Sundevall's concept of bird (1835) (after [17.9, p. 74])

**Fig. 17.9** Partial dynamic frame of Gadow's concept of bird (1893) (after [17.9, p. 88])

ing the existing ones. This construct paved the way to answering philosophical questions such as: How is it that model-based reasoning generates new conceptual representations? And how do models figure in this reasoning and facilitate the reasoning about phenomena?

Model-based reasoning is effective to create new candidate representations because it facilitates the

changes of constraints. By means of the processes of abstraction and integration of constraints from multiple domains in a hybrid model, new combinations of constraints can emerge, and these ones may fit structures and behaviors not represented previously. When scientific change is produced, concepts without precedent in the history of science emerge [17.14, Chap. 6].

## 17.4 Conclusions

From a cognitive-historical approach, Nersessian poses problems relevant to the creation of scientific concepts, thus introducing within the philosophy of science an issue that was traditionally considered not pertinent. Among them, two questions stand out:

1. A fundamental one asks which are the cognitive processes integrated within the environment that scientists develop in forming concepts without precedent in history.
2. The other, derived from the previous one, refers to the reasons that make those mechanisms efficient means to generate new scientific concepts.

As a result, the adoption of a cognitive-historical perspective creates a formulation of the problem that can produce a satisfactory answer. Throughout the chapter, it has been demonstrated that cognitive-historical analysis gathers together features that make it a very valuable tool for that: It makes it possible to obtain information about innovative historical scientific practices; it enables one to study cognitive processes and structures implied in those practices; it aims to investigate creative processes within their own context to avoid distortion; it retrieves data from various kinds of sources; it establishes general conclusions about creative scientific practices; and, finally, it is the method – within cognitive studies – that gives information about historically innovative processes that evolve over long periods of time.

It is possible to appreciate the fertility of the approach through the examination of certain hypothesis about the creation of scientific concepts that Nersessian succeeded in establishing. She obtains information

about historically creative scientific activities and interprets that information in terms of the cognitive sciences. So, on the one hand, she establishes that, through a cycle of bootstrapping modelings, scientists solve representational problems; those modeling processes are genuinely kinds of creative reasoning about a target problem; and model-based reasoning is a heuristic strategy. On the other hand, based on a conception of concepts that stipulates that these specify constraints, she states that the concept formation and change are processes of constraint generation or modification, and she defends the hypothesis that proves that model-based reasoning is effective for creating new candidate representations because they facilitate the change of constraints.

**Acknowledgments.** I wish to thank Alicia E. Gianella for the support she has always given me, and for her inexhaustible willingness to listen to and discuss my embryonic ideas. I am also extremely grateful to the encouragement Nancy Nersessian gave me to continue with my research, when I had the opportunity to meet her at the Conference *Logic, Reasoning and Rationality* held in September 2010 at the Universiteit Gent, Belgium. I highly appreciate the valuable comments of Carlos Oller to a first draft of this chapter, as well as Sandra Meta's help with the final version in English. Finally, I wish to specially mention Lorenzo Magnani for the confidence he granted me, and to the C.I.E.C.E. (Centro de Investigación en Epistemología de las Ciencias Económicas de la Facultad de Ciencias Económicas – Universidad de Buenos Aires), which has given me a space for productive intellectual exchange.

# 18. Physically Similar Systems – A History of the Concept

Susan G. Sterrett

The concept of *similar systems* arose in physics and appears to have originated with Newton in the seventeenth century. This chapter provides a critical history of the concept of *physically similar systems*, the twentieth century concept into which it developed. The concept was used in the nineteenth century in various fields of engineering (Froude, Bertrand, Reech), theoretical physics (van der Waals, Onnes, Lorentz, Maxwell, Boltzmann), and theoretical and experimental hydrodynamics (Stokes, Helmholtz, Reynolds, Prandtl, Rayleigh). In 1914, it was articulated in terms of ideas developed in the eighteenth century and used in nineteenth century mathematics and mechanics: equations, functions, and dimensional analysis. The terminology *physically similar systems* was proposed for this new characterization of similar systems by the physicist Edgar Buckingham. Related work by Vaschy, Bertrand, and Riabouchinsky had appeared by then. The concept is very powerful in studying physical phenomena both theoretically and experimentally. As it is not currently a part of the core curricula of science, technology, engineering, and mathematics (STEM) disciplines or philosophy of science, it is not as well known as it ought to be.

The concept of *similar systems* is one of the most powerful concepts in the natural sciences, yet one of the most neglected concepts in philosophy of science today. The concept of similar systems was developed specifically for physics, and its use in biology has generally been in terms of plant and animal physiology; hence, the term *physically similar systems* is often used. It remains an open research question whether, and how, the concept of similar systems might be applied to sciences other than physics, such as ecology, economics, and anthropology.

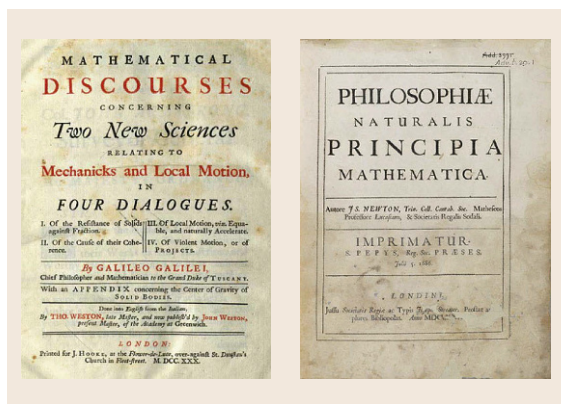

This chapter is devoted to providing a history of the concept of physically similar systems. It also aims, in doing so, to increase the understanding and apprecia-

tion of the concept of *similar systems* in philosophy. In addition to being neglected in philosophy of science, the concept of *similar systems* is also often not fully understood even when it is mentioned.

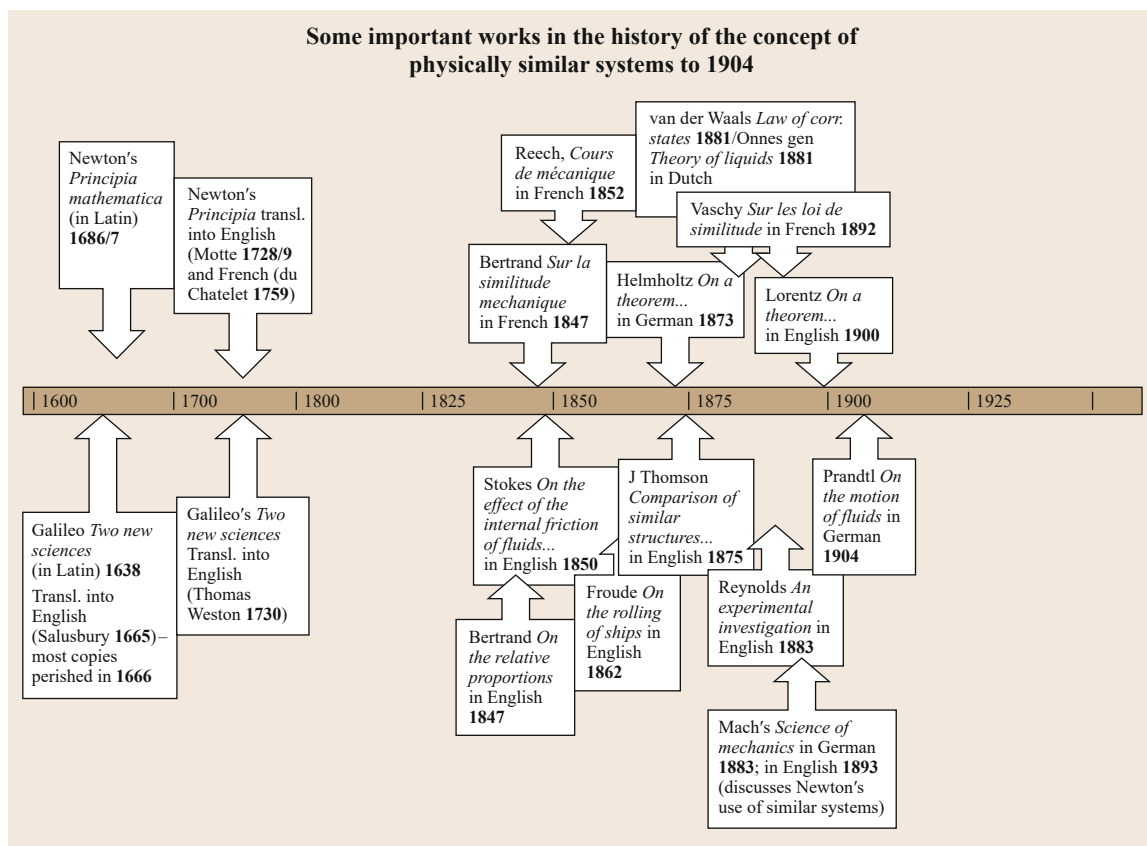

The concept of similar systems has been useful in developing methods for drawing inferences about the values of specific quantities in one system from observations on another system. Some know of the concept only in this derivative way, via applications to specific questions in physics, biology, or engineering.

The fact that it has such useful applications has sometimes led to an underappreciation of the fundamental nature, immense power, and broad scope of the concept. Yet, its utility in practical matters of determin-

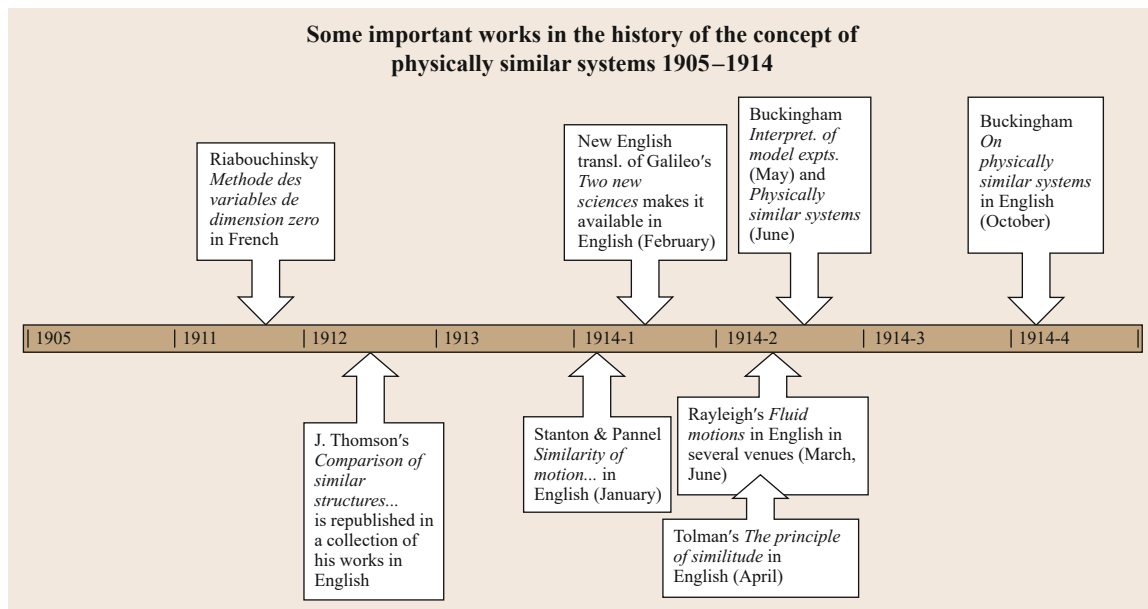

**Fig. 18.1** Newton seems to have been the first to use the term *similar systems* in his *Principia Mathematica*, but Galileo seems to have employed a closely kin idea in his reasoning in *Two New Sciences*

ing or predicting the value of a particular otherwise unobservable quantity is an important feature of the concept. It is due at least in part to the utility of methods involving the concept of similar systems in providing answers to some otherwise intractable problems that natural philosophers in the Renaissance such as Galileo Galilei and Isaac Newton reasoned using some version of the concept (Fig. 18.1), and, later, in the late nineteenth and early twentieth centuries, that scientists further developed it. Thus, the understanding of the concept developed over centuries (Figs. 18.2; 18.3). I will use the twentieth century understanding of *similar systems* to characterize the concept first, then go back to some early precursors from which it was developed and follow the path up to the twentieth century characterization of it. This history of the concept, though admittedly not exhaustively complete, should help clarify its role in reasoning and drawing inferences.

**Fig. 18.2** This timeline (not to scale) illustrates that the concept of similar systems is credited to Renaissance era thinkers Galileo and Newton, and was revived in the second half of the nineteenth century, when it was extended to chemistry, electromagnetic theory, heat, and thermodynamics

**Fig. 18.3** This timeline (not to scale) shows there was a lot of discussion about and interest in issues regarding similarity in 1914 and the years immediately preceding. In 1914 the term *physically similar systems* comes into use

## 18.1 Similar Systems, the Twentieth Century Concept

The landmark year in clarifying and articulating the concept of physically similar systems was 1914. There were two papers with *Physically Similar Systems* in the title that year by *Edgar Buckingham*: one in July (*Physically Similar Systems*) in the *Journal of the Washington Academy of Sciences* [18.1] and another in October 1914 (*On Physically Similar Systems: Illustrations of the Use of Dimensional Equations*) in *Physical Review* [18.2]. Though the latter one is well known and highly cited, and the former one little known, I think that it is the former, that is, the much shorter July 1914 piece, that represents a crucial link or advance, conceptually speaking. The October 1914 Buckingham paper is often credited for the theorem it contains, which is ironic: as Buckingham emphasized numerous times in later papers, a version of the theorem itself had been proven years before. His articulation and discussion of the notion of *physically similar systems*, however, were unusually reasoned and more general than any others accompanying the proof of the theorem.

For now, I just wish to characterize the concept as it is currently understood; for that, we look to the well-known October 1914 *Physical Review* paper [18.2]. The paper opens with a section “The Most General Form of Physical Equations,” which is about describ-

ing a relation that holds among physical quantities of different kinds, by an equation. This is followed by a section introducing and making use of the principle of dimensional homogeneity, entitled “Introduction of Dimensional Conditions.” After exhibiting those points in an example, comes “The General Form to Which Any Physical Equation is Reducible” which states as “a general conclusion from the principle of dimensional homogeneity” that [18.2, p. 350]

“If a relation subsists among any number of physical quantities of  $n$  different kinds, and if the symbols  $Q_1, Q_2, \dots, Q_n$  represent one quantity of each kind, while the remaining quantities of each kind are specified by their ratios  $r', r'', \dots$ , etc., to the particular quantity of that kind selected, then: any equation which describes this relation completely is reducible to the form

$$\Psi(\Pi_1, \Pi_2, \dots, \Pi_i, r', r'', \dots) = 0.”$$

As this form of the equation will be key in defining the notion of similar systems, let us give it a proper name; I’ll call it the *Reduced Relation Equation of 1914*. The number of  $\Pi$ ’s in this equation is the difference between:

“the number of fundamental units required in an absolute system for measuring the  $n$  kinds of quantity, and  $n$ , the kinds of quantity [involved in the relation].”

The function  $\Psi$  is not defined in this form of the equation, but that is perfectly fine; we still consider it an equation – it’s just an equation in which the form of the function is not specified. The equation states, basically, that such a function relating the  $\Pi$ ’s and  $r$ ’s does exist, and the conclusion is that this equation, the *Reduced Relation Equation of 1914*, is another form of the original physical equation, that is, that any physical equation can be reduced to this form. Next follows a short section illustrating how this conclusion can be applied to the same example given earlier in the paper to determine the relationships between some specific quantities in an elegant and particularly useful way. All this is done prior to, and independently of, defining the notion of physically similar systems.

It is in the section entitled “Physically Similar Systems,” the sixth section of the paper, that the notion of similar systems is first presented. Referring to the equation in his paper shown above, which I have called

the *Reduced Relation Equation of 1914*, Buckingham writes that “we may develop from it the notion of similar systems;” he develops it as follows [18.2, p. 353]:

“Let  $S$  be a physical system, and let a relation subsist among a number of quantities  $Q$  which pertain to  $S$ . Let us imagine  $S$  to be transformed into another system  $S'$  so that  $S'$  corresponds to  $S$  as regards the essential quantities. There is no point of the transformation at which we can suppose that the quantities cease to be dependent on one another: hence we must suppose that some relation will subsist among the quantities  $Q'$  in  $S'$  which correspond to the quantities  $Q$  in  $S$ . If this relation in  $S'$  is of the same form as the relation in  $S$  and is describable by the same equation, the two systems are *physically similar* as regards this relation.”

This is the notion of *physically similar systems* still currently in use today. It was first articulated in 1914 by the physicist Edgar Buckingham. But it did not arise from Buckingham’s cogitations out of the blue. For its precursors, we have to go back to the Renaissance.

## 18.2 Newton and Galileo

### 18.2.1 Newton on Similar Systems

Newton seems to have been the first to use the term *similar systems*. He uses it more than once, but the text usually associated with the concept of similar systems is in Book 2, Proposition 32, where he writes [18.3, p. 327]:

“Suppose two similar systems of bodies consisting of an equal number of particles, and let the correspondent particles be similar and proportional, each in one system to each in the other, and have a like situation among themselves, and the same given ratio of density to each other; and let them begin to move among themselves in proportional times, and with like motions (that is, those in one system among one another, and those in the other among one another.) And if the particles that are in the same system do not touch one another, except in the moments of reflection; nor attract, nor repel each other, except with accelerative forces that are inversely as the diameters of the correspondent particles, and directly as the squares of the velocities: I say, that the particles of those systems will continue to move among themselves with like motions and in proportional times.”

In his *Science of Mechanics*, Mach refers to Newton’s concept of similar systems in the context of his own discussion of oscillatory motion [18.4, p. 203]. Mach’s critical-historical work on mechanics was written to be accessible to the nonspecialist; his critique is informative of the understanding of similarity and similar systems at that time. After generalizing one of his own conclusions, Mach remarks: “The considerations last presented may be put in a very much abbreviated and very obvious form by a method of conception first employed by Newton.” He does not quite accept Newton’s use of the term similar system there, though [18.4, p. 166]

“Newton calls those material systems *similar* that have geometrically similar configurations and whose homologous masses bear to one another the same ratio. He says further that systems of this kind execute similar movements when the homologous points describe similar paths in proportional times.”

Mach admires Newton’s methodology here, but he points out an issue with Newton’s use of the term *similar* [18.4, p. 166]:

“Conformably to the geometrical terminology of the present day we should not be permitted to call me-

chanical structures of this kind (of five dimensions) *similar* unless their homologous linear dimensions as well as the times and the masses bore to one another the *same* ratio.”

I gather that what Mach is saying is that the notion of similar in use at the time he is writing is the notion of geometrical similarity, in which there is a kind of shrinking or enlarging of *every* linear quantity of *each* dimension by the *same* ratio (for geometrical similarity, there would usually not be more than three dimensions). That is, I believe he means that, if we are talking about a three-dimensional machine, similarity amounts to shrinking or enlarging quantities of each linear dimension *by the same ratio* while keeping the machine and all its parts exactly the same shape, that is, while preserving every ratio of linear quantities within the same machine. Now, of course, areas and volumes will bear a different ratio to their homologues than quantities of the linear dimensions do (e.g., if the ratio is 1 : 3 for the linear dimension, it will be 1 : 9 for an area and 1 : 27 for a volume), but the similarity can be defined in terms of the linear dimensions alone. That is how geometrical similarity works. Mach says, I think that a strict application of the notion of geometric similarity would require that the ratio between a quantity and its homologous quantity be the same for all five of the dimensions that Newton mentions for his case, and that the situation imagined in Newton’s proposition does not satisfy that constraint.

However – and what is significant and interesting – *Mach* does not say that Newton is wrong here; rather, what he says is that what Newton was doing is better understood in Mach’s day in terms of affine transformations [18.4, p. 204]:

“The structures might more appropriately be termed *affined* to one another.

We shall retain, however, the name phoronomically [kinematically] *similar* structures, and in the consideration that is to follow leave the masses entirely out of account.”

It is clear that *Newton* was interested in more than this, that he wanted to employ the notion of similar systems to reason about forces, too; in fact, he does so in the remarks that follow the quote above ([18.3, pp. 327–328], [18.5, pp. 766–768]). However, in leaving the masses out of the account, Mach picks out from Newton’s work what he wishes to endorse, and shows how the points he endorses ought to be understood in the terminology of the nineteenth century. *Mach* shows how to understand phoronomically (kinematically) similar structures for the topic of oscillation he has been discussing [18.4]:

“In two such similar motions, then, let the homologous paths be  $s$  and  $\alpha s$ , the homologous times be  $t$  and  $\beta t$ ; whence the homologous velocities are  $v = s/t$  and  $\alpha v = \alpha/\beta s/t$ , the homologous accelerations  $\phi = 2s/t^2$  and  $\epsilon\phi = \alpha/\beta^2 2s/t^2$ .

Now all oscillations which a body performs under the conditions above set forth with any two different amplitudes 1 and  $\alpha$ , will be readily recognized as *similar* motions.”

Thus, in spite of noting that *similar* generally means *geometrically similar* at the time he was writing, Mach indulges Newton in the use of the adjective *similar* to indicate phoronomically (kinematically) similar structures, which are, properly speaking (in the terminology of Mach’s day), not related by *similarity* but by *affinity* (that is, by affine transformations). After showing how elegantly theorems about centripetal motion can be obtained by such means, he remarks [18.4, p. 205]:

“It is a pity that investigations of this kind respecting mechanical and phoronomical *affinity* are not more extensively cultivated, since they promise the most beautiful and most elucidative extensions of insight imaginable.”

Thus, Mach sees the great power of the notion of similar systems. In terms of clarification of the notion itself, though, which is the topic of this article, Mach’s attention in his critique of Newton is on the *similar* in *similar systems*; he does not here discuss criteria for something counting as a *system*.

Newton is recognized for the concept today, as he has been throughout all of the nineteenth and twentieth centuries. In their *Similarity of Motion in Relation to the Surface Friction of Fluids* paper in early 1914, *Stanton* and *Pannell* credit George Greenhill with pointing out that the idea that relations “applicable to all fluids and conditions of flow” existed was “foreshadowed by Newton in Proposition 32, Book II of the *Principia*” [18.6, p. 199]. *Zahm*’s 1929 report *Theories of Flow Similitude* [18.7] also credits Newton for a method of “dynamically similar systems,” citing Newton’s Propositions 32 and 33. Also, in many more recent works, including [18.8, p. 86ff], [18.9, pp. 39–41], and [18.5, p. 766].

### 18.2.2 Galileo

Although Newton seems to have been the first to use the term *similar systems*, *Galileo*’s reasoning certainly used a notion of similar systems akin to, if not prescient of, Newton’s in discussing not only the motions of the bob

of a pendulum, but also the more complicated behavior of machines and structures with mass; this is especially clear in his *Dialogues Concerning Two New Sciences*. Galileo's dialogue begins with Salviati (usually taken to be the voice of Galileo), recounting numerous examples of a large structure that has the same proportions and ratios as a smaller structure but that is not proportionately strong. In these opening pages of the dialogue, Salviati explains to a puzzled Sagredo that "if a scantling can bear the weight of ten scantlings, a [geometrically] similar beam will by no means be able to bear the weight of ten like beams" [18.10, m.p. 52–53]. The phenomenon of the effect of size on the function of machines of similar design holds among natural as well as artificial forms, Salviati explains: "just as smaller animals are proportionately stronger or more robust than larger ones, so smaller plants will sustain themselves better" [18.10, m.p. 52–53].

Perhaps the most well known of Salviati's illustrations is about giants [18.10, m.p. 52–53]:

"I think you both know that if an oak were two hundred feet high, it could not support branches spread out similarly to those of an oak of average size. Only by a miracle could nature form a horse the size of twenty horses, or a giant ten times the height of a man – unless she greatly altered the proportions of the members, especially those of the skeleton, thickening the bones far beyond their ordinary symmetry."

Although Galileo's work opens with the wise participant in the dialogue reminding the others of the reasons for the lack of giant versions of naturally occurring life forms, it soon proceeds to the case of a *valid* use of a small (artificial) machine to infer the behavior of a large (artificial) machine. But *the basis for the similarity is not merely geometric similarity*. Later in this same work of Galileo's, Sagredo makes use of Salviati's statement that the "times of oscillation" of bodies [18.10, m.p. 139] suspended by threads of different lengths "are as the square roots of the string lengths; or we should say that the lengths are as the doubled ratios, or squares, of the times." From this, Sagredo uses one physical pendulum to infer the length of another physical pendulum [18.10, m.p. 140]:

"Then, if I understood correctly, I can easily know the length of a string hanging from any great height, even though the upper attachment is out of my sight, and I see only the lower end. For if I attach a heavy weight to the string down here, and set it in oscillation back and forth; and if a companion counts a number of its vibrations made by another move-

able hung to a thread exactly one braccio in length, I can find the length of the string from the numbers of vibrations of these two pendulums during the same period of time."

The reasoning that Sagredo uses to infer the length of one pendulum (the larger) from another (the smaller) is based upon the constancy of the value of a certain ratio involving the length and the frequency of a pendulum's oscillations. What Sagredo derives from the constancy of that ratio for all pendulums is a *law of correspondence* telling him how to find the corresponding length in the large pendulum from the length of the small (or vice versa) and the number of oscillations of the two pendulums observed during the same time period. (The time period itself during which the oscillations are observed is not needed; what is needed is only the (square of the) ratio of the number of oscillations of the two pendulums.) He works out an example [18.10, pp. 140]:

"[...] let us assume that in the time my friend has counted twenty vibrations of the long string, I have counted two hundred forty of my thread, which is one braccio long. Then after squaring the numbers 20 and 240, giving 400 and 57 600, I shall say that the long string contains 57 600 of those units [misure] of which my thread contains 400; and since my thread is a single braccio, I divide 57 600 by 400 and get 144, so 144 braccia is the length of the string."

Salviati (the voice of Galileo) responds approvingly to Sagredo's claim that this method will yield the length of the string: "Nor will you be in error by a span, especially if you take a large number of vibrations." This is reasoning much like Newton's use of similar systems, in that one pendulum is regarded as being similar to another pendulum, so that the period of oscillation and length of one of the pendulums is homologous to the period of oscillation and length of the other.

Of course, Galileo's reasoning here is not presented as a general method, as it is specific to pendulums, whereas Newton's notion of similar systems is. Nor do we find in Galileo's discussion here any explicit criteria for something being a machine that could serve to delineate the sorts of things on which this kind of reasoning could be used. However, Galileo's discussion does make clear that the two quantities that are considered homologous – the *time of vibration* and the length of the pendulum string – are fixed features of a pendulum, in contrast to other quantities such as the amplitude of the oscillations, or the weight of the bob [18.10, p. 141]:

"Take in hand any string you like, to which a weight is attached, and try the best you can to increase or

diminish the frequency of its vibrations; this will be a mere waste of effort. On the other hand, we confer motion on any pendulum, by merely blowing on it [...] This motion may be made quite large [...] yet it will take place only in accord with the time appropriate to its oscillations.”

Thus, each of the two quantities – length of the string, time of vibration – of a given pendulum determines the other. The point germane to the topic of the history of similar systems, though, is this: *every pendulum is related to every other pendulum* by a law of correspondence. The law of correspondence relates each of these two quantities in one pendulum to its homologue in another pendulum. I think that we can see this as akin to how Newton conceived similar systems to be related: by a law of correspondence between quantities in one system and their homologous quantities in the similar system. Only the length of the string and the time of vibration show up as homologous properties in comparison of the two pendulums. Thus, Galileo makes a point of distinguishing between quantities that characterize a given pendulum (length of string; time of oscillation) and quantities that do not (amplitude of oscillation; weight of bob), in addition to making the point about how *some* behaviors of *all*

pendulums are related to each other by a *law of correspondence*.

Because the point is so often missed, it may be helpful to state it a slightly different way. Clearly, Galileo sees that in a pendulum’s behavior, the quantities that characterize a pendulum’s behavior are related to each other in a fixed (though nonlinear) relation, as evidenced by his remarks about the time of oscillation of a pendulum being determined by the length of its string. Yet, rather than illustrating that one can use this relation to figure out the value of one quantity associated with a certain pendulum by measuring another quantity associated with *that same pendulum*, what Galileo is doing here is using a completely different method of inference: establishing a *law of correspondence* between two different pendulums. Then, from an observation of one quantity obtained experimentally on another pendulum chosen or constructed for the purpose, the law of correspondence he has established is invoked to *infer* the value of *the homologous quantity* in the pendulum. (In the passage from Galileo quoted above, the method was used to infer the length of one pendulum from the length of another pendulum.) It is the articulation of this method that justifies including Galileo along with Newton in a history of the concept of physically similar systems [18.11].

## 18.3 Late Nineteenth and Early Twentieth Century

By the late nineteenth century, mechanics and the mathematics used in it had changed dramatically from Newton’s – at least in terms of many of the mathematical methods used. The concept of mechanical similarity survived these major changes, though, and quite easily accommodated itself to the more advanced mathematics developed for mechanics. In fact, the notion of mechanical similarity was developed further, and more rigorously, into different kinds of similarity in mechanics – geometrical, kinematical, and dynamical – and extended to other areas of physics that had become quantitative, such as heat and electricity. The concept of similar systems survived, too, sometimes explicitly, sometimes only implicitly and in practice. More problematically, during the nineteenth century, the term was sometimes used to refer to something other than the rigorous notions associated with the term that were being developed in physics.

The advances in mathematics and physics to which the concept of similar systems and, along with it, the concept of similarity, were rather easily incorporated were not merely superficial matters such as the use of a different notation for calculus. By the late nineteenth

century, there was widespread use of the more advanced mathematical methods that had been developed: partial differential equations and associated analysis methods for continuum mechanics, hydrodynamics, gas theory, electricity, and magnetism. During the eighteenth century, there had been many advances in mathematics and mechanics that transformed the methods of inquiry used into ones we would be at home with even today. The question of what constitutes a system shifts from asking not only how to decide when a configuration of bodies constitutes a system (Newton and Galileo seem to have thought in terms of systems of that sort), to also being able to ask what features of a function (or equation) indicate that the relations between quantities that it expresses have also delineated a system. For, it is functions that the eighteenth century gave mechanics, and functions represented or expressed “relations among quantities in nature,” as *Hepburn* puts it [18.12, p. 129]. As noted in Sect. 18.1, when Buckingham articulated the concept of *physically similar systems* in 1914 [18.2], he did so by providing the “most general form of an equation,” and, as seen in the excerpt quoted above, he did so by describing that form in terms of an

equation using an unknown function

$$\Psi(\Pi_1, \Pi_2, \dots, \Pi_i, r', r'', \dots) = 0,$$

that is, the equation I have called the *Reduced Relation Equation of 1914*.

*Buckingham* did his doctoral work at the very end of the nineteenth century. Where were people employing or talking about the notion of similar systems during the late nineteenth century? By then, some notion of similar systems was known in theoretical physics, where it was occasionally explicitly discussed using the term *similar systems*, as well as in many branches of engineering, where it was involved, albeit sometimes implicitly or obliquely, in experimental investigations. Then, too, there were activities and investigations that did not fit neatly into one or the other of these categories, or straddled them. How did various thinkers producing these works think about and express the concepts associated with mechanical similarity and similar systems?

### 18.3.1 Engineering and Similarity Laws

#### Similar Structures

In engineering and science of the nineteenth century, the main notion invoked when reasoning with similar machines or systems was that of a *similarity law* or a *similarity principle*. *James Thomson* (1822–1892) (brother of *William Thomson*, *Lord Kelvin* (1824–1907)) gave an influential paper in 1875 entitled *Comparison of Similar Structures as to Elasticity, Strength, and Stability* [18.13] that tried to identify and lay out the methodology involved in the engineering design of structures such as bridges and buildings, but he used some other interesting examples such as obelisks and umbrellas, too. Thomson's examples are often about how to vary some quantity such that two structures of different sizes are similar in one of these respects I refer to as behavioral: that is, elasticity, strength, or stability. Thomson's paper was built upon and expanded in 1899 (by *Barr* [18.14]) and again in 1913 (by *Torrance* [18.15]).

The principle *James Thomson* identified was meant to be general. Yet, there were still different *kinds* of comparisons. In his 1875 paper, which became more widely available when his collected works were published in 1912, Thomson distinguished between two kinds of comparisons of similar structures, which, he said, were “very distinct, and which stand remarkably in contrast each with the other.” One kind of comparison of similar structures is “in respect to their elasticity and strength for resisting bending, or damage, or breakage by similarly applied systems of forces.” The other, contrasting kind was “comparisons of similar structures as

to their stability, when that is mainly or essentially due to their gravity [weight] or, as we may say, to the downward force which they receive from gravitation” [18.16, p. 362].

*Thomson* offered a “comprehensive but simple and easily intelligible principle” for the first kind of comparison: Similar structures, if strained similarly within limits of elasticity from their forms when free from applied forces, must have their systems of applied forces, similar in arrangement and of amounts, at homologous places, proportional to the squares of their homologous linear dimensions. His reasoning in establishing this principle is a deductive argument special to solid mechanics, the mechanics of deformable bodies. To establish this we have only to build up, in imagination, both structures out of similar small elements or blocks, alike strained, with the same intensity and direction of stress in each new pair of homologous elements built into the pair of objects [18.16, pp. 362–363]. These small elements or blocks are imagined to be so small in relation to the overall body that the stresses in them can be considered homogenous throughout the element or block. This is how the principle is derived, but the point of emphasis for both scientific understanding and engineering practice was that “similar structures of different dimensions must not be similarly loaded [...] if they are to be stressed with equal severity.” In saying that the structures must not be similarly loaded, he draws attention to the part of the principle that says that the loads in the two similar structures must vary by the squares of their linear dimensions, rather than by the simple multiplicative factor that the linear dimensions do.

This was commonly what was meant at the time by a *similarity principle* or, sometimes *similarity law* or *law of similarity*. Each one covered a certain class of cases. The point of the *principle* was usually to state how one variable – for example, density, stiffness – was to be varied as another, such as length, was varied. One form such reasoning took was to show how the ratio of variables of one type varied as a ratio of another type of variable did: for instance [18.17, p. 136],

“If the scale ratio for any two orifices, i. e., the ratio of any two corresponding linear dimensions, is  $S$ , the ratio of the areas of corresponding elements of the orifices will be  $S^2$ , while if similarly situated with respect to the water surface, their depths are proportional to  $S$ .”

However, sometimes the similarity law or principle for a certain kind of behavior was stated simply as a ratio, the implication being that that ratio was invariant for similar systems; setting the ratio equal to 1 and rearranging terms yielded the relations between

quantities that must be maintained in order to achieve the similarity of that type.

### Similar Interactions: A Law of Comparison for Model Ships

One of the most well-known engineering advances employing similarity and, implicitly, the notion of similar systems, was William Froude's (1810–1879) solution of significant, urgent, and previously unsolved problems in ship design for the British Admiralty ([18.18, p. 279], [18.5, 19, 20]). In the design of ships for stability and speed, not only does gravitational force enter into the consideration of a structure's behavior, but the ship's interaction with the water in which it is sitting or moving must also be considered.

Froude's reasoning about the stability of ships involved examining the motion of a pendulum in a resistive fluid [18.21, pp. 5ff, 15ff, 61]: the same question Newton addressed when he presented the proposition in which he introduced the idea of similar systems. Schaffer points out that, although the statement does not appear in the final version of the *Principia*, Newton had written that “if various shapes of ships were constructed as little models and compared with each other, one could test cheaply which was best for navigation” [18.22, p. 90].

Unlike Newton, Froude does not seem to analyze the notion of similar systems in thinking about a pendulum in a resistive medium. However, the idea of relating quantities in one physical situation to those in another is predominant in Froude's work; it is, in fact, the topic of his main contributions to the problem of the efficient design of large ships driven by propellers. As Zwart has pointed out [18.5], the naval architect John Scott Russell had already constructed and tested many small models, but his experience had convinced him that the little models, though they had provided him with much pleasure, could provide no help in determining how large ships behaved. The exchange between Russell and Froude following Froude's reading of his 1874 paper was recorded in a transcript and so is available today [18.23], showing that the problem of how to extrapolate observations on the behavior of small models of ships when placed in water to the behavior of full size ships was considered unsolved when Froude took it on ([18.5, p. 15], [18.20, pp. 128–130], [18.19, 23]). Hagler also notes that Froude's confidence that the smaller model ships (some of which were over 20 feet long) could be used to infer the behavior of larger full-scale ships was based in part on Rankine's investigations on streamlines. Froude explicitly discusses Rankine's work in his 1869's “The State of Existing Knowledge on the Stability, Propulsion and Seagoing Qualities of Ships” [18.20]. He convinced the Admiralty to fund

the construction of an experimental water tank to carry out the experiments he proposed. His methods for extrapolating from smaller, scale models of ships in his water tank to the full size ship were vindicated when the Admiralty conducted full-scale tests on the *HMS Greyhound* and Froude was able to compare the measurements taken on the full size *Greyhound* with those he had taken on his 1/16 model of the *HMS Greyhound* in his experimental tank. His *Law of Comparison* was soon adopted for all further ship design not only by the British Admiralty, but also by the US Navy, which constructed the Experimental Model Basin in Washington, DC in the 1890s. The Experimental Model Basin was constructed under the leadership of David Watson Taylor. Hagler [18.20] provides a good discussion of David Watson Taylor's writings on ship design; Taylor shows how the methodology used by the US in almost all its naval design work in the first half of the twentieth century is ultimately traceable to this work Froude did in the nineteenth century.

Froude similarity was developed specifically for the purpose of using model experimentation for ship design. As with the similarity laws in mechanics, Froude similarity can be expressed in terms of a ratio, the Froude number, which is a dimensionless parameter. Though no notion of similar systems is defined, a nascent notion of similar systems was involved in practice, since the similarity of situations is established when the Froude numbers for each of the two situations are equal. One formulation of the Froude number is  $v/\sqrt{gL}$ , where  $v$  is a velocity,  $L$  is a length, and  $g$  is the gravitational acceleration. The application of Froude similarity requires expertise; which velocity and characteristic length are relevant depends on the phenomenon being investigated. We can see from the form of the Froude dimensionless ratio, however, that quantities do not all scale linearly, much less by the same linear factor. Another point of note is that, as Froude similarity compares *homologous forces* as well as *homologous motions*, it is a kind of *dynamic* similarity, not merely a *kinematic* similarity.

### Bertrand and Reech: The French Connection Between Newton and Froude

Many have pointed out that Froude took over results due to others, naming in particular French engineering professor Ferdinand Reech and French mathematician Joseph Bertrand, both of whom wrote on similarity methods in mechanics ([18.24, p. 141ff], [18.25, p. 381], [18.26, p. 15], and [18.18, p. 279]). The extent to which this is true has been debated [18.24], but none deny that Froude holds a unique place as an experimentalist whose accomplishments advanced both the field of hydraulics and the industry of marine architecture.

Ferdinand Reech (1805–1884) publishing in 1852 on topics he had lectured about much earlier, explicitly followed Newton’s approach, discussing and deriving principles about how to relate observations of velocities and motions of one ship to other ships of different sizes. Like Newton, he considered bodies and forces on them, though he employed the term *similar system* in his discussions when deriving laws of comparison [18.27]. It is Joseph Bertrand who seems to have taken a conceptual step beyond Newton, though he heaps quite a great deal of credit for his work upon Newton, as though he is doing little more than showing the consequences of Newton’s theorems about similar systems.

*Joseph Bertrand* (1822–1900) produced many textbooks and treatises, including *Sur la similitude en mecanique*. He also published, in English in 1847, a sort of manifesto advocating that “persons occupied with the study of mechanics” attend to the theorem about similitude he derives using nineteenth century methods in mechanics, but for which he credits Newton. Of Newton’s theorem about similar systems in the *Principia*, he writes [18.28, p. 130]

“This theorem constitutes a real theory of similitude in mechanics. It will be seen, that any system being given, there exists an infinite number of possible systems, which may be regarded as similar to it; and that, instead of a single kind of similitude, as in geometry, we may suppose four, viz., those of length, time, forces, and masses; each of these is, according to Newton’s theorem, a consequence of the other three.”

*Bertrand* then went on in that same paper of 1847 to explain that he had

“endeavoured to substitute [...] a proposition founded upon dynamic equations, and which does not differ mainly from the form employed by M. Cauchy to deduce from the equations of the movement of elastic bodies the laws of the vibrations of similar bodies, [...] but this theorem of M. Cauchy, although analogous to that of Newton, cannot be regarded as a corollary of the same;”

using this instead, he deduces applications to laws of oscillation, centripetal force, speed of propagation of sound in various gases, and “a theorem relating to turbines” [18.28, p. 130]. *Bertrand*’s concern seems to be twofold: (i) to get people in the field of mechanics to appreciate the power of the theory (or principle) of similitude in providing solutions to otherwise insoluble problems, and, (ii) to get people who use model experiments to understand the appropriate precautions that must be taken in designing experiments using small models to prevent errors that can be anticipated us-

ing the theory. He explains how the notion of similar systems, though it may look rather limited, is in fact sometimes indispensable, that is, for problems not susceptible to a mathematical solution [18.28, p. 131]:

“It is true that only proportional results can be deduced from [the principle]; and that, consequently, it will only serve to solve a question, when another of an analogous nature and of an equivalent analytical difficulty shall have been solved. It may, however, be of great utility to determine in certain cases the analogy which exists between the movements of the two systems, even supposing each of them not to be susceptible of strict theoretical determination.”

He gives an example of the usefulness of the principle: the performance of “experiments on a small scale” to ascertain “the value of a mechanical invention, which is too expensive to put in operation on a large scale” [18.28, p. 131]. What is interesting is that in this same paper where he is advocating the use of the principle, he also discusses the kind of conundrums that arise in attempting to apply it to complicated cases such as a small-scale model of a locomotive; he cites an example of “an error which it is impossible to avoid, but which it is very essential to know.” This 1847 paper published in England is, thus, a call to improving engineering practice by attending to theoretical derivations in mechanics, that is, the theory of similitude. (*Bertrand* refers to it in the 1847 paper as the Cauchy theorem, which seems rather modest, for *Cajori* describes *Bertrand* as deriving “the principle of mechanical similitude” from “the principle of virtual velocities” [18.25, p. 380]. I mention *Bertrand*’s 1847 paper here for its use of late eighteenth and nineteenth century mechanics.)

### 18.3.2 Similar Systems in Theoretical Physics: Lorentz, Boltzmann, van der Waals, and Onnes

Mechanical similarity held an important place among some researchers in theoretical physics in the late nineteenth century as well. The notion of similar systems was often employed in theories about the relationship of microscopic configurations to macroscopic phenomena, sometimes explicitly. Sometimes the term *similar systems* was extended beyond the normal use it had had up to that time, too.

#### Lorentz

By the turn of the century, *Henrik Lorentz* (1853–1928) would note that “The consideration of similar systems

has already proved of great value in molecular theory,” as it had allowed Kamerlingh Onnes “to give a theoretical demonstration of van der Waals’s law of corresponding states” [18.29]. The experimental confirmation of that law, Lorentz wrote, “has taught us that a large number of really existing bodies may, to a certain approximation be regarded as similar.”

Lorentz had already developed a notion of corresponding states for use in electrodynamics by 1900. The context in which he made the observation above, though, was his paper *The Theory of Radiation and the Second Law of Thermodynamics*, in which he was concerned with the question of the similarity in the structure of different bodies that would be mandated by thermodynamics [18.29, p. 440]. It would take us too far afield to explain everything that Lorentz was trying to do in this paper; here we restrict our discussion to what concept of *similar systems* Lorentz employed or seems to have had in mind.

Lorentz’ idea of *similar systems* involves starting with one system and then constructing a second one from the first. Lorentz writes of “comparing two systems”; what he says is that the systems he compares are: “[...] in a wide sense of the word, *similar*, that is, such that, for every kind of geometrical or physical quantity involved, there is a fixed ratio between its corresponding values in the two systems, [...]” [18.29]. It is not clear on what basis he justifies being able to say that “We shall begin by supposing that, in passing from one system to another, the dimensions, masses and molecular forces may be arbitrarily modified,” as this seems to require a certain kind of independence among the things being modified. He argues that “if the second system, as compared with the original one, is to satisfy Boltzmann’s and Wien’s laws,” that “we shall find that the charges of the electrons must remain unaltered.”

He first describes a certain system  $S$  that includes a “ponderable body” enclosed in a space. Some of the features of  $S$  are delineated (he ascribes an “irregular molecular motion” and the “power of acting on one another with certain molecular forces” to the particles making up the body, for instance, and adds that some are electrically charged) but other features are not (there may be other (molecular) forces of another kind, acting on the electron) [18.29, p. 443]. The description of the “really existing” system  $S$  is meant to pick out something that actually exists, in contrast to the system  $S'$ , which “perhaps will be only an imaginary one” [18.29, p. 444]. To complete the description of the state of  $S'$ , “we indicate, for each of the physical quantities involved, the number by which we must multiply its value in  $S$ , in order to obtain its value in  $S'$  at corresponding points and times.” He then explores the constraints on

these numbers; some are constrained by laws of motion, but others are not. This leaves him free to “imagine a large variety of systems  $S'$ , similar to  $S$ , and which must be deemed possible as far as our equations of motion are concerned” [18.29, p. 445].

Lorentz uses the notion of similar systems to explore the constraints on theory, as opposed to using theory to state how one can construct a system  $S'$  to be similar to a certain system  $S$ , in order to make inferences about one of the systems based upon observations about the other. This seems a different use of the notion than Galileo or Newton made of it; it also allows the contemplation of unprecedented kinds of similarity. It may, Lorentz realizes, even give rise to systems of a different ontological status; he explains why that, too, may be useful [18.29, pp. 447–448]:

“It might be argued that two bodies existing in nature will hardly ever be similar in the sense we have given to the word, and that therefore, if  $S$  corresponds to a real system, this will not be the case with  $S'$ . But this seems to be no objection. Suppose, we have formed an image of a class of phenomena, with a view to certain laws that have been derived from observation or from general principles. If, then, we wish to know, which of the features of our picture are essential and which not, i. e., which of them are necessary for the agreement with the laws in question we have only to seek in how far these latter will still hold after different modifications of the image; it will not at all be necessary that every image which agrees in its essential characteristics with the one we have first formed corresponds to a natural object.”

Thus, Lorentz’s exploratory use of similar systems in fields beyond mechanics was motivated by the example of van der Waals’ and Onnes’ highly successful results using mechanical similarity to derive new theoretical results.

### Van der Waals and Onnes

In his 1881 *General Theory of Liquids*, Onnes argued that van der Waals’ “law of corresponding states”, which had just been published the previous year, could be derived from scaling arguments, in conjunction with assumptions about how molecules behaved. Van der Waals was impressed with the paper, and a long friendship between the two ensued (Fig. 18.4). Van der Waals was awarded the Nobel Prize in Physics in 1910 for “The equation of state for gases and liquids” [18.30], and Onnes was awarded it in 1913 [18.31], for “Investigations into the properties of substances at low temperatures, which have led, amongst other things, to the preparation of liquid helium.” In his lecture delivered for the occasion, Onnes highlighted the connection between

**Fig. 18.4** Heike Kamerlingh Onnes and Johannes Dederik van der Waals in the laboratory with the helium *liquefactor*. Onnes used the theory of corresponding states along with experimental data on one substance to predict the conditions at which helium would liquefy

his investigations into properties of substances at low temperatures and similarity principles [18.32, p. 306]:

“[...] From the very beginning [...] I allowed myself to be led by van der Waal’s theories, particularly by the law of corresponding states which at that time had just been deduced by van der Waals.

This law had a particular attraction for me because I thought to find the basis for it in the stationary mechanical similarity of substances and from this point of view the study of deviations in substances of simple chemical structure with low critical temperatures seemed particularly important.”

What is special about the low temperatures Onnes needed to achieve in order to liquefy helium is that, according to the kinetic theory of gases on which van der Waals’ equation of state was based, there would be much less molecular motion than in the usual kinds of cases considered. Onnes’s approach in looking for the foundation of the law of corresponding states has a slightly different emphasis than the kinetic theory of gases. Boyle’s law (often called the ideal gas law) and van der Waals’ equation were based on investigating the relationship between the microscale (the molecular level) and the macroscale (the properties of the substance, such as temperature and density). But Onnes was instead looking at the foundation for the similarity of states. Like van der Waals, he looked to mechanics and physics for governing principles, but Onnes pointed out that it was also useful to look at principles of sim-

ilarity. At low enough temperatures, where the motion of the molecules was not the predominant factor, the relevant principles of similarity would be principles of static mechanical similarity, as opposed to dynamical similarity.

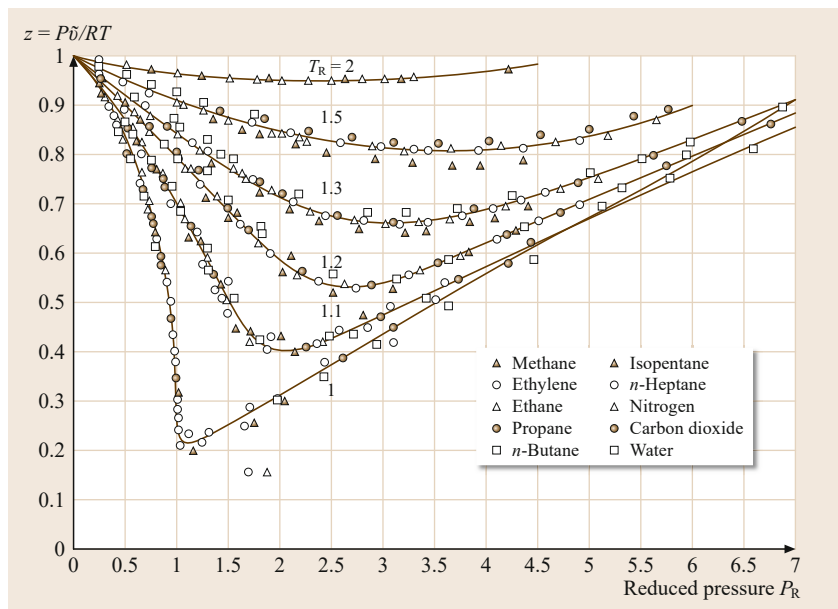

The criterion for similarity Onnes developed arose out of investigations into the transition from one regime to another. This had been the case in work in hydrodynamics, too. In Osborne Reynolds work, discussed below, it was the critical point at which fluid flow underwent a transition from laminar to turbulent flow (or, in his terminology, from “lamellar” to “eddying” flow [18.6, p. 200]) that led to the identification of the dimensionless parameter that later became known as the Reynolds number. The Reynolds number is in a way a criterion of similarity, in that fluid systems with the same Reynolds number will be in the same flow regime, regardless of the fluid. So it was with thermodynamics, Onnes showed: the critical point at which a substance undergoes a transition from the gaseous state to the liquid state led to the identification of a criterion of similarity of states that held for all substances.

Van der Waals was interested in the continuity of states and used the critical values of pressure, volume, and temperature in a brilliant way to normalize them. He defined “reduced pressure”, “reduced volume”, and “reduced temperature” to yield an equation of state in which none of the parameters that are characteristic of a particular substance appear. As *Levelt Sengers* notes [18.33, p. 25], “This is a truly remarkable result.” The equation of state is [18.33, p. 25]:

“universal; all characteristics of individual fluids have disappeared from it or, rather, have been hidden in the reduction factors. The reduced pressures of two fluids are the same if the fluids are in *corresponding states*, that is, at the same reduced pressure and volume.”

This is an important part of the history of similar systems in that the principle of corresponding states allowed the production of curves (Fig. 18.5) representative of all substances from experiments on a particular substance [18.33, p. 26]:

“The principle of corresponding states [...] frees the scientist from the particular constraints of the van der Waals equation. The properties of a fluid can now be predicted if only its critical parameters are known, simply from correspondence with the properties of a well characterized reference fluid. Alternatively, unknown critical properties of a fluid can be predicted if its properties are known in a region not necessarily close to criticality, based on the behavior of the reference fluid.”

**Fig. 18.5** This graph of empirical results illustrates the theory of corresponding states that van der Waals presented in 1880; fluids in *corresponding states* have the same *reduced pressure*: the data for different substances all *fall on top of each other*. Onnes later derived it using a law of mechanical similarity he ascribed to Newton

Onnes used this insight about corresponding states to set up an experimental apparatus to liquefy helium, which has an extremely low critical temperature. What is so exciting about his story is that he had to rely on the law of corresponding states to estimate the critical temperature so that he would know where to look – that is, so that he would know what conditions to create in order for helium to liquefy. What is especially relevant to the history of the notion of *physically similar systems* is that he did more than just use van der Waals’ law of corresponding states. He also gave a foundation for it that was independent of the exact form of van der Waals’ equation and did not depend on results in statistical mechanics. Instead, he used *mechanical similarity* [18.33, p. 30]:

“Kamerlingh Onnes’s (1881) purpose is to demonstrate that the principle of corresponding states can be derived on the basis of what he calls the principle of similarity of motion, which he ascribes to Newton. He assumes, with van der Waals, that the molecules are elastic bodies of constant size, which are subjected to attractive forces only when in the boundary layer near a wall, since the attractive forces in the interior of the volume are assumed to balance each other [...] He realizes this can be valid only if there is a large number of molecules within the range of attraction [...] Onnes] considered a state in which  $N$  molecules occupy a volume  $v$ , and all have the same speed  $u$  (no Maxwellian distribution!). The problem is to express the external pressure  $p$ , required to keep the system of moving

particles in balance, as a function of the five parameters. He solves this problem by deriving a set of scaling relations for  $M$ ,  $A$ ,  $v$ ,  $u$ , and  $p$ , which pertain if the units of length, mass, and time are changed.”

Onnes provides a criterion for corresponding states based on these scaling relations, along with assumptions about what the molecular-sized objects are like. *Levelt Sengers* remarks [18.33, p. 30]:

“Two fluids are in corresponding states if, by proper scaling of length, time and mass for each fluid, they can be brought into the same “state of motion.” It is not clearly stated what he means by this, but he must have had in mind an exact mapping of the molecular motion in one system onto that of another system if the systems are in corresponding states.”

*Levelt Sengers* illustrates what being in the same “state of motion” means “in modern terms” [18.33, p. 30]:

“[...] suppose a movie is made of the molecular motions in one fluid. Then, after setting the initial positions and speed of the molecules, choosing the temperature and volume of a second fluid appropriately, and adjusting the film speed, a movie of the molecular motion in a second fluid can be made to be an exact replica of that in the first fluid.”

Appeal to such imagined visual images is very much in keeping with nineteenth century science, and one can see here an attempt to generalize Newton’s use

of similar systems in the *Principia* to thermodynamics. Onnes used the principle of corresponding states for more than visualizing, though, and, even, for more than theorizing; he used it to show how one could make a prediction about one fluid from knowledge about another. *Wisniak* explains [18.34, p. 569]

“Kamerlingh Onnes proposed to use the law of corresponding states to examine the possibility of cooling hydrogen further by its own expansion. He then used this law to predict from the known experience with oxygen what was to be expected from the apparatus for the cooling of hydrogen: [quoting Onnes:] But let us return to the thermodynamically corresponding substances. If two such substances are brought in corresponding engines and if these engines are set in motion with corresponding velocities, then they will run correspondingly as long as there is given off a corresponding quantity of heat in the corresponding times by the walls of the machine.”

Thus, Onnes has introduced not just corresponding motions and times, as in mechanical similarity, but also corresponding quantities of heat. *Wisniak* continues [18.34, p. 569]

“He [Onnes] then introduced the notion of thermodynamically corresponding operations to argue that if then in a model, working with oxygen, after a given time a given volume of liquid oxygen is found, there will be obtained in the corresponding hydrogen apparatus after the corresponding time a corresponding volume of liquid hydrogen.”

By *model* here, Onnes clearly means physical model, and the model includes the contained gases such as oxygen and hydrogen. The model is an actual physical model: a physical setup, an actual, physical machine. By the end of the nineteenth century, the physics of machines included the thermodynamics of machines. And, as in Newton and Galileo’s day, one could talk both about imagined similar systems, and about actual similar machines.

### Maxwell and Boltzmann

As several scholars have noted, Ludwig Boltzmann (1844–1906) mentioned *similar systems* in his investigations into the theory of gases, too. It’s been noted that, in his 1884 and 1887 papers, Boltzmann [18.35, pp. 56–57]:

“tried to deepen the foundation of the new theory [that was to become known as statistical mechanics] by introducing the concept of *Ergoden* – meaning a collection (ensemble) of similar systems (of gas

molecules) having the same energy but different initial conditions.”

*Stephen G. Brush*, also citing Boltzmann’s 1884 and 1887 papers, remarks that [18.36, pp. 75–76]:

“There has been considerable confusion about what Maxwell and Boltzmann really meant by ergodic systems. It appears that they did not have in mind completely deterministic mechanical systems following a single trajectory unaffected by external conditions; [ . . . ]

In fact, when Boltzmann first introduced the words *Ergoden* and *ergodische*, he used them not for single systems but for the collections of similar systems with the same energy but different conditions. In the papers published in 1884 and 1887, Boltzmann was continuing his earlier analysis of mechanical analogies for the Second Law of Thermodynamics, and also developing what is now (following J. Willard Gibbs) known as *ensemble theory*. Here again, Boltzmann was following a trail blazed by Maxwell, who had introduced the ensemble concept in his 1879 paper. But while Maxwell never got past the restriction that all systems in the ensemble must have the same energy, Boltzmann suggested more general possibilities, and Gibbs ultimately showed that it is most useful to consider ensembles in which not only the energy but also the number of particles can have any value, with a specified probability.”

What these commentators on Boltzmann are referring to in mentioning the influence of *Maxwell* are Maxwell’s remarks in his *On Boltzmann’s Theorem on the average distribution of energy in a system of material points* [18.37]. There, *Maxwell* wrote, speaking of the case “in which the system is supposed to be contained within a fixed vessel” [18.37, pp. 715ff]:

“I have found it convenient, instead of considering one system of material particles, to consider a large number of systems similar to each other in all respects except in the initial circumstances of the motion, which are supposed to vary from system to system, the total energy being the same in all. In the statistical investigation of the motion, we confine our attention to the number of these systems which at a given time are in a phase such that the variables which define it lie within given limits. [Emphasis in italic added.]

If the number of systems which are in a given phase (defined with respect to configuration and velocity) does not vary with the time, the distribution of the systems is said to be *steady*.”

It is not clear how the use of the notion of similar systems here, i.e., in forming ensembles in thermodynamics in order to study their behavior statistically, might be related to either Newton's notion of similar systems or the notion involved in the principle of corresponding states. It is certainly a use of similar systems that is very different from using one system experimentally to infer the values of quantities in another. So, if, as Brush's comment implies, Boltzmann was thinking of more general kinds of similar systems, it seems he was no longer restricting the notion of similar systems to systems that are behaviorally similar to each other with respect to motions, and he was not restricting its use to the use of one system or machine to infer the behavior of another.

Yet Boltzmann's departure from Newton's use of the term similar systems was almost certainly not a matter of confusion on Boltzmann's part about the notion in the sense Newton had used it, for *Boltzmann's* encyclopedia entry on models [18.38] shows that he was well aware of, and respected the distinctive nature of, the use of experimental models of machines, in which one machine is specially constructed in order to infer the behavior of another. Boltzmann, in fact, associates the latter kind of model with Newton's insights.

On the approach in which physical models constructed with our own hands are actually a continuation and integration of our process of thought, *Boltzmann* says in that encyclopedia article (*Model*) [18.38]:

“physical theory is merely a mental construction of mechanical models, the working of which we make plain to ourselves by the analogy of mechanisms we hold in our hands.”

In contrast, *Boltzmann* explicitly described experimental models as of a different sort than the kind with which he was comparing mental models, and explained why they must be distinguished [18.38]:

“A distinction must be observed between the models which have been described and those experimental models which present on a small scale a machine that is subsequently to be completed on a larger, so as to afford a trial of its capabilities. Here it must be noted that a mere alteration in dimensions is often sufficient to cause a material alteration in the action, since the various capabilities depend in various ways on the linear dimensions. Thus the weight varies as the cube of the linear dimensions, the surface of any single part and the phenomena that depend on such surfaces are proportionate to the square, while other effects – such as friction, expansion and condition of heat, etc., vary according

to other laws. Hence a flying-machine, which when made on a small scale is able to support its own weight, loses its power when its dimensions are increased. The theory, initiated by Sir Isaac Newton, of the dependence of various effects on the linear dimensions, is treated in the article Units, Dimensions Of.”

The use of a flying machine to illustrate the point was not incidental; in his *On Aeronautics*, Boltzmann urged research into solving the problem of flight, and expressed his opinion that experimentation with kites was the appropriate approach. The complexities of air-flow over an airplane wing, he said, were too difficult to study using hydrodynamics [18.39, p. 256]. Yet, the basis for extrapolating from experiments on a kite or flying machine from one observed situation to another, unobserved, situation (even with a machine of the same size) owes something to hydrodynamics. The dimensionless parameters yielding the appropriate correspondences between homologous quantities for kites and flying machines were provided by Helmholtz's innovative use of the equations of hydrodynamics.

### 18.3.3 Similar Systems in Theoretical Physics

#### Stokes and Helmholtz

Hermann von Helmholtz (1821–1894), like Ludwig Boltzmann and so many other physicists of the nineteenth century, contributed to the scientific literature on research into flight. Some of these contributions took the form of investigations concerning the earth's atmosphere. Six of the 20 papers in the important and selective 1891 anthology *The Mechanics of the Earth's Atmosphere: A Collection of Translations* by Cleveland Abbe [18.40] were by Helmholtz; one of these was his 1873 *On a Theorem Relative to Movements That Are Geometrically Similar in Fluid Bodies, Together with an Application to the Problem of Steering Balloons* [18.41, 42]. It is the only one of Helmholtz's papers in that volume that explicitly addresses an application to the problem of flight. What is relevant to the history of the concept of similar systems is the kind of reasoning he uses in the paper.

*Helmholtz's* starting point is “the hydrodynamic equations” which, he argues, can be considered “the exact expression of the laws controlling the motions of fluids” ([18.41, p. 67], [18.42]). What about the well-known contradictions between observations and the consequences of the equations? Those, he argues, are only apparent contradictions, which disappear once the phenomenon of “surfaces of separation” is no longer neglected [18.41, p. 67]; his *On Discontinuous Motions*

in *Liquids* [18.43, 44], also included in the same collection of translations, aims to establish their existence.

The *Discontinuous Motions* paper [18.43] is an extraordinarily interesting contribution to the methods of reasoning by analogy between fluid currents, electrical currents, and heat currents. For, the paper begins by pointing out that “the partial differential equations for the interior of an incompressible fluid that is not subject to friction and whose particles have no motion of rotation” are precisely the same as the partial differential equations for “stationary currents of electricity or heat in conductors of uniform conductivity” [18.43, p. 58]. Yet, he notes, even for the same configurations and boundary conditions, the behavior of these different kinds of currents can differ. How can this be? It would be easy to assume that the difference is a matter of the equations being, in the case of hydrodynamics, an “imperfect approximation to reality,” possibly due to friction or viscosity. Yet, Helmholtz argues, various observations indicate that this is not plausible. Instead, he proposes, the difference in behavior between fluid currents on the one hand and electrical and heat currents on the other is due to “a surface of separation” that exists or arises in the case of the fluid. In some situations, “the liquid is torn asunder,” whereas electricity and heat flows are not. Though the main point of the paper is to propose his detailed account of what happens in the liquid to cause this difference (the pressure becomes negative), it is interesting, especially in the context of nineteenth century, that Helmholtz discusses a case in which physical entities described by the same partial differential equations do *not* behave in the same way. Yet, once the existence of discontinuous motions in fluids is recognized, *Helmholtz* says, the contradictions that “have been made to appear to exist between many apparent consequences of the hydro-dynamic equations on one hand and the observed reality on the other” will then “disappear” [18.41, p. 67].

The problem with the hydrodynamic equations is not that they are wrong, for they are not; they are “the exact expressions of the laws controlling the motions of fluids”. The problem is that [18.41, p. 67]

“it is only for a relatively few and specially simple experimental cases that we are able to deduce from these differential equations the corresponding integrals appropriate to the conditions of the given special cases.”

So, the hydrodynamic equations are impeccable; it’s their solution that is the problem. Simplifying is not going to work, either, since in some cases “the nature of the problem is such that the internal friction [viscosity] and the formation of surfaces of discontinuity can not be neglected.” These surfaces of discontinuity present

a very fundamental problem to finding a neat solution, too, for [18.41, p. 67]

“The discontinuous surfaces are extremely variable, since they possess a sort of unstable equilibrium, and with every disturbance in the whirl they strive to unroll themselves; this circumstance makes their theoretical treatment very difficult.”

Theory being of very little use in prediction here, [18.41, p. 68]

“we are thrown almost entirely back upon experimental trials, [...] as to the result of new modifications of our hydraulic machines, aqueducts, or propelling apparatus.”

That was how things stood but, *Helmholtz* says, there is another method, one that is neither a matter of prediction from theory nor an experimental trial of the machine whose behavior one wishes to predict. His description deserves to be read closely [18.41, p. 68]:

“In this state of affairs [the insolubility of the hydrodynamic equations for many cases of interest] I desire to call attention to an application of the hydro-dynamic equations that allows one to transfer the results of observations made upon any fluid and with an apparatus of given dimensions and velocity over to a geometrically similar mass of another fluid and to apparatus of other magnitudes and to other velocities of motion.”

The method Helmholtz is referring to, which he presented in this now-classic paper in 1873, thus differs from deducing predictions from theory in the same way that Newton’s notion of similar systems and Galileo’s use of one pendulum to inform him about another differ from deducing predictions from theory: theory is involved in the inference, but the *way* that theory is involved is to allow someone to “transfer the results of observations” made on one thing (system, machine, mass of fluid, apparatus) over to another thing (system, machine, mass of fluid, apparatus).

The way Helmholtz proceeds to establish this different “application of the hydro-dynamic equations” appeals to a formalism not available to either Galileo or Newton, though: “[t]he equations of motion in the Eulerian form introducing the frictional forces, as is done by Stokes.” Although Helmholtz does not use the term “similar system” here, *Stokes* did use it, in his *On the Effect of the Internal Friction of Fluids on the Motion of Pendulums*, presented in 1850 [18.45, p. 19]. In that paper, before attempting a solution of some flow equations, *Stokes* first examined “the general laws which follow merely from the dimensions of the several terms which appear in the equations.” To do this,

Stokes had employed “similar systems” [18.45, pp. 16–17]:

“Consider any number of similar systems, composed of similar solids, oscillating in a similar manner in different fluids or in the same fluid. Let  $a, a', a'' \dots$  be homologous lines in the different systems;  $T, T', T'' \dots$  corresponding times, such for example as the times of oscillation from rest to rest. Let  $x, y, z$  be measured from similarly situated origins, and in corresponding directions, and  $t$  from corresponding epochs, such for example as the commencements of oscillations when the systems are beginning to move from a given side of the mean position.”

Then, Stokes says that the form of the equations shows that the equations being satisfied for one system will be satisfied for all the systems, if certain relations between the quantities in those equations are met, which he lays out. He adds the condition needed in order for the systems to be dynamically similar; then, if we “compare similarly situated points,” the motions in the systems will also be similar, and the “resultants [of pressure of the fluids on the solids] in two similar systems are to one another” in a certain ratio that he shows how to obtain. Stokes does not end there; the paper contains further discussion about establishing similarity between the two systems, having to do with how the fluids are confined. This much about *Stokes* should give a general idea of how he conceived of and used the notion of “similar systems” [18.45, p. 19].

Helmholtz’ approach probably owes much to Stokes; *David Cahan’s* study *Helmholtz and the British Scientific Elite: From Force Conservation to Energy Conservation* identifies Stokes as one of the British elites with whom Helmholtz built a relationship during the 1850s and 1860s [18.46]. Helmholtz does refer to Stokes, to be sure, but there is also something creative in what he does in his own paper. Helmholtz turns the idea of how the Eulerian equations for flow are related to similar systems around, so that he sees how one might, in principle at least, use the equations in conjunction with model experiments on ships to inform us about how to predict and direct the motions of balloons (dirigibles).

The discussion and derivation of the conclusions *Helmholtz* reached for all the cases he considered in his 1873 paper [18.41] are too long to summarize here, but a few points can be mentioned:

1. Helmholtz’s strategy is to consider two given fluids and use the hydrodynamic equations to infer the way or ways in which their quantities must be related. For the first fluid, the directions of its

coordinate axes are designated  $x, y,$  and  $z$ ; the components of velocity associated with them are designated  $u, v,$  and  $w$ . The time  $t$ , fluid density  $\varepsilon$ , pressure  $p$ , and coefficient of friction  $k$  (viscosity) are also named, which allows him to construct the equations of motion of the first fluid in the Eulerian form. The second fluid is then given designations of  $U, V, W$  for the components of velocity (in coordinate axes  $X, Y, Z$ ), the pressure  $P$ , the fluid density  $E$ , and the viscosity constant by  $K$ . Three additional constants  $q, r,$  and  $n$  are named, so that the quantities in the second fluid can then be related to the designated quantities in the first fluid such that the quantities in the second fluid will also satisfy the equations of motion that were constructed for the first fluid. For example, the densities of the two fluids are related by  $E = r\varepsilon$ ; their coefficients of friction are related by  $K = qk$ ; and the velocity components, by  $U = nu, V = nv,$  and  $W = nw$ . Then, the pressures must be related by  $P = n^2rp + \text{constant}$ , and the times in the two fluids must be related by  $T = qt/n^2$ . Putting the terms for the quantities of the second fluid expressed in terms of the quantities of the first fluid into the equations of motion for the first fluid shows that they satisfy those equations.

2. The nature of the two fluids determines how their densities and coefficients of friction are related to each other, so two of the three constants,  $q$  and  $r$ , are determined. Helmholtz then considers various kinds of cases (e.g., compressible versus incompressible, cohesive versus noncohesive (liquid vs gaseous fluids), certain boundary conditions, whether friction can be neglected), and what they permit to be inferred about the third undetermined constant  $n$ . The paper contains a variety of interesting remarks, some of great practical significance, about how other quantities of the two fluids (e.g., velocity of sound) must be related to each other.
3. When Helmholtz comes to addressing the practical problem mentioned in the title: “driving balloons forward relative to the surrounding air,” he uses not two masses of air in which two different air balloons are situated, but rather: for the second fluid, *a mass of air in which an air balloon is situated*, and, for the first fluid, *a mass of water in which a ship is situated*. He writes: “our propositions allow us to compare this problem [driving balloons forward relative to the surrounding air] with the other one that is practically executed in many forms, namely, to drive a ship forward in water by means of oar-like or screw-like means of motion [...] we must [...] imagine to ourselves a ship driven along under the surface. Such a balloon which presents

a surface above and below that is congruent with the submerged surface of an ordinary ship scarcely differs in its powers of motion from an ordinary ship” [18.41, p. 73]. Then, letting “the small letters of the two above given systems of hydrodynamic equations refer to water and the large letters to the air,” he examines the practical conditions under which he can “apply the transference from ship to balloon with complete consideration of the peculiarities of air and water.”

Helmholtz’s discussion contains many subtle points concerning what would need to be considered if actually building the kind of ship needed to model an air balloon. As he indicates, the practical considerations involved in applying the method are not trivial and can sometimes even be prohibitive; nevertheless, the point is that the approach he outlines permits one to make a proper analysis of any such comparison, or “transference” using the hydrodynamic equations, and can sometimes yield a solution when the hydrodynamic equations are insoluble [18.41, p. 74]. Evidence of the influence and significance of this particular paper of Helmholtz’s into the twentieth century appears in *Zahm’s Theories of Flow Similitude* [18.7]. Zahm identifies three methods, one with Isaac Newton, one with Stokes and Helmholtz, and one with Rayleigh. The sole paper by Helmholtz cited there is this paper of 1873 [18.41].

The significance to the history of physically similar systems is that Helmholtz’s account of his method involves a differential equation, that the equation is so central to the account, and that how it is involved is stated so clearly. What is not stated very clearly is whatever it is that plays the role of system; sometimes Helmholtz seems to be saying that the transference is from one mass of fluid to another; other times, that it is between the objects situated within the fluid. If we denote whatever ought to play that role by the term system, though, we would say that, in Helmholtz’s analysis, the hydrodynamic equations are not only the core of the criterion for allowing the “transference” of results [18.41, p. 74] observed in one situation to another, but they indirectly give a criterion for, and thus specify, what a system is, that is, what the similarity in *similar systems* is between. If we use the term system this way, then it is implicit in Helmholtz’s account that a system is the mass and its configuration (including anything situated within the mass), with boundary conditions, to which the partial differential equation applies. We might also take note of the fact that what the equation applies to is in equilibrium (though not necessarily static equilibrium). The governing differential equations are important, too, in the

specification of what quantities need to be considered in the analysis.

Yet, Helmholtz is careful not to overreach concerning what can be deduced from the *form* of an equation; as he points out in his *Discontinuous Motions* paper [18.43] when investigating the example of fluid being “torn asunder”: *just because a certain situation is governed by an equation of the same form as another equation governing a different situation, does not in itself guarantee that the two situations will exhibit analogous behavior* – even when the configuration and boundary conditions are also analogous. It is for the confluence of all these points that I consider Helmholtz’ 1873 paper [18.41] such a major contribution to the history of the concept of similar systems.

### Reynolds

Osborne Reynolds’ (1842–1912) work and influence on similarity was immense, but it was by no means his only major achievement [18.47]. Unless one has invested the time required to read a significant part of his work, any evaluation of his achievements and influence will sound like hyperbole. I mention here only his most significant contribution relevant to the history of the concept of similar systems.

The decisive difference Reynolds made in the notion of similar systems was to show that it applied beyond well-behaved regimes. In fact, he showed, it applied during the transition between well-behaved regimes and chaotic ones. And, not only that, but that the critical point of transition between well-behaved (laminar flow) and chaotic (turbulent flow) regimes could be characterized, and characterized by a parameter that was independent of the fluid. *Stokes* put it well in the statement he made in his role as President of the Royal Society on the occasion of presenting a Royal Medal to Reynolds on November 30, 1888 [18.45, p. 234]:

“In an important paper published in the *Philosophical Transactions* for 1883, [Osborne Reynolds] has given an account of an investigation, both theoretical and experimental, of the circumstances which determine whether the motion of water shall be direct or sinuous, or, in other words, regular and stable, or else eddying and unstable. The dimensions of the terms in the equations of motion of a fluid when viscosity is taken into account involve, as had been pointed out, the conditions of dynamical similarity in geometrically similar systems in which the motion is regular; but when the motion becomes eddying it seemed no longer to be amenable to mathematical treatment. But Professor Reynolds has shown that the same conditions of similarity

hold good, as to the average effect, even when the motion is of the eddying kind; and moreover that if in one system the motion is on the border between steady and eddying, in another system it will also be on the border, provided the system satisfies the above conditions of dynamical as well as geometrical similarity.”

Stokes does not here use the term *similar systems*, but that is what he means in using the grammatical construction: “if in one system [...], in another system it will also [...], provided the system satisfies the above conditions of dynamical as well as geometrical similarity.” What this means is that there are some (experimentally determined) functions of a certain (dimensionless) parameter that describe the behavior of fluids, whatever the fluid. The parameter is not a single measured quantity such as distance, velocity, or viscosity; rather, it is a ratio involving a number of quantities (e.g., density, velocity, characteristic length, and viscosity). The ratio is without units, as it is dimensionless. Reynolds is often cited for coming up with the criterion of dynamical similarity, but obviously, the idea predated his work, as Stokes’ statement recognizes. Rather, what *Reynolds* did that was so decisive for the future of hydrodynamics (and aerodynamics) was, as he explained in a letter to Stokes, that there was a *critical value (or values)* for “what may be called the parameter of dynamical similarity [the dimensionless parameter mentioned earlier, which is now known as Reynolds number]” [18.48, p. 233].

In the excerpt from his statement quoted above, Stokes puts his finger on why what *Reynolds* did was so significant in terms of a fundamental understanding of fluid behavior, but *Reynolds*’ 1883 paper also had practical significance for research in the field as well. *Stokes* continued [18.49, p. 234]:

“This is a matter of great practical importance, because the resistance to the flow of water in channels and conduits usually depends mainly on the formation of eddies; and though we cannot determine mathematically the actual resistance, yet the application of the above proposition leads to a formula for the flow, in which there is a most material reduction in the number of constants for the determination of which we are obliged to have recourse to experiment.”

It is not surprising that interest in applying the methods of similar systems grew in the subsequent years.

### Prandtl

*Prandtl*’s work in experimental hydrodynamics and aerodynamics is singularly prominent in work done in

the field in Germany in the twentieth century. *Ludwig Prandtl* (1873–1953) was an ex-engineer-turned-professor in the Polytechnic at Hanover conducting research on air flow when he presented a paper at the Third International Congress of Mathematicians in 1904: *Motion of Fluids with Very Little Viscosity* [18.50]. It did not make much of a splash – except with Felix Klein, then a prominent mathematician at the University of Göttingen. In his paper, *Prandtl* laid out a plan to treat flow around bodies. What he proposed was that the problem be analyzed into several distinct questions [18.50]:

1. What happened at the boundary of the *skin* that formed against the body, and what happened on each side of it, that is
2. What happened in the fluid on the side of the boundary that was within the *skin*, and
3. What happened in the fluid on the other side of the boundary, within the main fluid stream.

*Prandtl* showed that, in the mainstream, the mathematical solutions that were obtained by neglecting viscosity could be applied to even these real fluids. In the part of the flow under the *skin* formed around the body, however, viscosity did have to be taken into account. And, crucially, what happened in the mainstream – the formation of vortices – set conditions for what happened on the other side of the boundary, via setting boundary conditions at the interface between the two layers. Klein saw the potential of *Prandtl*’s approach and brought him to a post in Göttingen right away [18.11].

In Göttingen, *Prandtl* then made use of the knowledge that had been developed about hydrodynamical similarity, using a water tank for some of his most famous experiments. Rather than towing an object in the water, though, *Prandtl* used a water wheel to move the fluid in the water tank, much like fans were being used to push air through wind tunnels which by then were replacing the whirling arm or moving rail-car apparatuses used earlier in aerodynamical research. *Prandtl*’s results for airfoils were based on hydrodynamical similarity and, hence, on the concept of dynamically similar systems. His approach went beyond that, too, including fundamental questions he addressed by combining mathematical solutions and experimental results in an uncommon kind of synthesis. *William Lanchester* in England also employed dynamic similarity and authored significant works about his theoretical and experimental research in aerodynamics; his visit to *Prandtl* in 1908 may have contributed somewhat to *Prandtl* developing these ideas, since *Prandtl* was in a position to understand *Lanchester*’s work, and appreciate its significance [18.11].

### Rayleigh

Lord Rayleigh (John William Strutt) (1842–1919) became a proponent of dynamic similarity in Great Britain. The context of his advocacy of the method was part scientific, part political. The scientific part was an appreciation for the significance of dynamical similarity in effective research; the political part was a feeling that Britain ought not be left behind in aeronautical research. His political, social, and professional prominence put him in a position to be an effective advocate. He was the first president of the British Advisory Committee on Aeronautics, founded in 1909. Its first report includes his *Note as to the Application of the Principle of Dynamical Similarity* [18.51]; he introduces the topic by first citing Lanchester for one application of the principle of dynamical similarity, then noting his own communications of “a somewhat more general statement which may be found to possess advantages.” The next year, 1910–1911, the committee’s annual report included two papers on dynamical similarity, one of them by Rayleigh, under the *General Questions in Aerodynamics* section of the report [18.52]. In 1911–1912, the annual report mentions plans for experiments on an airship to determine its resistance “by towing tests in the William Froude National Tank” [18.53]. Under a section, *The Law of Dynamical Similarity and the Use of Models in Aeronautics*, the report notes its significance to all their research [18.52]:

“The theory relating to dynamical similarity explained by Lord Rayleigh and Mr. Lanchester in the first of the Annual Reports of the Committee is of fundamental importance in all applications of the method of models to the determination of the forces acting on bodies moving in air or in water.”

The next year, the annual report noted that [18.54]:

“Much evidence has now been accumulated in favour of the truth of the law of dynamical similarity to which attention was drawn by Lord Rayleigh and Mr. Lanchester in the first Report of this Committee.”

In June of 1914, the journal *Nature* featured a kind of survey paper, *Fluid Motions*, based on “a discourse delivered at the Royal Institution on March 20” by Rayleigh [18.55]. Here, we see Rayleigh actively campaigning for wider appreciation and use of the principle, which he credits Stokes with having “laid down in all its completeness.” We know that Stokes explicitly used the notion of similar systems in developing and explaining the use of the principle, so it is fair to say that Rayleigh means his discussion and use of it to be consistent with Stokes’ notion of similar systems.

In this paper, Rayleigh pointed out that it appeared that viscosity was important in many cases where it was so small that it seemed improbable that it should matter. When viscosities were low, as in water, one would not expect that the actual value of viscosity would be a significant factor in water’s qualitative behavior. As explained above, Osborne Reynolds’ results on fluid flow in pipes had shown that it is; Reynolds began to suspect that viscosity was important even in water when he observed unexpected changes in fluid flow as the temperature was varied. Since viscosity varies with temperature, he investigated the effect of viscosity and found that it was indeed important for fluid flow through pipes, even for nonviscous fluids such as water. Rayleigh added that Reynolds also investigated cases where viscosity was the “leading consideration,” as Rayleigh put it, in remarking that “It appears that in the extreme cases, when viscosity can be neglected and again when it is paramount, we are able to give a pretty good account of what passes, it is in the intermediate region, where both inertia and viscosity are of influence, that the difficulty is the greatest” [18.55]. This is the lead-in to his advocacy for the law of dynamic similarity: “But even here we are not wholly without guidance.” What is this guidance? He continues [18.55, p. 364]:

“There is a general law, called the law of dynamical similarity, which is often of great service. In the past this law has been unaccountably neglected, and not only in the present field. It allows us to infer what will happen upon one scale of operations from what has been observed at another.”

Rayleigh also notes: “But the principle is at least equally important in effecting a comparison between different fluids. If we know what happens on a certain scale and at a certain velocity in *water*, [emphasis in the original] we can infer what will happen in *air* on any other scale, provided the velocity is chosen suitably.” This is, of course, the point Helmholtz had made in 1873. Rayleigh notes that the point applies only in the range where the velocities are small in comparison to the velocity of sound [18.55].

Rayleigh gives an example of a use of the principle which permits one observation or experiment to be regarded as representative of a whole class of actual cases: that is, the class of all the other cases to which it is similar, even though the cases may have very different values of measurable quantities such as velocity. The important fact about the situation is expressed by the formula for the dimensionless parameter, which picks out the cases to which it is similar [18.55, p. 364]:

“It appears that similar motions may take place provided a certain condition be satisfied, viz. that the

product of the linear dimension and the velocity, divided by the kinematic viscosity of the fluid, remain unchanged.”

Put more specifically, the important feature of a particular situation is the value of this dimensionless parameter; what Rayleigh is saying is that, even in cases of a different fluid, so long as this dimensionless product is the same (and, of course, that one is in the applicable velocity range for which it was derived), the motions will be similar.

One might think that, by 1914, when the use of wind tunnels had become recognized as essential to practical aeronautical research, this principle would have become accepted and would no longer be in question, at least among aeronautical researchers. But if Rayleigh’s estimation of the state of the profession is correct, apart from Lanchester’s work, this was not so, even as late as March of 1914; he says that:

“although the principle of similarity is well established on the theoretical side and has met with some confirmation in experiment, there has been much hesitation in applying it, [. . .]”

He especially mentions problems in its acceptance in aeronautics due to skepticism that viscosity, which is extremely small in air, should be considered an important parameter:

“In order to remove these doubts it is very desirable to experiment with different viscosities, but this is not easy to do on a moderately large scale, as in the wind channels used for aeronautical purposes.”

Rayleigh tries to persuade the reader of the significance of the effects of viscosity on the velocity of fluid flow by relating some experiments he performed with a cleverly designed apparatus in his laboratory. The apparatus consisted of two bottles containing fluid at different heights, connected by a tube with a constriction, through which fluid flowed due to the difference in “head”, or height of fluid, in the two bottles [18.55, p. 364]. The tube with the constriction contained fittings that allow the measurement of pressure head at the constriction, and on either side of it. To investigate the effects of viscosity, Rayleigh varied the temperature of the fluid, which changes the fluid viscosity, and he observed how the velocity of the fluid flowing between the two bottles was affected. The kind of relationship he establishes and uses is of the form Galileo employed in reasoning from one pendulum to another. In other words, he worked in terms of ratios (ratios of velocities, ratios of viscosities, ratios of heads), and he employed the fact that some ratios are the square root of others [18.55]. He took the experimental results he reported in this 1914 paper to conclusively settle the question of the relevance of viscosity to fluid motions. This is an example of the kind of exploratory work that can be involved in order to answer one of the questions needed in order to use the principle of similarity properly: What quantities are relevant to the behavior of interest (in the range of interest)? Although the researcher’s experience and judgment are involved, sometimes new experiments should be, and are, conceived and carried out to help determine the question.

Rayleigh delivered this “Discourse” in early 1914 [18.55]. 1914 was a very special year for the concept of similar systems, and deserves a section all its own.

## 18.4 1914: The Year of *Physically Similar Systems*

In terms of an advance in the understanding and formalization of physically similar systems, 1914 was a landmark year, just as 1850 (*Stokes’* paper [18.45]), 1873 (*Helmholtz’s* paper [18.41]), and 1883 (*Reynolds’* paper [18.56]) would still be nineteenth century landmarks in any history of the concept of dynamical similarity. Going back to earlier eras, many would also consider the dates 1638 (*Galileo’s Two New Sciences* [18.10]) and 1673 (*Newton’s Principia* [18.3]) significant to the concept of similar systems. My review above suggests additions to the above list of dates in the nineteenth century that should be recognized as important in the history of the concept of similar systems: the years around 1880 (*van der Waals* paper [18.57]) and 1881 (*Onnes’* paper [18.32]). The role of the no-

tion of similar systems in both the development and the understanding of the principle of corresponding states in physical chemistry should enjoy far more recognition among philosophers of science than it has to date, and perhaps Lorentz ought to be included, too, for his recognition of the importance of the method of similar systems. A strong argument could also be made for including a date commemorating one of Froude’s influential achievements in the nineteenth century list.

In contrast, however, dates for the papers by Maxwell and Boltzmann using the term *similar systems* should not be included on this list, in my view. This exclusion is not a lack of generosity, but an effort at clarification. Their use of the term *similar system* in statistical mechanics, a term that already had a fairly

well-defined meaning in the theories of mechanical similarity and dynamical similarity, may have caused, or at least contributed to, confusion about the concepts of *similar system* and similarity as they are used in connection with mechanical and dynamical similarity. As we shall see, confusions about these concepts came to a head in 1914; perhaps it is no coincidence that at least one source of the confusion was a proposal by someone known for his work in statistical thermodynamics.

#### 18.4.1 Overview of Relevant Events of the Year 1914

In the part of 1914 leading up to *Buckingham's* landmark paper in October 1914 [18.2] that developed the notion of physically similar systems, hardly a month went by without some major work concerning similarity and similar systems appearing (Fig. 18.3):

- In January 1914, *Stanton* and *Pannell* publish a major compendium of work [18.6] done at Britain's National Physical Laboratory over the previous four years, *Investigation into Similarity of Motions*
- In February 1914, a much anticipated English translation of *Galileo's Two New Sciences* [18.10] was published.
- In March 1914, *Rayleigh* delivered his lecture *Fluid Motions* [18.55] at the Royal Institute (March 20, 1914).
- In April 1914, *Richard Chace Tolman's* *The Principle of Similitude* appears in *Physical Review* [18.58], and *Rayleigh's* *Fluid Motions* [18.55] is published in the periodical *Engineering*, 97 (April 8, 1914).
- In May 1914, *Buckingham* gives a paper on *The Interpretation of Model Experiments* to the Washington Academy of Sciences [18.59].
- In June 1914, *Rayleigh's* review article *Fluid Motions* was published in *Nature* [18.55].
- In July 1914, *Buckingham's* *Physically Similar Systems* was published in *Journal of the Washington Academy of Science* [18.1].
- In October 1914, *Buckingham's* *Physically Similar Systems: Illustrations of the Use of Dimensional Equations* [18.2].

And sometime during 1914, *Philipp Forchheimer's* *Hydraulik* [18.60] was published, which contains a section on *The Law of Similarity* (Das Ähnlichkeitgesetz). *Hydraulik* becomes a highly regarded compendium and reference work on Hydraulics for many decades afterward. In the concluding paragraph of the section on the law of similarity, *Forchheimer* writes that every hy-

draulic equation that fulfills the law of similarity can be expressed in the form of an equation consisting of an unidentified function  $F$  of three dimensionless ratios set equal to an unidentified constant. He indicates that the law of similarity is shown to be merely a special case of the general law according to which all the terms of any of the equations of importance in mechanics, need to be of equal dimension, inasmuch as the law of similarity treats one body as a prototype, and the others as copies of it.

#### 18.4.2 Stanton and Pannell

In January of 1914, *Stanton* and *Pannell* read their paper *Similarity of Motion in Relation to the Surface Friction of Fluids* [18.6] to the Royal Society of London. *Stanton* was superintendent of Britain's National Physical Laboratory (NPL) Engineering Department. The paper was a compendium of the work done there on similarity, and had been submitted to the Society in December 1913. It begins with references to *Helmholtz's* and *Stokes's* work using equations for non-ideal fluid flow, refers to *Newton's Principia* on similar motions, and uses *Rayleigh's* equation for fluid resistance. It explains that *Stanton* and *Pannell's* work involves investigating “the conditions under which similar motions can be produced under practical conditions.” The work had been carried out due in part to interest in the possibilities of using small-scale models in wind tunnels for engineering research. With one exception, they began, the experimental study of similar motions of fluids was very recent [18.6, p. 200]:

“Apart from the researches on similarity of motion of fluids, which have been in progress in the Aeronautical Department of the National Physical Laboratory during the last four years, the only previous experimental investigation on the subject, as far as the authors are aware, has been that of *Osborne Reynolds* [...]”

*Stanton* and *Pannell* cite several of *Reynolds's* major discoveries:

1. that there is a critical point at which fluid flow suddenly changed from “lamellar motion” to “eddy motion” [18.6, p. 200]
2. that the critical velocity is directly proportional to the kinematical viscosity of the water and inversely proportional to the diameter of the tube, and
3. that for geometrically similar tubes, the dimensionless product: (critical velocity)  $\times$  (diameter)/(kinematic viscosity of water) is constant.

*Stanton* and *Pannell* also noted a complication: surface roughness needed to be taken into account; this is

a matter of geometry on a much smaller scale making a difference. However, the overall approach of the use of dimensionless parameters to establish similar situations was still seen to be valid, as indicated by their extensive experiments [18.6, p. 201]:

“From the foregoing it appears that similarity of motion in fluids at constant values of the variable  $vd/\nu$  [velocity  $\times$  diameter/kinematic viscosity of water] will exist, provided the surfaces relative to which the fluids move are geometrically similar, which similarity, as Lord RAYLEIGH pointed out, must extend to those irregularities in the surfaces which constitute roughness. In view of the practical value of the ability to apply this principle to the prediction of the resistance of aircraft from experiments on models, experimental investigation of the conditions under which similar motions can be produced under practical conditions becomes of considerable importance, [...] By the use of colouring matter to reveal the eddy systems at the back of similar inclined plates in streams of air and water, photographs of the systems existing in the two fluids when the value of  $vd/\nu$  was the same for each, have been obtained, and their comparison has revealed a remarkable similarity in the motions.”

In referring to the dimensionless parameter  $vd/\nu$  as a *variable*, what Stanton and Pannell meant was that their equation for the resistance  $R$  includes a function of this dimensionless parameter, that is, resistance  $R = (\text{density}) \times (\text{velocity})^2 \times (\text{some function of } vd/\nu)$ . As they put it,  $R = \rho v^2 F(vd/\nu)$ , where  $F(vd/\nu)$  indicates some unspecified function of  $vd/\nu$ . Hence,  $vd/\nu$  is a variable in the sense that the relation for resistance includes an unspecified function of  $vd/\nu$ . It is also a variable in a more practical sense: it can be physically manipulated.

Stanton and Pannell presented this relation as a consequence of the principle of dynamical similarity (in conjunction with assumptions about what “the resistance of bodies immersed in fluids moving relatively to them” depends on. Evidently, it was Rayleigh who suggested the generalization; they cite *Rayleigh’s* contribution in the Report to the Advisory Committee for Aeronautics, 1909–1910 [18.51, p. 38]. Rayleigh had there spoken of the possibility of taking a more general approach than current researchers were taking in applying the “principle of dynamical similarity.”

In presenting the results they obtained at the National Laboratory in the paper, it is noteworthy that the results are presented in graphs where one of the variables plotted is the term  $R/\rho v^2$ , which is just another expression for the unspecified function, and is dimensionless. What this implies is that the laboratory

experiments are not conceived of in terms of the values of individual measurable quantities such as velocity but in terms of the value of a dimensionless parameter.

Rayleigh, too, presented a kind of survey paper in early 1914, as mentioned above. In that March 1914 paper [18.55], *Rayleigh* noted that the principle of dynamical similarity “allows us to infer what will happen upon one scale of operations from what has been observed at another.” That is, one use of the principle is to use an observation or experiment as representative of a whole class of actual cases: all the other cases to which it is similar, even though the cases may have very different values of measurable individual quantities such as velocity. The important fact of the situation is the dimensionless parameter just mentioned [18.55]:

“It appears that similar motions may take place provided a certain condition be satisfied, viz. that the product of the linear dimension and the velocity, divided by the kinematic viscosity of the fluid, remain unchanged.”

A consequence of this fact is that, even in cases of a different fluid, so long as this dimensionless product is the same, the motions will be similar: no mention of the fluid! Not only is this striking claim correct, but it is responsible for a particularly useful application of Stanton and Pannell’s work, of which they were well aware: tests done on water can be used to infer behavior about systems where the fluid is air. Not because air and water are similar – the relevant fluid properties are very different, in fact – but because the dimensionless parameter relating a number of the features of the fluid and of the situation is the same. Air and water are about as different as can be [18.6, p. 202]:

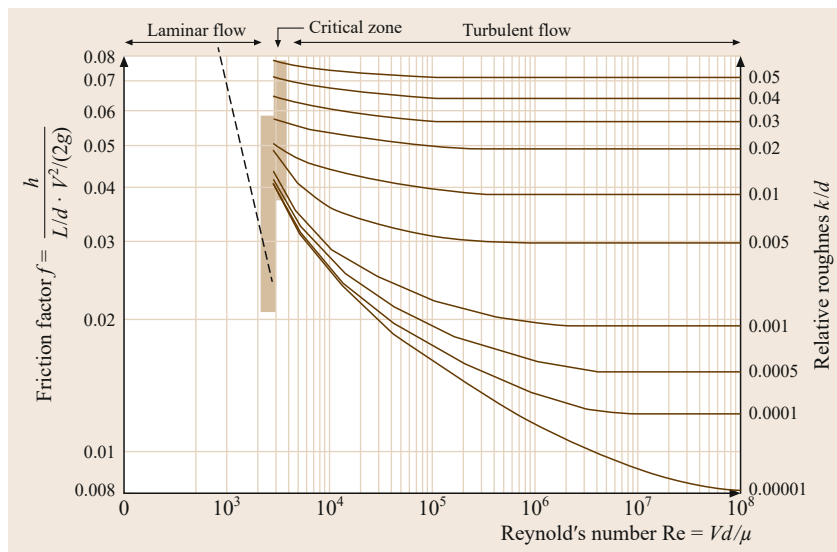

“The fluids used in the majority of the experiments have been air and water. The physical properties of these are so widely different that observations on others are hardly necessary [...]”

Just as the theorem of corresponding states in physical chemistry allowed the construction of a function such that the values for many different kinds of fluids all fell on the same line, so here, too: that the function of the variable  $vd/\nu$  is the same for air, water, and oil is experimentally illustrated by Fig. 18.6 from the paper.

### 18.4.3 Buckingham and Tolman

#### Buckingham’s Background in 1914

Edgar Buckingham (1867–1940) was a physicist who had been working at the National Bureau of Standards in Washington, DC, since 1906. He had little previous experience or background in aeronautics when he began working on issues related to aeronautical research. His

**Fig. 18.6** The approach in Stanton and Pannell’s paper of 1913/1914 expressing experimental results in terms of Reynolds number remains the fundamental approach even today. The chart above, a Moody diagram, illustrates that the fluid behavior for flow in pipes can be expressed in a manner that is independent of the nature of the fluid and other specifics of the configuration

involvement arose as a consequence of efforts afoot to establish a government agency devoted to aeronautical research in the United States, modeled on the British Advisory Committee for Aeronautics; one spot was allocated for a physicist from the National Bureau of Standards [18.61]. How did it end up that it was Buckingham, then, who authored the paper that has become such a landmark in hydrodynamics and aerodynamics? In a letter to Rayleigh in 1915, *Buckingham* explained the origins of his 1914 paper *On Physically Similar Systems: Illustrations of the Use of Dimensional Equations* [18.62]:

“Some three or four years ago, having occasion to occupy myself with practical hydro- and aerodynamics, I at once found that I needed to know more about the method [of dimensions] in order to use it with confidence for my own purposes. Since you and the few others who have made much use of the method of dimensions have generally referred to it somewhat casually as to a subject with which everyone was familiar, I supposed that the hiatus in my education would be easily filled.”

But it was not [18.62]:

“[...] upon looking through your collected papers, the *Sound* [probably a reference to Rayleigh’s *Theory of Sound*], Stokes’s papers, and a few standard books such as Thompson and Tait [*Principles of Mechanics*] and Routh’s *Rigid Dynamics* I was amazed at my failure to find any simple but comprehensive exposition of the method which could be used as a textbook. [...] Each one of your nu-

merous applications of the method seemed perfectly clear, and yet their simplicity gave them the appearance of magic and made the general principle rather elusive.”

It is noteworthy that Buckingham mentions looking at the main *mechanics* textbooks used in Britain, rather than engineering texts. Approaching aerodynamics from the point of view of a physicist was consistent with the kind of community in which Buckingham worked and had been educated. He had earned an undergraduate degree in physics at Harvard University (graduating in 1887) and a doctorate in physics from Leipzig in 1894. Descriptions of him as *an engineer* or *physicist-engineer* as mentioned in *Maila Walter’s* book [18.8] are somewhat misleading. After a few years as a physics professor, Buckingham worked as a physicist at US government agencies; first at the USDA Bureau of Soils (where he did very original theoretical work, applying energy methods), and then at the National Bureau of Standards [18.11]. Involving physicists on aerodynamical research planning made sense, and it also helped cultivate a more prestigious image of a research institution concerned with aerodynamics in 1914. *Buckingham* seemed aware of this, as evidenced by his remark to Rayleigh about the latter’s *Nature* article on the principle of dynamical similarity; he wrote Rayleigh that [18.62]:

“a note, such as the one in *Nature* of March 18th, which has your authority behind it, has an effect far more important in the present state of affairs than any detailed exposition of the subject, however good, because physicists will be sure to read it.”

One of Buckingham's special areas of expertise within physics was thermodynamics. He did not view thermodynamics as merely a subspecialty in physics, though, but rather as an enlightened view of science in which thermodynamics encompassed all of classical mechanics. In his 1900 book, *Outline of a Theory of Thermodynamics*, Buckingham had written [18.63, p. 16]:

“Thermodynamics [...] aims at the study of all the properties or qualities of material systems, and of all the forms of energy which they possess. It must, therefore, be held, in a general sense, to include pure dynamics, which is then to be looked upon as the thermodynamics of systems of which a number of nonmechanical properties are considered invariable. For *thermodynamics*, in this larger sense, the more appropriate name *energetics* is often used, the word *thermodynamics* being reserved to designate the treatment of problems which are directly concerned with temperature and heat.”

Buckingham's approach toward formalizing physics in his 1900 book on the foundations of thermodynamics had been to make the formalism he proposed as flexible as possible, and to build as few assumptions into it as possible. In generalizing the existing science of dynamics, he chose to regard as variable certain properties that are often considered invariable in dynamics. As Buckingham obtained his doctorate in Leipzig under Wilhelm Ostwald, a friend of Boltzmann who was often engaged with him in discussions and debates about foundational issues in science, Buckingham was familiar with debates in philosophy of science [18.11]. Buckingham developed (if he had not already had) a penchant for asking foundational questions, too; in his new role of advisor on research into aeronautics, he set for himself the task of discerning the foundations of the methods he saw being used in aeronautical research.

#### Buckingham's Papers at the Washington Academy of Sciences in 1914

By the middle of 1914, Buckingham had figured out some things about the foundations of the methods used in aerodynamical research. As his note to Rayleigh indicates, he had been concentrating on understanding how “the method of dimensions,” or dimensional analysis, was employed in aerodynamical and hydrodynamical research. On May 23, 1914, he presented a paper entitled *The interpretation of experiments on models* to the Washington Academy of Sciences in Washington, DC, of which he was a member; 27 people were present, and four discussed the paper afterward [18.59]. The account published in the academy's journal stated that:

“The speaker began by deducing a general theorem regarding the form which physical equations must have in order to satisfy the requirement of dimensional homogeneity.”

Dimensional homogeneity is an exceedingly general requirement of an equation; if the terms in an equation have any units (as equations in physics do), the equation is not really considered an equation if it does not meet the requirement of dimensional homogeneity. Thus, this deduction is of something very fundamental in physics; it is about the logic of equations. The account continues [18.59]:

“The theorem may be stated as follows: If a relation subsists among a number of physical quantities, and if we form all the possible independent dimensionless products of powers of those quantities, any equation which describes the relation is reducible to the statement that some unknown function of these dimensionless products, taken as independent arguments, must vanish.”

The antecedent of the theorem is extremely general: “If a relation subsists among a number of physical quantities [...]”; what is striking is that the antecedent of the theorem is not a requirement that the relation mentioned *be known*, only that it *exist*. The theorem was described as a “general summary of the requirement of dimensional homogeneity.” The report on Buckingham's talk added that the method of determining the number and forms of the independent dimensionless products was explained. There is no mention of similar systems in the journal's account of this May 1914 talk, but it does add that the theorem “may be looked at from various standpoints and utilized for various purposes,” and that “several illustrative examples” were given showing the “practical operation of the theorem” [18.59].

In July 1914, the academy's journal featured a short, six-page paper by Buckingham. The topic identified was more general than model experiments, and this time it did mention *similar systems*; in fact, the paper was titled *Physically Similar Systems*. That *Buckingham* meant the July paper to be seen as a generalization of the earlier paper on the interpretation of model experiments was indicated in the closing sentence of the paper [18.2, p. 353]:

“A particular form of this theorem, known as the principle of *dynamical similarity* is in familiar use for the *interpretation of experiments on mechanical models*; but the theorem is equally applicable to problems in heat and electromagnetism” (emphasis added).”

Like the May 1914 talk, the short July 1914 paper is notable for the generality of its approach. It did not imply that there were any set fundamental quantities, nor how many there were. It did not talk about physics, even. It spoke of quantities, relations between quantities, and equations. It is spare and elegant. It begins [18.1]:

“Let  $n$  physical quantities,  $Q$ , of  $n$  different kinds, be so related that the value of any one is fixed by the others. If no further quantity is involved in the phenomenon characterized by the relation, the relation is complete and may be described by an equation of the form  $\Sigma MQ_1^{b_1} Q_2^{b_2} Q_3^{b_3} \dots Q_n^{b_n} = 0$ , in which the coefficients  $M$  are dimensionless or pure numbers”

He makes it clear that it is a matter of choice which units are to be regarded as fundamental ones.

“Let  $k$  be the number of fundamental units needed in an absolute system for measuring the  $n$  kinds of quantity. Then among the  $n$  units required, there is always at least one set of  $k$  which are independent and not derivable from one another, and which might therefore be used as fundamental units, the remaining  $(n - k)$  being derived from them.”

Together, these allow him to say how the quantities *other than* those that are taken to be among the  $k$  fundamental quantities *are related to* those fundamental quantities. Denoting the fundamental units by  $[Q_1]$  through  $[Q_k]$  – in this July 1914 paper he sometimes uses the square brackets indicate the *units* of the enclosed quantity – and the remaining  $(n - k)$  units that are derived from them by  $[P_1]$ ,  $[P_2]$ , and so on up to  $[P_{n-k}]$ , we get  $(n - k)$  equations that relate the units of the  $(n - k)$   $P$ s to the units of the  $k$   $Q$ s. Putting these requirements in terms of dimensions rather than units allows one to apply the requirement of dimensional homogeneity – doing so for each of the fundamental units gives  $k$  equations; each of the  $k$  equations is a result of setting the exponents of one of the units to zero. It can then be shown that the number of independent dimensionless parameters  $\Pi_i$ s is  $(n - k)$  [18.1].

The generality of the treatment here marks this work on similar systems by Buckingham’s off from the earlier work by *Stokes* in 1850 [18.45] and *Helmholtz* in 1873 [18.41]. Whereas *Stokes* spoke of “similar systems, composed of similar solids, oscillating in a similar manner” and of comparing [18.45]:

“similarly situated points in inferring from the circumstance that [the relevant hydrodynamical equations] are satisfied for one system that they will be satisfied for all [the other similar] systems,”

*Buckingham* spoke of an undetermined function whose arguments were dimensionless parameters and he spoke of varying the quantities ( $Q$ s and  $P$ s above) in ways that “are not entirely arbitrary but subjected to the  $(n - k - 1)$  conditions that [certain] dimensionless  $\Pi_i$ ’s remain constant” [18.1].

Putting it in other terms, Buckingham characterized systems as similar in terms of a (nonunique) set of invariants. His emphasis is on the principle of dimensional homogeneity, which is really about the *logic* of the *equations* of physics. The concept of similar systems arises from reflecting on how the principle of dimensional homogeneity might actually be put to use, what it might allow one to infer. After the paper’s opening pages, in which he laid out the observations about the nature of equations that express relations in nature (i. e., wherein the value of one quantity is fixed by the others) stated above, he writes:

“The chief value of the principle of dimensional homogeneity is found in its application to problems in which it is possible to arrange matters so that the [dimensionless ratios]  $r$ ’s and the [dimensionless parameters]  $\Pi$ ’s of [the set of linear equations relating the  $P$ ’s to the  $Q$ ’s and the (unknown) function  $\phi$  of the dimensionless  $r$ ’s and  $\Pi$ ’s] remain constant,”

so that the unknown function  $\phi$  takes on a fixed value, thus giving a definite relation between the  $P$ s and  $Q$ s in terms of the value of the unknown function  $\phi$ . As he remarks, the point is not that dimensional analysis *provides* the function  $\phi$  or even the *value*  $\phi$  takes on once the values of the invariants are set. Rather, the principle allows one to express the relations between quantities in terms of  $\phi$ , which has a fixed value if all its arguments (the dimensionless parameters) are fixed. Hence, doing an experiment on one case yields the relation for all the cases in which the dimensionless parameters that are the arguments of  $\phi$  have the same value, even if the individual quantities from which those parameters are formed are all different.

Though Buckingham was, he said, only aiming to give a clear treatment of the same idea that *Stokes* and others had stated, a lot had happened in mathematics and physics (especially in physical chemistry and thermodynamics), in the intervening decades. In their works on similar systems, *Stokes* and *Helmholtz* worked with physical equations, the partial differential equations of fluids and fields; *Buckingham*, as a physicist, was certainly cognizant of and competent in working with them, too, but in the July 1914 paper on similar systems, he worked with (more abstract) dimensional equations. The goal here, in this lean paper that featured no examples or applications, was to get straight on things that

(so far as he was aware) had not yet been articulated by others who had employed the method. He would later write to Rayleigh about these first papers on the method [18.62]:

“I had therefore [...] to write an elementary textbook on the subject for my own information. My object has been to reduce the method to a mere algebraic routine of general applicability, making it clear that Physics came in only at the start in deciding what variables should be considered, and that the rest was a necessary consequence of the physical knowledge used at the beginning; thus distinguishing sharply between what was assumed, either hypothetically or from observation, and what was mere logic and therefore certain.

The resulting exposition is naturally, in its general form, very cumbersome in appearance, and a large number of problems can be handled vastly more simply without dragging in so much mathematical machinery.”

His exposition treats of a system  $S$  characterized very abstractly: “The quantities involved in a physical relation pertain to some particular physical system which may usually be treated as of very limited extent” [18.1, p. 352]. The system constructed to be similar to it, likewise, is described very formally [18.1, p. 352]:

“Let  $S'$  be a second system into which  $S$  would be transformed if all quantities of each kind  $Q$  involved in [the equation expressing the physical relation pertaining to the system] were changed in some arbitrary ratio, so that the  $r$ 's for all quantities of these kinds remained constant, while the particular quantities  $Q_1, Q_2, \dots, Q_k$  changed in  $k$  independent ratios.”

After completing the specification of the constraints on how the quantities change in concert with each other so that  $S'$  also satisfies the relation: “Two systems  $S$  and  $S'$  which are related in the manner just described are similar as regards the physical relation in question.” [18.1, p. 352]

The exposition may have been cumbersome, but the point is elegant and spare: the constraints that must be satisfied in constructing the system  $S'$  are just these: to keep the value of the dimensionless parameters that appear in the general form of the equation – the arguments of the function  $\phi$  – the same in  $S'$  as in  $S$ . So, what is crucial is to identify a set of dimensionless parameters that can serve as the arguments of the undetermined function  $\phi$ . For Buckingham, unlike for some predecessors writing about similar systems or dynamic similarity, the method underlying the construction of

physically similar systems is not a method peculiar to mechanics; it applies to *any equation describing a complete relation that holds between quantities*.

#### Richard Chace Tolman's *Principle of Similitude*

Meanwhile, another physicist in the United States was publishing on similitude, too, though with considerably less rigor. Richard Chace Tolman (1881–1948) was an assistant professor of the relatively new field of physical chemistry at the University of California when Onnes won the Nobel Prize for his work in physical chemistry on the liquefaction of helium; Onnes delivered his Nobel Prize Lecture in December 1913 [18.31, 64]. As noted above, *Onnes* had aimed to “demonstrate that the principle of corresponding states can be derived on the basis of what he calls the principle of similarity of motion, which he ascribes to Newton” [18.32].

*Tolman* published *The Principle of Similitude* in the March 1914 *Physical Review*, in which he proposed the following [18.58, p. 244]:

“The fundamental entities out of which the physical universe is constructed are of such a nature that from them a miniature universe could be constructed exactly similar in every respect to the present universe.”

*Tolman* then (he claimed) showed that he could derive a variety of laws, including the ideal gas law, from the principle of similitude he had proposed, proceeding in somewhat the same way as *Onnes* had proceeded in showing that the principle of corresponding states was a consequence of mechanical similarity. *Tolman* seemed to appeal to a criterion that the two universes should be observationally equivalent [18.58, p. 245]

“[...] let us consider two observers,  $O$  and  $O'$ , provided with instruments for making physical measurements.  $O$  is provided with ordinary meter sticks, clocks and other measuring apparatus of the kind and size which we now possess, and makes measurements in our present physical universe.  $O'$ , however, is provided with a shorter meter stick, and corresponding altered clocks and other apparatus so that he could make measurements in the miniature universe of which we have spoken, and in accordance with our postulate obtain exactly the same numerical results in all his experiments as does  $O$  in the analogous measurements made in the real universe.”

He brings up some other considerations, some from physics (Coulomb's law), some from the theory of dimensions, and then tries to show how various physical relations, such as the ideal gas law, can be deduced from simple physical assumptions and his proposed principle

of similitude. For relations involving gravitation, however, a contradiction arises; his response is to use the contradiction as motivation to propose a new criterion for an acceptable theory of gravitation. He concludes that his proposed principle is a new relativity principle: the “principle of the relativity of size” [18.58, p. 255].

*Tolman* believes that, in his paper, he has laid out transformation equations that specify the changes that have to be made in lengths, masses, time intervals, energy quantities, etc., in order to construct a miniature world such that [18.58, p. 255]:

“If, now, throughout the universe a simultaneous change in all physical magnitudes of just the nature required by these transformation equations should suddenly occur, it is evident that to any observer the universe would appear entirely unchanged. The length of any physical object would still appear to him as before, since his meter sticks would all be changed in the same ratio as the dimensions of the object, and similar considerations would apply to intervals of time, etc. From this point of view we can see that it is meaningless to speak of the absolute length of an object, all we can talk about are the relative lengths of objects, the relative duration of lengths of time, etc. The principle of similitude is thus identical with the principle of the relativity of size.”

*Tolman*’s suggestion differs from the concept of similar systems mentioned so far, though the difference may not be obvious. Others working on similar systems where quantities or paths were homologous between similar systems noted that there were limits of applicability; they recognized the fact that there are ranges in which size matters (e.g., surface tension matters disproportionately at small scales [18.21]; the restriction in *Helmholtz*’ 1873 paper that velocities must be small with respect to the velocity of sound [18.41], Reynolds’ recognition of the role of “mean range” of molecules in transpiration [18.11]). *Helmholtz* even explicitly discussed the practical difficulties of constructing models of a different size than the configuration modeled, raising the question of whether in some cases it may not be possible to do so [18.41]. *Tolman* not only does not recognize such limits; he suggests making the denial that they exist a principle of physics. It seems pretty clear that *Tolman* is here modeling his exposition on Einstein’s 1905 paper on the special theory of relativity. *Tolman* proposes that the relativity of size be regarded along the lines of the relativity of motion: in his paper on special relativity, Einstein had considered it a principle that observers cannot tell one state
